Multiple mechanisms control the overexpression of the E4 and FE4 genes in resistant lines but gene amplification is the major one (Field *et al.*, 1999) (**Table 2**). Either gene can be amplified up to 80 times within a highly resistant R3 strain. Differences in resistance and esterase activity among the R1, R2, and R3 phenotypes largely correlate with the number of copies of the esterase genes. Normally only one of E4 or FE4 is amplified within a single line. The unit of amplification is large, approximately 24 kb for E4 and 20 kb for FE4, with each amplicon containing just one copy of the respective esterase gene and no other open reading frames. Amplicons are generally arranged in a head-to-tail configuration. In many resistant lines the E4 amplifications are also associated with a particular chromosomal translocation, with the amplicons generally all located at a single site on one of the translocation chromosomes. In one resistant clone, however, sites of E4 amplification have been found on three separate chromosomes. The FE4 gene is not associated with any translocations but the amplicons are distributed across the genome at from three to eight sites (Blackman *et al.*, 1995, 1999).

Restriction fragment length polymorphism (RFLP) patterns and 5′ sequence for E4 and FE4 genes from several resistant clones suggest that there was a single original amplification event for each of E4 and FE4 (Field *et al.*, 1994). Several subsequent mutations then generated the three major classes of resistance phenotype, the variation in the chromosomal sites for some of the E4 amplicons, and also some minor variation in gene copy number within the major phenotypic classes (Blackman *et al.*, 1995).

The levels of expression of E4 are also controlled by DNA methylation, with decreased methylation in some lines carrying amplifications resulting in reduced gene expression and reversion to a more susceptible phenotype (ffrench-Constant

Table 2 Esterase amplicons associated with insecticide resistance in *Myzus persicae* and *Culex pipiens*

Amplicon	*Genetics and biochemistry*	*References*
Myzus persicae		
E4	Secreted esterase with high affinity for OPs and carbamates, very slow turnover for OPs, and effectively none for carbamates. Up to 80-fold amplifications associated with a translocation (can be several sites) confers up to 500-fold resistance to OPs and 15-fold to carbamates. Quantitative variation in resistance correlates with amplification level. Reversion to susceptibility due to decreased flanking sequence methylation	Sawicki *et al.* (1978), Devonshire and Sawicki (1979), Devonshire and Moores (1982), Devonshire *et al.* (1986), ffrench-Constant and Devonshire (1988), Field *et al.* (1988, 1989, 1997), Blackman *et al.* (1995), Field and Devonshire (1998), Field (2000), Field and Blackman (2003)
FE4	As for E4 except for: slightly high turnover of OPs, amplification not associated with translocation, and no reversion due to altered methylation	As for E4
Culex pipiens complex		
Estα1	Low frequency in France, ≤70-fold amplification	Mouchès *et al.* (1987), Raymond *et al.* (1989), Chevillon *et al.* (1997), Lenormand *et al.* (1998b)
Estβ1²	Widespread in the Americas and China, ≤250-fold amplification, at least three sequence variants	Georghiou *et al.* (1980), Beyssat-Arnaouty *et al.* (1989), Mouchès *et al.* (1990), Cuany *et al.* (1993), Qiao and Raymond (1995), Vaughan *et al.* (1995)
Estβ6	Rare variant	Xu *et al.* (1994)
Estβ7	Rare variant	Xu *et al.* (1994)
Estβ8	Rare variant	Vaughan *et al.* (1995)
Estα2¹Estβ2¹	Common worldwide, partially replaced *Estβ1* in North America, but now declining in frequency in some European populations, ≤60-fold amplification	Raymond *et al.* (1987, 1991), Wirth *et al.* (1990), Rivet *et al.* (1993), Karunaratne *et al.* (1995), Qiao and Raymond, (1995), Guillemaud *et al.* (1996, 1997) Chevillon *et al.* (1997), Lenormand *et al.* (1998b), Hemingway *et al.* (2000), Weill *et al.* (2000), Pasteur *et al.* (2001)
Estα3Estβ1	South/Central American amplicon, two *Estβ1* sequence variants	De Silva *et al.* (1997)
Estα4Estβ4	Becoming more common in France, ≤50-fold amplification	Poirié *et al.* (1992), Chevillon *et al.* (1997), Lenormand *et al.* (1998b)
Estα5Estβ5	Becoming more common in Cyprus, ≤250-fold amplification	Poirié *et al.* (1992), Wirth and Georghiou (1996)

and Devonshire, 1988; Field *et al.*, 1989; Hick *et al.*, 1996; Field, 2000). No examples of such reversion have been described for the FE4 amplification suggesting that the phenomenon may be locus-specific. Methylation of the E4 gene in revertants is confined to CpG doublets within the coding region and is absent from CpG-rich regions in the 5′ and 3′ flanking DNA (Field, 2000). DNA methylation within a highly expressed gene is itself unusual in eukaryotes, methylation typically being associated with pretranscriptional gene silencing.

While the E4 and FE4 esterases are highly sensitive to inhibition by the insecticides they show poor hydrolytic activity against them. Thus the bimolecular rate constant (k_i) for the phosphorylation of E4 by paraoxon is about 133 μM^{-1} min^{-1} (Devonshire, 1977). However, its maximum rate of hydrolysis (k_3) for dimethyl OPs is about 3 h^{-1}, for diethyl OPs it is less than 1 h^{-1}, and it is even slower for carbamates (Devonshire and Moores, 1982). FE4 hydrolyzes both dimethyl and diethyl OPs approximately 1.5 times faster than E4 (Devonshire, 1989). Because their kinetics are so poor, the enzymes are thought to protect the organism from OPs and carbamates by first sequestering the insecticide and then, at least for dimethyl OPs, very slowly degrading it (Devonshire and Moores, 1989).

Very similar elevated esterase phenotypes are also associated with OP resistance in populations of a tobacco-feeding form (Abdel-Aal *et al.*, 1990, 1992; Wolff *et al.*, 1994) originally classified as a distinct species, *Myzus nicotianae* (Blackman, 1987). It is now clear that the elevated E4/FE4 esterases and encoding amplicons in this form are identical to those of *M. persicae*, and that the amplicons were acquired by introgression through sexual hybridization rather than by independent evolution (Field *et al.*, 1994). Given this, and studies of RFLP and randomly amplified polymorphic DNA (RAPD) patterns, it is now considered that *M. persicae* and *M. nicotianae* are conspecific (Clements *et al.*, 2000).

A similar case of amplification-based resistance has also been described in the brown rice planthopper *Nilaparvata lugens*. In this species two esterase isozymes stain more intensely in OP and carbamate resistant strains (Chen and Sun, 1994; Karunaratne *et al.*, 1999; Small and Hemingway, 2000a). The two isozymes are differently glycosylated forms of the same protein (Small and Hemingway, 2000a). The encoding gene is amplified three to seven times in strains resistant to OPs and carbamates, and there is an eight- to tenfold increase in measured esterase activity (Small and Hemingway, 2000b; Vontas *et al.*, 2000). Detailed kinetic analyses have not been reported for this system, but it is assumed that sequestration is a major part of the resistance mechanism.

The situation is more complicated in the greenbug *Schizaphis graminum*, where there are two types of esterase-based metabolic resistance to OPs, each associated with elevated staining intensities of esterase isozymes (Siegfried and Ono, 1993a, 1993b; Shufran *et al.*, 1996; Siegfried *et al.*, 1997; Ono *et al.*, 1999). One well-characterized type involves overexpression of a single esterase, whose gene shares intron positions and shows strong sequence similarity to E4/FE4 from *M. persicae* (about 73% identity at the amino acid level across the partial sequence available). The encoded enzyme cross-reacts strongly with antibody raised against *M. persicae* E4. Four- to eightfold amplification of this esterase gene confers broad spectrum OP resistance, while reversion to susceptibility occurs despite retention of the amplified genes because of changes in methylation. As in *M. persicae*, the amplified genes in resistant strains are methylated at CCGG sites, but revertants do not show methylation in upstream sequences. And also as with *M. persicae*, the mechanism of resistance seems primarily to involve sequestration rather than hydrolysis of the pesticide.

The second resistance mechanism in *S. graminum* is associated with elevated staining intensities of several esterase isozymes, although one, not the same as that in the first type above, clearly predominates. Patterns of antibody cross-reactivity suggest that none of the more intensely staining esterases in this so-called type 2 resistance are as closely related to *M. persicae* E4 as the overexpressed esterase in Type 1 resistance. The major type 2 esterase from *S. graminum* has been partially purified and shows slightly different electrophoretic mobility in type 2 strains, while Western blots using a type 2 esterase antibody suggest similar levels of expression across susceptible type 1 and type 2 strains (Siegfried and Zera, 1994; Siegfried *et al.*, 1997). These data suggest that Type 2 resistance in *S. graminum* is, unusually among the Hemiptera, not simply a result of overexpression and gene amplification. The extent to which it involves sequestration versus hydrolysis is therefore also an open question.

One feature of the hemipteran esterases like E4/FE4 and their relatives in clade E which may predispose them to a role in insecticide resistance is that they all appear to be secreted enzymes. It may be particularly useful for a sucking insect to secrete the enzyme into the gut, or perhaps preferentially into the salivary secretions, which are pumped into the plant as they feed. Salivary secretions are characteristically replete with digestive hydrolases, and this

may indeed be the ancestral function of the esterases recruited to a role in insecticide resistance.

Measurable fitness costs have been associated with the amplified esterases in at least some of the cases above (Dawson *et al.*, 1983; Foster *et al.*, 2003). These costs have been confounded in the case of *M. persicae* by the simultaneous presence in many clones of other resistance mechanisms with differing impacts on fitness (see Section 5.10.3.1.2). However the contributions from the various resistances are now being dissected, and the presence of the amplified esterase genes has been shown to slow the intrinsic rate of population increase (Foster *et al.*, 2003). With the possible exception of type 2 resistance in *S. graminum*, there are no known structural differences between the amplified esterases and their susceptible ancestors, so they would be expected still to perform the ancestral function. Nor does the metabolic cost associated with the production of such large amounts of an enzyme fully account for the fitness costs because, in *M. persicae* at least, revertants still appear to be less fit than susceptible aphids (Foster *et al.*, 1996).

5.10.4.4. Semiochemical Esterases

Clade D currently comprises one moth esterase and three *D. melanogaster* homologs. All appear catalytically active and three have good consensus secretion signals. While nothing is known of the functions of the *D. melanogaster* enzymes the moth esterase has been implicated in pheromone signaling. A clade A enzyme from the same species has also been tentatively implicated in this role but this section is used to review the topic of esterase involvement in pheromone and other semiochemically triggered signaling processes.

Sensitive and specific sensing of volatile chemical cues is crucial to the ability of insects to interpret their environment and signal to one another. Efficient degradation of the cues is an integral part of the signal reception and tranduction process and several specific odor degrading enzymes (ODEs) have now been identified in insects. Many of these ODEs are esterases because many of the semiochemical signals are esters (see **Chapter 3.15**). So far 231 esters, many of them C10–C16 acetates, have been identified as components of moth sex pheromone blends (http://www-pherolist.slu.se), while some of the 169 esters that have been identified in floral scents may be involved in the attraction of pollinators (Knudsen *et al.*, 1993). Little is known about esterases for other semiochemicals but there is quite detailed knowledge of some esterases involved in the reception of sex pheromones.

Sex pheromones are commonly found and mostly studied in Lepidoptera but they probably occur quite widely across insects (see **Chapters 3.14** and **3.15**). They are produced mainly by females to attract and court conspecific males. At least in the lepidopteran model systems studied, the males receive the signal in specialized sensillar hairs on their antennae. Inside these hollow sensillar hairs is an aqueous lymph where the external blend of volatiles is thought to be recreated for a subset of the molecules that can be bound by locally abundant pheromone binding proteins. The latter act to solubilize and transport the chemical signal to the dendrites of specific neurons that extend into the lymph. ODEs in the lymph compete to remove the signal, thereby maintaining the system's ability to respond to new stimuli. Receptors on the dendritic membrane, probably members of the G protein coupled receptor superfamily, specifically recognize the signal and trigger a signaling cascade that results in a neuronal impulse being sent to the antennal lobe and then the brain.

As well as the sensillar lymph, ODEs are also required at at least one and probably two other points in the process. One which is relatively well characterized involves cleaning pheromone off the external surface of the insect; most pheromone molecules are strongly hydrophobic and therefore prone to adhere to waxy surfaces. The males need to remove this material from their integument so that they do not become their own source of signal, while the females may need to remove it so that they can better control their signal (Vogt and Riddiford, 1981). The other point in the process where an esterase may be required is in the removal of bound pheromone off the receptor inside the olfactory neuron cells, if the signal remains bound to the receptor as it gets reset through vesicle cycling inside the cell (see **Chapter 3.15**).

The saturnid moth *Antheraea polyphemus* is one of the preferred models for studying the biochemistry of sex pheromone signal transduction, in large part because its large branched antennae and long sex pheromone-sensitive sensilla (sensillar tricoidea) are relatively amenable to study. Its sex pheromone is a 9 : 1 blend of the ester (*E*,*Z*)-6,11-hexadecadienyl acetate and the corresponding aldehyde (*E*,*Z*)-6, 11-hexadecadienal (Kochansky *et al.*, 1975). Four esterase isozymes extracted from *A. polyphemus* may have functions in the processing of the ester component of its pheromone blend: one from its scales, two from its antennal integument, and one from the lymph inside its sensillar tricoidea (Vogt and Riddiford, 1981, 1986; Klein, 1987).

An isozyme able to degrade radiolabeled (*E*,*Z*)-6, 11-hexadecadienyl acetate has been found in the body scales of both sexes (Vogt and Riddiford, 1986). The enzyme appears to be a carboxylesterase, as is it inhibited by typical OP inhibitors (Vogt and Riddiford, 1986). It requires solubilization by detergents suggesting some membrane association. It migrates very slowly on native PAGE and has a presumptively dimeric molecular mass of 100 kDa (Klein, 1987). Closely related species using different pheromones were found to have scale esterases that did not have activity against (*E*,*Z*)-6,11-hexadecadienyl acetate (Vogt and Riddiford, 1986).

Two soluble, OP-inhibitable esterase isozymes have also been associated with the antennal integument of both male and female *A. polyphemus* (Klein, 1987). One, of molecular mass 65 kDa, resolves as two forms under IEF (pI 5.85 and 6.0). The other, of 90 kDa, resolves as a single band under isoelectric focussing (IEF) (pI 5.0). The latter may be a homodimer as the molecular weight was estimated under native conditions. Neither of these is found in sensillar lymph but one, probably the 65 kDa enzyme, is also found in various other cuticular tissues, including wing, head and abdominal cuticle, and trachea, albeit not the brain, ventral nerve cord, fat body, or hemolymph (Vogt and Riddiford, 1981); hence the name integument esterase. As with the membrane-associated scale esterase above, this soluble integument esterase can hydrolyze the pheromone ester to the corresponding alcohol (Vogt and Riddiford, 1981).

An esterase isozyme has been identified in the sensillar lymph of male but not female *A. polyphemus*. This sensillar enzyme has a molecular mass typical of the subunit sizes of other carboxyl/cholinesterases (55 kDa) but an unusually low pI (3.0), and is not inhibited by several of the usual OP and other carboxyl/cholinesterase inhibitors (Vogt *et al.*, 1985; Klein, 1987). The pheromone analog 1,1,1-trifluoro-2-tetradecanone is a potent inhibitor (IC_{50} 5 nM) and kinetic analysis shows good affinity for the pheromone ($K_m = \sim 2 \times 10^{-6}$ M). Inhibition studies of the enzyme's ability to hydrolyze artificial substrates like naphthyl acetate with a range of pheromone-like compounds suggest that it has a high level of specificity for the native pheromone, including for the sites of unsaturation in its acyl chain backbone (Vogt *et al.*, 1985). Although it is perhaps four orders of magnitude less abundant than the pheromone binding protein, Vogt *et al.* (1985) have estimated that its V_{max} should be sufficient to clear half of the pheromone inside the sensillar lymph in 15 ms.

No esterases or other ODEs have yet been reported from inside pheromone-receptive neuronal cells but they may well occur there. It is known that many neurotransmitter-receiving G protein coupled receptors are internalized into the cell once activated by ligand binding (McClintock and Sammeta, 2003). The sensitivity of the neuron to further stimulation is then controlled by the balance between recycling to the cell surface and degradation of the receptor within the endosomes. If pheromone receptors are endocytosed in this fashion, then the ligand may well also become internalized and require hydrolysis within the neuron (see **Chapter 3.15**).

Ishida and Leal (2002) have used a degerate PCR approach to clone an esterase gene from *A. polyphemus* cDNA that they suggest encodes the 65 kDa integument esterase (clade D, sequence 41 in **Figure 2**). This assignment is based on the similar predicted size (61.7 kDa) and broadly similar pI (7.49) of protein 41 to the 65 kDa integument isozyme, the presence of a predicted secretion signal in protein 41, and the expression of the 41 gene in cuticular tissues, including male legs, as well as in male and female antennae. Esterase genes similar to 41 are also present in other moth antennal EST collections. One from female antennal cDNA of *M. sexta* is 70% identical to 41 over 120 amino acids (GenBank Accession no. BE015493), while another from male antennae of the light brown apple moth *Epiphyas postvittana* is 56% identical over 234 amino acids (R.D. Newcomb, unpublished data). Although *M. sexta* uses a sex pheromone composed of aldehydes, mainly (*E*,*E*,*Z*)-10,12,14-hexadecatrienal (Tumlinson *et al.*, 1989), *E. postvittana* uses a blend of two acetate esters (Bellas *et al.*, 1983).

Ishida and Leal (2002) also cloned another esterase gene that is expressed in the antennae of *A. polyphemus* using their degenerate PCR approach. This gene (19 in **Figure 2**) sits not in clade D as above, but in clade A. The authors suggest that it may encode the sensillar esterase, since it is expressed in male but not female antennae. It is also predicted to have a secretion signal (which would be necessary for it to be found in the sensillar lymph) under the software used by Ishida and Leal (2002), albeit not by the packages that are used (**Figure 2**). Other possible anomalies in respect of this assignment are the slightly larger size of the predicted protein (60 versus 55 kDa) and its substantially higher predicted pI (6.6 versus 3.0). The link between 19 and the sensillar esterase therefore remains to be confirmed.

It is nevertheless noteworthy that 19, like 41, shows significant similarity to sequences in three

antennal EST collections. In our phylogenetic analysis, 19 is most similar to an esterase from the cotton aphid *Aphis gossypii* (18) of no known function. However, esterase ESTs similar to 19 occur in male antennal cDNA libraries of *M. sexta* (GenBank Accession no. BF047018, 44% identical over 221 amino acids; GenBank Accession no. BF046933, 44% identical over 199 amino acids) and *E. postvittana* (42% identical over 321 amino acids) (R.D. Newcomb, unpublished data). Another esterase EST (GenBank Accession no. BP183087) very similar to 19 (70% identical over 148 amino acids) is also expressed in the pheromone gland of female silkmoth *Bombyx mori*. This moth uses an alcohol pheromone, bombycol ((*E*,*Z*)-10,12-hexadecadien-1-ol) (Butenandt *et al*., 1959). Perhaps an ester is made in the gland but is hydrolyzed to the alcohol for use as the sex pheromone.

The three *D. melanogaster* esterases (39, 40, and 42) in clade D have yet to be characterized functionally and no mutants are available. However, sites of expression can at least be identified from EST data. No ESTs have been detected for 39 at the time of writing but ESTs corresponding to 42 have been recovered in adult testis, and to 40 in adult head and salivary gland cDNA libraries. Microarray life cycle data are also available for 40 (http://flygenome.yale.edu/Lifecycle/) showing a peak of expression in prepupae and adults. It remains to be determined whether these esterase genes play any role in hormone hydrolysis in *Drosophila*.

We are unaware of any reports of esterases for plant semiochemicals among insects as yet. However, the large number of volatile plant esters which elicit specific responses in insects suggest that they probably exist. Three examples serve to illustrate the diversity of plant ester cues and insect responses to them. First, the noctuid moth *Autographa gamma* is attracted to a number of flowering plants that have in common the floral scent compound benzyl benzoate. Wind tunnel and electrophysiological experiments indicate that the response is specific to this ester (Plepys *et al*., 2002a, 2002b). Second, the volatile ester methyl salicylate is produced by many plants when they are attacked by herbivores (Shulaev *et al*., 1997) and females of many parasitoids use this compound as a cue to locate a host (Poecke *et al*., 2001). Finally, the ester ethyl (2*E*,4*Z*)-2,4-decadienoate produced by the Bartlett pear *Pyrus communis* is a powerful attractant for neonate larvae of the codling moth *Cydia pomonella* and is used by them to locate the fruit (Knight and Light, 2001). All these plant esters detected by insects will require rapid degradation by the insect to allow new incoming signal to be detected.

5.10.5. Intracellular Catalytic Clades

There are three major clades of mainly intracellular carboxyl/cholinesterases, all members so far identified apparently being catalytically active (clades A–C in **Figure 2**). Currently all but two of the sequences in these clades come from the Diptera. One clade is exclusively populated at the moment by an extensive radiation within the higher Diptera. Conversely, its sister clade, whilst not so extensively radiated, currently contains only lower dipteran sequences. These two clades, the lower and higher dipteran microsomal α-esterases (see Sections 5.10.5.1 and 5.10.5.2), are relatively intensively studied because of the involvement of certain members in metabolic resistance to various chemical insecticides. Less can be said as yet about the third major clade in this group, which appears to contain several cytosolic and a few secreted and mitochondrial enzymes. These enzymes are mainly from the lower Diptera, plus two from *D. melanogaster* and one each from a wasp, a moth, and an aphid. Interestingly the wasp esterase is also involved in insecticide resistance (see Section 5.10.5.3).

5.10.5.1. Lower Dipteran Microsomal α-Esterases

Both the anopheline and culicine mosquitoes studied to date contain a two-member cluster of genes encoding soluble/microsomal esterases. This two-member cluster in the mosquitoes constitutes clade C (**Figure 2**). In the culicines, where they are best studied, the two esterase genes are commonly designated *estα* and *estβ* because the corresponding enzymes, respectively, prefer α- and β-naphthyl acetate as substrates (Hemingway *et al*., 2000). However, they also appear as *est3* and *est2*, respectively, in some literature (see, e.g., Pasteur and Georghiou, 1981; Pasteur *et al*., 1981a). The *estα* and *estβ* genes share several intron positions and the amino acid sequences of the encoded Estα and Estβ proteins are about 50% identical (Vaughan *et al*., 1995, 1997a; Ranson *et al*., 2002). This compares with the 98% identity between the products of the duplicated aphid β-esterases implicated in OP and carbamate resistance (see Section 5.10.4.3.2), making duplication of the *estα* and *estβ* genes a much older event. Consistent with this, there is little immunological cross-reactivity between the two enzymes in *Culex pipiens* (Mouchès *et al*., 1987; Karunaratne *et al*., 1994).

The two genes are arranged head to head, with only about 600 bp between their coding regions in *A. gambiae* and about 1.7 kb between them in the wild-type (OP susceptible) *C. pipiens* (Vaughan *et al*., 1997a; Ranson *et al*., 2002). Although divergently

transcribed, in *C. pipiens* at least it appears that the two genes may share some promoter elements (Hawkes and Hemingway, 2002). Expression levels are not particularly high in susceptible *C. pipiens* and the two enzymes can be difficult to detect in some electrophoretic assays, despite their relatively high activities for the naphthyl ester substrates (Karunaratne *et al*., 1995). The *C. pipiens* enzymes separate mainly in the soluble fraction during purification but the presence of C-terminal KDEL motifs suggests at least a weak microsomal association (Fournier *et al*., 1987; Merryweather *et al*., 1990) (see Section 5.10.2.1). Estα and Estβ are highly polymorphic for isozyme variants in *C. pipiens*, with as much as 5% amino acid sequence differences reported among Estβ variants (Raymond *et al*., 1991; Hemingway and Karunaratne, 1998). Estα behaves as a homodimer while Estβ behaves as a monomer (Fournier *et al*., 1987). Monomer molecular weights of around 60 and 67 kDa for Estα and Estβ, respectively, are typical for carboxyl/cholinesterases (Fournier *et al*., 1987).

Mutations of the *estα* and *estβ* genes have been associated with broad spectrum OP resistance in *C. pipiens* populations from diverse localities around the world. These populations cover both *C. pipiens pipiens* and *C. pipiens quinquefasciatus*, and indeed many of the same alleles are found in both subspecies (e.g., Beyssat-Arnaouty *et al*., 1989; Hemingway and Karunaratne, 1998) (**Table 2**). In all cases characterized, resistance has been associated with overproduction of either or both of the Estα and Estβ proteins, and in almost all cases this in turn has been associated with amplification of either or both of the *estα* and *estβ* genes. One case of resistance apparently not due to amplification involves overproduction of the Estα1 variant by some other, as yet uncharacterized, mechanism (Rooker *et al*., 1996).

At least nine different *estα* and/or *estβ* amplicons have now been described in *C. pipiens*, at least one involving just *estα*, four just *estβ*, and four involving both (Pasteur *et al*., 1981b; Guillemaud *et al*., 1998; Hemingway and Karunaratne, 1998; Hemingway *et al*., 2000) (**Table 2**). These numbers are likely to be underestimates because several of the studies have only used isozyme mobilities to discriminate phenotypes and it is clear that these methods will miss many variants (Poirié *et al*., 1992; Vaughan *et al*., 1995; Karunaratne *et al*., 1995). While many populations are polymorphic for several amplicons, two are widespread, *estβ1²* and *estα2¹/estβ2¹*, with the latter particularly common and apparently replacing several amplicons, including the former, in many populations around the world over time (Raymond *et al*., 1987; Qiao and Raymond, 1995). Intriguingly now in France and Cyprus the *estα4/estβ4* and *estα5/estβ5* amplicons, respectively, are in turn superceding the *estα2¹/estβ2¹* amplicon (Poirié *et al*., 1992; Lenormand *et al*., 1998b). The amplifications characterized to date map to broadly the same region of the chromosome, but they are adjacent insertions rather than allelic substitutions of the wild-type genes (Nance *et al*., 1990; Wirth *et al*., 1990; Karunaratne *et al*., 1995; Hemingway *et al*., 2000).

Quantitative PCR and dot blot methods have also revealed substantial quantitative variation in amplicon copy number among strains with the same type of amplicon (Mouchès *et al*., 1985; Pasteur and Georghiou, 1989; Callaghan *et al*., 1998; Weill *et al*., 2000). This variation in turn underlies variation in levels of esterase activity and OP resistance (Villani *et al*., 1983; El-Khatib and Georghiou, 1985). Copy numbers as high as 250 have been reported, associated with activity increases of 500-fold and resistance factors of 800-fold (Mouchès *et al*., 1990; Poirié *et al*., 1992). Copy number is stable over many generations in homozygous laboratory lines in the absence of selection (Raymond *et al*., 1993). However, copy number has been readily increased in the laboratory by further OP selection (Wirth *et al*., 1990). It is suggested that unequal crossing-over generates at least some of the variation in copy number (Weill *et al*., 2000; Berticat *et al*., 2001). Differences in DNA methylation as seen in the amplified aphid esterases (see Section 5.10.4.3.2) have not been reported for *C. pipiens* *estα* or *estβ*.

The resistance mechanism mediated by the *M. persicae* E4/FE4 enzymes involves predominantly sequestration but with some role for very slow hydrolysis for dimethyl OPs (Devonshire, 1977; Devonshire and Moores, 1982) (see Section 5.10.4.3.2). However, the mechanism mediated by the amplified *C. pipiens* esterases appears to depend even more strongly on sequestration. Thus the overexpressed Estα2 and Estβ2 isozymes characterized to date are all highly reactive with OPs, but have negligible turnover rates for them (Ketterman *et al*., 1992, 1993; Karunaratne *et al*., 1993, 1995). For example, estimates of bimolecular rate constants for the phosphorylation of Estα2¹ or Estβ2¹ with various OPs range from 0.02 to 155 $\mu M^{-1} min^{-1}$ (18 and 17, respectively, for paraoxon, cf. 133 $\mu M^{-1} min^{-1}$ for *M. persicae* E4) (Devonshire, 1977) (see Section 5.10.4.3.2). The corresponding turnover rates (k_3) for paraoxon are only about 0.06 h^{-1} compared to 0.6 h^{-1} for *M. persicae* E4 (Devonshire, 1977). Coupled with their abundance – as much as 0.4% of the

total soluble protein of the organism (Karunaratne *et al.*, 1993) (cf. up to 1% for the *M. persicae* enzymes) (Devonshire, 1989) (see Section 5.10.4.3.2) – the overproduced enzymes can clearly provide the organism with an effective sink for insecticide.

There are several reports of significant differences in OP kinetics among the minority of the amplified Estα and Estβ isozymes that have been investigated in detail (Karunaratne *et al.*, 1993, 1995; Ketterman *et al.*, 1993; but see also Hemingway *et al.*, 2000). These include suggestions that the Estβ isozymes involved in amplification and resistance may have greater reactivity with OPs than Estβ isozymes that are not implicated in amplification and resistance. Further, thoroughgoing comparisons of the OP kinetics across amplified and nonamplified Estα and Estβ isozymes utilizing compounds used in the field might not only explain why particular isozymes are involved in resistance, but also elucidate the allele succession phenomena that are occurring among amplicons in the field.

Unlike the amplified aphid esterases, the amplified *C. pipiens* enzymes are only slightly reactive against carbamates biochemically (Cuany *et al.*, 1993; Karunaratne *et al.*, 1993) and do not confer carbamate resistance (Georghiou *et al.*, 1980; Priester *et al.*, 1981).

Two of the *C. pipiens* amplicons have been characterized intensively at a molecular level, one just involving the *estβ1*^{2} allele and the other involving both *estα2*^{1} and *estβ2*^{1}. In the first case, typified by the TEMR strain, the amplicon is some 30 kb in length, containing a highly conserved internal 25 kb core region (Mouchès *et al.*, 1990; Vaughan *et al.*, 1995; Rooker *et al.*, 1996). The amplicons are arranged in a tandem array adjacent to the wild-type locus on chromosome 2; they create a noticeably longer chromosome cytologically (Nance *et al.*, 1990; Wirth *et al.*, 1990). This *estβ1*^{2} amplicon was one of the first detected after the introduction of OPs, and has since declined in frequency in many localities where two-gene amplicons like *estα2*^{1}/*estβ2*^{1}, *estα4*/*estβ4*, and *estα5*/*estβ5* are proliferating (Raymond *et al.*, 1991; Poirié *et al.*, 1992; Rivet *et al.*, 1993; Lenormand *et al.*, 1998b).

The 25 kb *estα2*^{1}/*estβ2*^{1} amplicon as typified by the PelRR strain contains both esterase genes in a head-to-head configuration as per the wild-type unamplified genes (Villani *et al.*, 1983; Raymond *et al.*, 1987; Hemingway *et al.*, 1990). However, in PelRR the two genes are separated by 2.7 kb, whereas in susceptible strains like PelSS they are only separated by 1.7 kb, due to two insertions in the intergenic region in PelRR. There are also various single nucleotide substitutional differences between the intergenic regions of the two strains (Vaughan *et al.*, 1997a).

Although amplification of the two esterase genes in the PelRR strain results in a 1 : 1 ratio in gene number there is about threefold more Estβ2^{1} protein in PelRR flies than Estα2^{1} (Karunaratne, 1994, cited in Hawkes and Hemingway, 2002). Moreover, the two proteins differ in their tissue specificity (Pasteur *et al.*, 2001). Both are highly expressed in the alimentary canal, Malpighian tubules, and the oenocytes in the body cavity of larvae and adults. These are all tissues where a variety of detoxification functions are known to be carried out. However, Estβ2^{1} is also expressed in the CNS, where its proximity to the target site, AChE, may confer an additional level of protection. Presumably these differences can be accounted for by differences in promoter function between *estα2*^{1} and *estβ1*^{1}. They may be encoded by the intergenic insertions noted above. Gel shift assays have indeed indicated altered binding of at least one transcription factor in Pel RR (Hawkes and Hemingway, 2002).

Another explanation suggested for the success of the *estα2*^{1}/*estβ2*^{1} amplicon involves the presence of an additional gene on the amplicon. A functional aldehyde oxidase gene (*ao1*) is also amplified in this strain (Hemingway *et al.*, 2000), resulting in mosquitoes which also have elevated aldehyde oxidase activity. It is suggested that this might be advantageous for the detoxification of pesticides or other xenobiotics containing aromatic groups. The *estβ1*^{2} and *estα3*/*estβ1* amplicons were found not to contain intact functional copies of *ao1*.

Perhaps unsurprisingly, given the production of such large amounts of esterase protein, several of the amplification alleles are clearly associated with some fitness costs in the absence of insecticide. It appears that some resistant strains are not able to overwinter as well as susceptible strains (Gazave *et al.*, 2001), and that resistant males are not as successful in competing for mates as susceptible males (Berticat *et al.*, 2002). Amplicons with such fitness costs include *estα2*^{1}/*estβ1*^{1} but significantly, at least in terms of overwintering ability in French populations, apparently not *estα4*/*estβ4* (Chevillon *et al.*, 1997; Lenormand *et al.*, 1998b).

Intriguingly it seems that, along with insecticide resistance, the overexpressed *C. pipiens* esterases may also be associated with reduced levels of filarial parasites (McCarroll *et al.*, 2000). It will be of interest to see if any causal basis can be established for this correlation in the future. There were also earlier reports associating a particular esterase isozyme in *A. gambiae* with reduced transmission of the malarial parasite plasmodium (Collins *et al.*, 1986;

Vernick *et al*., 1988; Vernick and Collins, 1989) but more detailed investigations subsequently argued against any causal connection with the esterase (Crews-Oyen *et al*., 1993).

Although not yet fully characterized, amplifications of both *estα* and *estβ* genes have also been associated with broad spectrum OP resistance in *C. tritaeniorhynchus* and *C. tarsalis* (**Table 3**, below).

There are clearly fundamental similarities between the OP resistance mechanisms based on these amplified culicine α-esterases and the amplified hemipteran β-esterases reviewed above (see Section 5.10.4.3.2). In both cases high levels of resistance against a broad spectrum of OPs are principally achieved by a pesticide sequestration mechanism that uses massive gene amplification to dramatically overexpress a carboxylesterase isozyme with very high affinity for OPs. The versatility of this basic mechanism is borne out by some of the genetic and biochemical differences between the systems, for example, the relatively low levels of sequence similarity and the secreted versus intracellular locations of the enzymes. However in the following section we see how in the higher Diptera α-esterases with high affinity for OPs have also been recruited to a fundamentally different OP resistance mechanism. In this case a structural change in the enzyme converts it to an OP hydrolase, whilst qualitatively reducing its carboxylesterase activity in conventionally stained isozyme gels.

5.10.5.2. Higher Dipteran Microsomal α-Esterases

The *D. melanogaster* α-esterase radiation comprises 10 physically clustered genes plus one other located at a remote chromosomal location (Robin *et al*., 1996, 2000a, 2000b; Russell *et al*., 1996) (**Figure 9**). The 10 clustered α-esterase genes lie in a 60 kb segment that also contains four unrelated open reading frames and a closely related α-esterase pseudogene (*αE4a*, lying within an intron of *αE6*). All but one of the esterases in the cluster are oriented in the same direction. This α-esterase cluster is one of the largest clusters of sequence-related enzyme coding genes in the *D. melanogaster* genome (Adams *et al*., 2000).

At the nucleotide level, all members of the higher dipteran α-esterase radiation show a distinctive pattern of introns (Oakeshott *et al*., 1999). At the protein level, they show 37–66% amino acid identity, plus a distinctive pattern of small indels, a characteristic motif in a region corresponding to a peripheral binding site in AChE (plus some characteristic residues corresponding to the lining of the gorge in AChE) and the lack of an identifiable signal peptide, but almost all possess a carboxy terminal endoplasmic reticulum retention signal (Oakeshott *et al*., 1999) (**Figure 6**); hence their assignment as microsomal α-esterases.

All the esterase genes in the α-cluster are expressed to some degree. Diverse and noncomplementary roles are suggested by considerable differences between the genes in developmental patterns, overall expression levels, and tissue and sex specificities (Campbell *et al*., 2003). For example, three show varying degrees of male specificity, with one predominantly expressed in heads (*DmαE8*), another abundant in testes (*DmαE3*), and the third restricted to the germ line (*DmαE6*). Others are expressed broadly across feeding stages and this would be consistent with a role for at least some in the digestion of dietary or xenobiotic esters. A role in detoxification of xenobiotics is also implied by the role of several orthologs of one (*αE7*) in metabolic resistance to OPs (see below).

Figure 10 shows how some of the major events generating the *D. melanogaster* α-esterase radiation can be discerned by combining the evidence on the branch orders for their divergences in **Figure 2** with the information on their physical locations in **Figure 9**. Briefly, five major phases can be discerned. The first gave rise to four of the central genes in the extant cluster by a series of single gene duplications from the progenitor gene. The original progenitor then duplicated to generate one progenitor for the remainder of the genes on the left side of the cluster, and another progenitor for the remainder of those on its right side. Then successive single gene duplications of these latter two progenitors, respectively, generated the rest of the cluster, with one late-stage event also duplicating the left-terminal gene to generate the one remotely located member of the radiation. In general terms the radiation was thus generated from the inside outwards by a sequence of single gene duplications, mostly to adjacent locations and mostly in the same orientation.

This scenario can then be embellished by reference to available data on the composition of the α-esterase cluster in some other species, including fairly complete data for *D. pseudoobscura* and *D. buzzatii* and partial data for the *M. domestica* (**Figure 10**) (Oakeshott *et al*., 1999; Robin *et al*., 2000a; http://www.hgsc.bcm.tmc.edu). It is seen that most members of the cluster as now seen in *D. melanogaster* had arisen before the split of the drosophilids from the Muscidae (about 80 million years ago). However, it is also seen that the left end in particular remains a focus for ongoing change within the cluster, including both recurrent gene duplication and occasional gene loss. *Drosophila pseudoobscura*

Table 3 Summary of cases of esterases implicated in metabolic resistance to OPs (excluding malathion-specific resistance; see **Table 4**) and carbamates

Species	*Biochemistry*	*Reference*
Dictyoptera		
Blattella germanica (German cockroach)	Greater intensities of ≥3 OP- and carbamate-inhibitable esterase isozymes in OP and carbamate resistant strains	Prabhakaran and Kamble (1995), Scharf *et al.* (1997)
Thysanoptera		
Frankliniella occidentalis	Esterase activity in an OP resistant strain is lower and less sensitive to OP inhibition	Zhao *et al.* (1994)
Scirtothrips citri	Greater esterase activity in OP resistant strains	Ferrari *et al.* (1993)
Hemiptera		
Acyrthosiphon pisum (pea aphid)	Greater esterase activity in OP selected strains	Marullo *et al.* (1988)
Aphis gossypii	Greater esterase activity and ≥3 different or more intense esterase isozymes in OP and carbamate resistant strains	Furk *et al.* (1980), O'Brien *et al.* (1992)
Bemisia tabaci	Greater esterase activity in an OP-selected strain. However, the B-biotype $E_{0.14}$ esterase isozyme involved in SP resistance is not involved (see **Table 5**)	Bloch and Wool (1994), Byrne *et al.* (2000)
Brevicoryne brassicae (cabbage aphid)	Greater esterase activity in carbamate selected strains	Marullo *et al.* (1988)
Lygus hesperus	Greater OP-inhibitable esterase activity in strains whose OP resistance is also suppressed by carboxylesterase inhibitors	Zhu and Brindley (1990a, 1990b, 1992)
Myzus persicae	See **Table 2** and Section 5.10.4.3.2	
Myzus nicotianae[a] (tobacco aphid)	Greater esterase activity and more intense esterase isozymes in OP and carbamate resistant strains due to introgression of E4 and FE4 amplicons from *M. persicae* (see Section 5.10.4.3.2)	Abdel-Aal *et al.* (1990, 1992), Field *et al.* (1994), Wolff *et al.* (1994)
Nasonovia ribisnigri (currant-lettuce aphid)	Intense esterase isozyme in some carbamate resistant strains	Barber *et al.* (1999)
Nephotettix cincticeps	Greater esterase activity and ∼4 more intense esterase isozymes in OP resistant strains	Hasui and Ozaki (1984), Motoyama *et al.* (1984), Chiang and Sun (1996)
Nilaparvata lugens (brown rice planthopper)	Greater esterase activity and two more intense isozymes (generated by different glycosylation) due to a three- to sevenfold amplification of an esterase gene in OP and carbamate resistant strains (see Section 5.10.4.3.2)	Karunaratne *et al.* (1999), Small and Hemingway (2000a, 2000b), Vontas *et al.* (2000)
Phorodon humuli (damson-hop aphid)	Greater esterase activity and greater intensity of ≥4 esterase isozymes in OP and carbamate resistant strains	Lewis and Madge (1984), Wachendorff and Zoebelein (1988)
Schizaphis graminum (greenbug)	Increased esterase activity and (mainly) two more intense isozyme zones in strains whose OP resistance is partially suppressed by carboxylesterase inhibitors. Elevation in one zone (type I) is due to four- to eightfold amplification of an esterase gene with strong similarity to *M. persicae* E4/FE4. Reversion to susceptibility due to reduced methylation as with E4. Elevation in the other zone (type 2) apparently due to structural differences in an isozyme produced in similar amount in susceptible and resistant strains (see Section 5.10.4.3.2)	Siegfried and Ono (1993a, 1993b), Siegfried and Zera (1994), Shufran *et al.* (1996), Siegfried *et al.* (1997), Ono *et al.* (1999)
Coleoptera		
Diabrotica virgifera	Greater intensity of at least one major esterase isozyme zone and greater carbamate and OP hydrolytic activity *in vivo* in strains whose OP and carbamate resistance is suppressed by carboxylesterase inhibitors	Miota *et al.* (1998), Scharf *et al.* (1999a, 1999b), Zhou *et al.* (2002)
Leptinotarsa decemlineata	Novel OP-inhibitable esterase isozyme in an OP resistant strain	Anspaugh *et al.* (1995)
Oryzaephilus surinamensis (saw-toothed grain beetle)	Greater esterase activity in a chlorpyrifos-methyl (CPM) and fenitrothion (FT) resistant strain is due to greater amounts of an esterase isozyme zone with greater sensitivity to OP inhibition (but no OP hydrolytic activity). A strain with high CPM but low FT resistance produces an alternate isozyme zone still highly sensitive to CPM inhibition but less sensitive to FT inhibition	Collins *et al.* (1992), Conyers *et al.* (1998), Rossiter *et al.* (2001)

Continued

Table 3 Continued

Species	*Biochemistry*	*Reference*
Lepidoptera		
Cydia pomonella (codling moth)	Reduced esterase activities in some OP resistant strains	Bush *et al.* (1993)
Epiphyas postvittana (light brown apple moth)	Greater esterase activity due to greater intensities of many esterase isozymes in OP resistant strains	Armstrong and Suckling (1988)
Heliothis virescens	Novel metal-activated esterase isozyme insensitive to OP inhibition but with OP hydrolytic activity isolated from an OP (methyl paraoxon) resistant strain	Konno *et al.* (1990), Kasai *et al.* (1992)
	Greater esterase activity due to three more intense esterase isozymes in a carbamate selected strain whose resistance is partially suppressed by carboxylesterase inhibitors and which also shows elevated cross-resistance to OPs	Goh *et al.* (1995), Zhao *et al.* (1996)
	Greater esterase activity due to greater intensities of several esterase isozymes, one in place of an alternate esterase isozyme, in OP (profenofos) resistant strains	Harold and Ottea (1997, 2000)
Platynota idaeusalis (tufted apple bud moth)	Greater esterase activity due to greater intensities of one major and several minor esterase isozymes and greater OP hydrolytic activity *in vivo* in strains whose OP resistance is suppressed by carboxylesterase inhibitors	Karoly *et al.* (1996)
Diptera		
Aedes aegypti (yellow fever mosquito)	Greater OP-inhibitable esterase activity in strains whose OP resistance is suppressed by carboxylesterase inhibitors	Mazzarri and Georghiou (1995)
Anopheles albimanus	Greater esterase activity and a more intense zone of esterase isozymes in a strain whose OP resistance is suppressed by carboxylesterase inhibitors	Brogdon and Barber (1990)
Culex pipiens complex	See **Table 2** and Section 5.10.5.1	
Culex tarsalis	Greater esterase activity and more intense isozyme zone due to ~30-fold amplification of orthologs of *Estα*/*Estβ* in *C. pipiens* in an OP resistant strain (see Section 5.10.5.1)	Mouchès *et al.* (1987), Beyssat-Arnaouty *et al.* (1989), Raymond *et al.* (1989)
Culex tritaenorhynchus	Greater esterase activity and more intense isozyme due to amplification of an orthologs of *C. pipiens Estα*/*Estβ* in an OP resistant strain (see Section 5.10.5.1)	Karunaratne *et al.* (1998), Karunaratne and Hemingway (2000, 2001)
Haematobia irritans (buffalo fly)	Greater esterase activity and greater intensity of an esterase isozyme is associated with increased expression of the LcαE7 ortholog in some OP resistant strains (see Section 5.10.5.2)	Guerrero *et al.* (2000)
Lucilia cuprina (Australian sheep blowfly)	Reduced general esterase activity and E3 isozyme staining intensity and significant OP hydrolase activity associated with Asp137 (and Ser/Leu251) variants of LcαE7 in strains with OP resistance partially suppressible by carboxylesterase inhibitors (see Section 5.10.5.2)	Hughes and Devonshire (1982), Hughes and Raftos (1985), Russell *et al.* (1990), McKenzie *et al.* (1992), Newcomb *et al.* (1997, 2004), Campbell *et al.* (1998a, 1998c), Devonshire *et al.* (2003)
Lucilia sericata (green bottle fly)	Asp137 (and Ser/Leu251) variants of the ortholog of LcαE7 in populations known to segregate for general OP resistance (see Section 5.10.5.2)	R.D. Newcomb, C.G. Young, and J.R. Stevens, unpublished data
Musca domestica	Reduced general esterase activity and Ali isozyme staining intensity associated with Asp137 (and Ser/Leu251) variants of MdαE7 in OP resistant strains (see Section 5.10.5.2)	Oppenoorth and van Asperen (1960), Campbell *et al.* (1997), Claudianos *et al.* (1999, 2001), Scott and Zhang (2003)
Simulium damnosum and *Simulium sanctipauli* (black flies)	Greater esterase activity and greater *in vivo* OP hydrolytic activity in strains whose OP resistance is suppressed by carboxylesterase inhibitors	Hemingway *et al.* (1989)
Acarina		
Amblyseius pontentillae	Less intense esterase in an OP resistant strain; the isozyme is highly reactive with OPs but has insufficient OP hydrolytic activity to be a major contributor to resistance	Anber and Oppenoorth (1989), Oppenoorth (1990)
Boophilus microplus	Greater intensities of several esterase isozymes in OP resistant strains	Rosario-Cruz *et al.* (1997)
Tetranychus kanzawai	Greater esterase activity in strains whose OP resistance is suppressed by carboxylesterase inhibitors	Kuwahara *et al.* (1982)

[a]Note that *M. nicotianae* is now recognized as conspecific with *M. persicae* (see Section 5.10.4.3.2).

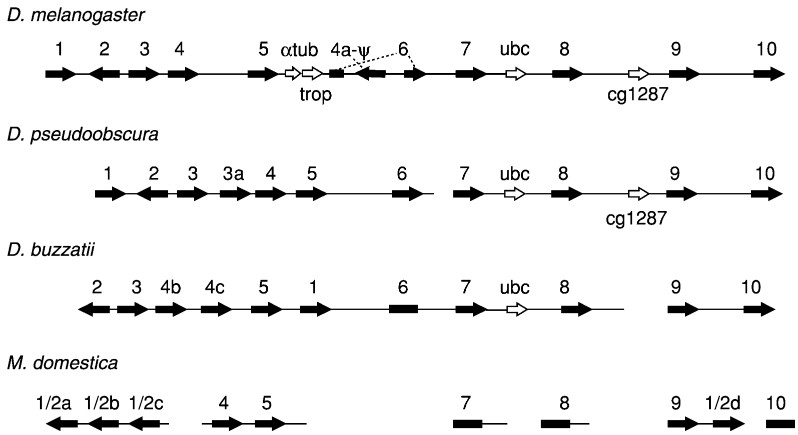

Figure 9 Organization of the α-esterase clusters as characterized to date from *D. melanogaster, D. pseudoobscura, D. buzzatii*, and *M. domestica* (Oakeshott *et al.*, 1999; Adams *et al.*, 2000; Robin *et al.*, 2000a; http://www.hgsc.bcm.tmc.edu). The whole of the cluster has been recovered from *D. melanogaster* and most of it at least from *D. pseudoobscura* and *D. buzzatii*, but it is only partly characterized in *M. domestica*. Nonesterase genes are unshaded (ubc, ubiquitin conjugating enzyme; trop, putative tropomyosin; αtub, α-tubulin; CG1287, functionally anonymous open reading frame). The contig in *D. melanogaster* is about 60 kb. Line breaks indicate uncharacterized gaps in *D. pseudoobscura, D. buzzatii*, and *M. domestica*. The orientations of some genes are unknown and accordingly shown as blocks rather than arrows. There is ambiguity as to the orthologs of the *Drosophila αE1* and *αE2* genes in *M. domestica* so the four candidates are shown as *αE1/2a–d*. Note that orthologs for six of the genes (*αE1/2*, *αE5*, *αE7*, *αE8*, *αE9*, *αE10*) have also been recovered from *Lucilia cuprina* but there is no information on their contig arrangement (Newcomb *et al.*, 1996).

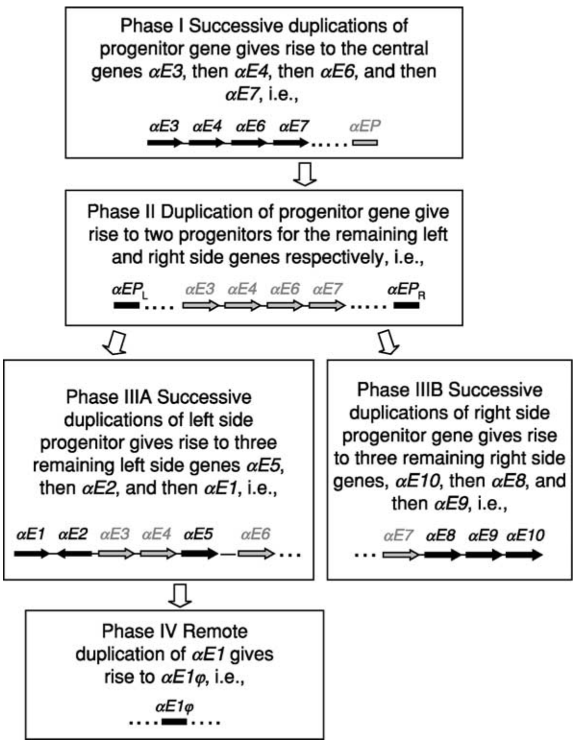

Figure 10 Schematic diagram showing a parsimonious reconstruction of the major phases in the evolution of the extant α-esterase cluster in *D. melanogaster*. Genes added in each phase are shown in bold, with pre-existing genes in gray. Genes of unknown orientation are shown as blocks rather than arrows. Distances are not to scale. *αEP* = progenitor α-esterase gene; αEP_L and αEP_R = progenitors for genes on the left and right side of the cluster, respectively.

lacks the *αE4a* pseudogene duplication and two of the nonesterase genes in the cluster, but has a tandem duplication of *αE3*. *Drosophila buzzatii* shows evidence of a different duplication of *αE4* and has its *αE1* in a different, central location within the cluster. Alternatively, *M. domestica* has two additional copies of *αE1/αE2*, including one at the other end of the cluster. It is not clear why the left end genes in particular should be a focus for change, but it may be relevant that they show relatively similar and broad expression profiles and lower levels of amino acid sequence conservation than the other genes.

Homologs of several of the α-esterases have also been identified in another higher dipteran, the calliphorid *L. cuprina* (Figure 9) (Oakeshott *et al.*, 1999) and, as with *M. domestica*, presumptive orthologs have been identified for several genes at the right end of the drosophilid cluster. The conservation of these orthologs across the Drosophilidae, Muscidae, and Calliphoridae clearly suggests the retention of important physiological functions, although as noted above there is as yet only indirect evidence as to the identities of these functions. The most highly conserved of the presumptive orthologs is αE7 (about 64% amino acid identities across the two lineages). This is also the one that has been implicated in metabolic resistance to OPs in a few muscid or calliphorid species involving what is often termed the mutant ali-esterase mechanism (Oppenoorth and van Asperen, 1960).

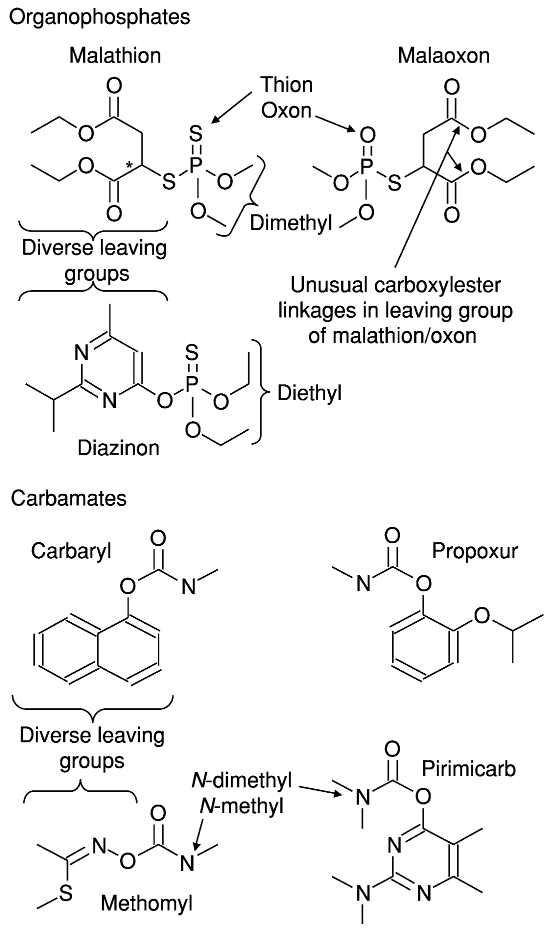

Figure 11 Structures of organophosphate (OP) and carbamate insecticides. OP insecticides all contain a central phosphorus atom. Most are produced in the thion form in which the phosphorus is linked by a double bond to a sulfur atom (phosphorothionates, exemplified here by diazinon, or phosphorothiolothionates when the leaving group is linked via another sulfur, exemplified here by malathion). Thion OPs are not the active forms of the insecticides but are converted *in vivo* by p450 oxidases to active oxon forms (phosphates, or phosphorothiolates when the leaving group is linked via a sulfur). Some OP insecticides (e.g., chlorfenvinphos) are produced in the oxon form and, therefore, do not require *in vivo* activation. The leaving groups are diverse electron-withdrawing groups that are displaced when oxon OPs react to phosphorylate the catalytic serine residue of a carboxyl/cholinesterase (**Figure 1**). They may be aromatic or aliphatic, may contain heteroatoms, and may be linked to the central phosphorus through an oxygen (most common), a sulfur or other atoms. The remaining two moieties attached to the central phosphorus are typically two methoxy groups (dimethyl) or two ethoxy groups (diethyl) although some other variations exist among commercial OPs. Malathion/oxon is unusual in that its leaving group contains two carboxylester linkages (and hydrolysis of either inactivates the OP). The optical center of malathion mentioned in the text is indicated with a asterisk. Carbamate insecticides resemble ordinary carboxylesters except that a nitrogen atom is adjacent to the carbonyl carbon of the carboxylester linkage. As with the OPs, the leaving groups are diverse, with varied sizes, aromatic or aliphatic groups, heteroatoms, etc. Where the leaving group is linked through a nitrogen atom rather than the more common carbon the carbamate is an oxime exemplified here by methomyl. The acyl group of most carbamate insecticides is *N*-methyl although there are variations, such as the *N*-dimethyl pirimicarb.

OP insecticides all contain a central phosphotriester moiety, which is crucial to their mode of action (**Figure 11**). It enables them to inhibit carboxyl/cholinesterases by acting as suicide substrates (see Section 5.10.3.1.2). Thus they rapidly phosphorylate the catalytic serine residue in an analogous manner to the first, acylation step in carboxylester hydrolysis. However, the second step (dephosphorylation for OPs rather than deacylation) proceeds at very slow to negligible rates, due to stereochemical differences between OP and carboxylester substrates. Carbamates (**Figure 11**) also inhibit by a similar mechanism. Commercial OP insecticides are mostly produced in an inactive "thion" form and must be activated to "oxons" by P450 enzymes in the insect before they inhibit as described above. Two of the three ester linkages around the central phosphorus in most commercial OPs involve methyl (dimethyl OPs) or ethyl groups (diethyl OPs), while the third is an electron-withdrawing "leaving group" (**Figure 11**). Hydrolysis of this third linkage detoxifies the insecticide. A few OP insecticides, most notably malathion, also contain carboxylester moieties within the leaving group, the hydrolysis of which also inactivates the insecticide. This leads to a special case of OP resistance, often termed malathion-specific resistance, which is discussed in detail below (see Section 5.10.6.2).

Three shared features of LcαE7 and MdαE7 have been suggested as predisposing them for a role in metabolic resistance to OPs (Campbell *et al.*, 1997). First, the wild-type enzymes are highly susceptible to inhibition by the activated, oxon forms of many OPs; indeed both interact more rapidly with many OPs than does the presumed target, AChE (Newcomb *et al.*, 1997; Chen *et al.*, 2001). For example, the k_i of LcαE7 with paraoxon is 6.3×10^7 $M^{-1}\,min^{-1}$ compared with 5.1×10^6 $M^{-1}\,min^{-1}$ for *L. cuprina* AChE (Newcomb *et al.*, 1997; Chen *et al.*, 2001). Second, the enzymes are expressed quite abundantly across the feeding life stages, larvae and adults, when the animals are likely to come in contact with insecticides (Parker *et al.*, 1991, 1996). Finally, they also show good kinetics (specificity constants $\sim 10^6\,M^{-1}\,s^{-1}$) towards the carboxylester groups of malathion (malathion carboxylesterase activity, MCE), leading to the involvement of certain alleles in malathion-specific resistance.

Resistance to a broad spectrum of OPs in both *M. domestica* and *L. cuprina* has been conferred by amino acid substitutions at either of two positions in the active site of αE7. In both species a Gly137Asp substitution confers one class of broad-spectrum resistance while Trp251Ser/Leu substitutions confer a different class of broad-spectrum resistance, coupled with malathion-specific resistance (Campbell *et al.*, 1998a, 1998c). None of the substitutions confers cross-resistance to carbamates. In both species it appears that each resistance substitution initially occurred at least twice in different allelic backgrounds although only one allele encoding each type of resistance is now relatively common in each species (Claudianos *et al.*, 1999, 2001; Smyth *et al.*, 2000; Scott and Zhang, 2003; Newcomb *et al.*, 2004).

Alleles showing the Gly137Asp substitution now dominate contemporary populations of both *L. cuprina* and *M. domestica* (Newcomb *et al.*, 1997, 2004; Claudianos *et al.*, 1999; Smyth *et al.*, 2000; Scott and Zhang, 2003). The resulting mutant enzyme has improved ability to hydrolyze OPs, with a preference for diethyl (55-fold increase in hydrolytic ability) over dimethyl OPs (33-fold increase) (Devonshire *et al.*, 2003). While these increases represent very low turnover numbers (about three turnovers per hour per molecule of enzyme), they are sufficient to account for modest levels of resistance to dimethyl OPs (4–12-fold) and about twofold greater resistance to diethyl OPs (7–20-fold resistance in adult *L. cuprina*) (Campbell *et al.*, 1998a, 1998c; Devonshire *et al.*, 2003). Interestingly, the turnover numbers of Asp137-αE7 with OPs are very comparable to those that the *M. persicae* E4/FE4 enzymes achieve for the particular case of malathion, and larger than those for the *M. persicae* enzymes with dimethyl OPs. In both cases Devonshire and Moores (1989) have argued that hydrolysis plays a significant supplementary role to sequestration in the resistance mechanism (see Section 5.10.4.3.2).

Asp137 is a nonconservative substitution of the Gly137 whose main chain nitrogen atom contributes to the oxyanion hole within the active site (**Figure 5**). The increased ability of the Asp137 enzyme to hydrolyze OPs may be due to the ability of this residue to activate a water molecule in a suitable orientation for nucleophilic attack and dephosphorylation of the phosphoryl-enzyme intermediate (Newcomb *et al.*, 1997), in an analogous manner to the second, deacylation step of carboxylester hydrolysis (**Figure 1**) (see Section 5.10.1.2). Thus the OP is turned over as a normal substrate rather than blocking the active site as a suicide substrate. A similar mechanism is proposed to explain the increased OP hydrolytic activity caused by a substitution to a histidine at a similar position in the oxyanion hole of human BuChE (Lockridge *et al.*, 1997). Forms of αE7 with Asp137 show drastically reduced carboxylesterase activities, possibly due to compromised functioning of the oxyanion hole for carboxylester hydrolysis (Newcomb *et al.*, 1997; Claudianos *et al.*, 1999). This then accounts for the association of OP resistance with apparent null phenotypes for the corresponding isozymes (E3 and Ali for *L. cuprina* and *M. domestica*, respectively) (Hughes and Raftos, 1985; Campbell *et al.*, 1997; Claudianos *et al.*, 1999) and reduced whole body homogenate activities for artificial substrates like naphthyl acetate or methyl butyrate (termed ali-esterase activity by Oppenoorth and van Asperen (1960)). It is this coincident gain of OP hydrolytic activity and loss of “ali-esterase” activity that defines the mutant ali-esterase mechanism.

Less abundant in *L. cuprina* and *M. domestica* populations are OP resistance alleles of α*E7* in which Trp251 is substituted by Leu or Ser (Claudianos *et al.*, 1999; Smyth *et al.*, 2000). Flies with these active site substitutions also show reduced ali-esterase activities as this mutation interferes with some, although not all of the susceptible enzyme’s carboxylesterase activities (Campbell *et al.*, 1998a). Like the Asp137 mutants, this enzyme has improved ability to hydrolyze OPs, except that in this case dimethyl OPs are preferred over diethyl OPs (34- and tenfold increases, respectively, over wild-type in OP turnover for the Leu251 enzyme from *L. cuprina*) (Devonshire *et al.*, 2003). This preference is reflected in two- to fivefold greater resistance to dimethyl OPs (5–27-fold resistance in adult *L. cuprina*) than their diethyl analogs (two to sixfold) (Campbell *et al.*, 1998c). Exceptional resistance levels are seen, however, for malathion (>130-fold) (see below). The effect of the Leu/Ser251 mutations is proposed to depend on replacement of a bulky aromatic group in the active site by smaller residues, which might provide less steric hindrance to the inversion about the tetrahedral phosphorus that must occur during hydrolysis of the serine–phosphorus bond (Campbell *et al.*, 1998a).

The exceptional resistance to malathion shown by *M. domestica* and *L. cuprina* with Leu or Ser251 variants of αE7 is due to the combination of MCE and OP hydrolase activities in these particular forms of the enzyme. Hydrolysis of the carboxylester groups of malathion accounts for the main products of detoxification of malathion in resistant flies, yet *in vitro* MCE activity seems poorly correlated with resistance (Smyth *et al.*, 2000). Flies with the Asp137 variant of αE7 show very low *in vitro* MCE activity (Asp137-αE7 loses nearly all carboxylesterase

activity) but do not differ in their susceptibility to malathion from flies showing general OP susceptibility and far more *in vitro* MCE activity (having Gly137/Trp251-αE7). Alternatively, flies with Leu/Ser251-αE7 show modest increases of *in vitro* MCE activity over OP susceptible flies yet show very high level resistance to malathion. Here one needs to remember that malathion is converted *in vivo* to malaoxon, a potent dimethyl OP esterase inhibitor. Campbell *et al.* (1998c) showed that the OP susceptible (Gly137/Trp251) form of αE7 rapidly loses its MCE activity in the presence of malaoxon, modeling the rapid loss of detoxification capacity that would occur in an OP susceptible fly exposed to malathion. However, the Leu251 form of the enzyme was able to sustain its MCE activity in the presence of malaoxon. Devonshire *et al.* (2003) and Heidari *et al.* (2004a) demonstrated that the Leu251 and Ser251 enzymes' MCE kinetics are only slightly improved over those of the OP susceptible form but their abilities to hydrolyze dimethyl OPs are greatly enhanced as described above. Thus the Leu251 and Ser251 enzymes are able to reactivate due to their OP hydrolase activity if their catalytic serines become phosphorylated by malaoxon and, therefore, they can continue to contribute their MCE activity to the task of detoxification.

Consistent with the specificity of the OP hydrolase activity, malathion resistant *M. domestica* and *L. cuprina* show little resistance to higher (nondimethyl OP) analogs of malathion, even though these molecules are identical around the carboxylester groups that are hydrolyzed by MCE (Campbell *et al.*, 1997, 1998c and references therein). Detoxification of malathion analogs by carboxylesterase activity only occurs for those analogs where the enzyme's minor OP hydrolase activity allows reactivation of the oxon OP-inhibited enzyme.

Although confirmatory bioassay data are not yet available for all the sequenced isolates, it appears that parallel mutations at the 137 and 251 sites of the orthologous αE7 enzyme may also confer the two types of resistance on another blowfly, *Lucilia sericata*. Thus this species is known to show the two types of resistance. Recent allelic sequencing work has revealed one (presumptive diethyl OP resistant) Asp137 haplotype from New Zealand and three unrelated (presumptive dimethyl OP/malathion-specific resistant) Ser251 or Leu251 haplotypes from Europe, North America, and Africa, in addition to seven unique (presumptive OP susceptible) Gly137/Trp251 *LsαE7* haplotypes (R.D. Newcomb, C.G. Young, and J.R. Stevens, unpublished data).

In light of the recurrence of αE7-based OP resistance, Heidari *et al.* (2004a) explored the catalytic consequences of various rational substitutions around the LcαE7 enzyme's active site. Substitutions at residue 137 generally reduced carboxylesterase activities, but none was as effective as the naturally occurring Asp for enhancing OP turnover. Substitutions of Trp251 with smaller residues generally produced enzymes with qualitatively similar properties to the naturally occurring Leu or Ser substitutions. This is consistent with the idea that the substitutions remove a steric constraint on OP hydrolysis. Notably, two of the synthetic mutants, bearing W251T and W251A, had quantitatively better dimethyl OP hydrolytic activity than the naturally occurring mutants. The fact that these mutants have not been found in the field may be because they would both require a double mutation in the wild-type (susceptible) codon. The synthetic W251G mutation was interesting for a different reason. Compared with all the other substitutions at this site, Gly251 led to lesser improvements in OP turnover but 20-fold better MCE kinetics. It is noteworthy then that a glycine substitution at the homologous position occurs in an overexpressed esterase from a parasitoid wasp, *Anisopteromalus calandrae*, which shows high malathion-specific resistance (Zhu *et al.*, 1999a, 1999b) (see Section 5.10.5.3). Substitutions of various other residues around the active site were mostly detrimental to OP hydrolysis and MCE activities, while the natural mutations combined in one molecule (Asp137 + Leu251) caused no improvement over either mutation alone.

As noted earlier, the function of αE7 prior to selection with OPs is unknown. However, it is noteworthy that αE7-mediated resistance in *L. cuprina* was initially associated with a fitness cost and measurable fluctuating (bilateral) asymmetry in the absence of the insecticide (McKenzie *et al.*, 1982; Davies *et al.*, 1996). Resistance due to αE7 in fact did not rise to high frequency until the 1970s when a *modifier* gene arose at another locus which redressed the cost and asymmetry problems (Davies *et al.*, 1996). The cost in OP resistant flies was presumably due to compromised activity towards the enzyme's native substrate and, consistent with this, the Asp137 enzyme shows more comprehensive loss of carboxylesterase activities and was associated with more severe asymmetry than the Leu/Ser251 enzymes. The biochemical function of the *modifier* gene product is unknown, although it is now known not to be the ortholog of the developmental gene *Notch* in *D. melanogaster* (P.C. Batterham, personal communication). Clearly identification of the *modifier* gene function would yield important insights into the function of αE7 beyond detoxification of OPs.

Another set of mutations has apparently also occurred in *L. cuprina* since the spread of the original α*E7* resistance alleles (Smyth *et al*., 2000; Newcomb *et al*., 2004). These are duplications of the chromosomal region containing α*E7* which result in two copies of this gene and others from the α-esterase cluster being carried on one chromosome. So far three independent duplications have been observed at low frequencies. Importantly, these duplications result in dissimilar resistance alleles on the same chromosome, Asp137 alleles linked with Leu251 alleles. As a result strains homozygous for these duplications show both high levels of malathion resistance and slightly higher resistance levels to diazinon (a diethyl OP) than do nonduplicate Asp137 strains (Campbell *et al*., 1998c).

An αE7 ortholog has also recently been implicated in OP resistance in the horn fly *Haemotobia irritans*, also in the Muscidae. In this case, however, resistance appears to have been achieved through overexpression of αE7 without amino acid changes (Guerrero, 2000). AChE is presumably protected because the OPs preferentially react with the very abundant HiαE7 in a fashion analogous to that of the overexpressed hemipteran esterases discussed earlier (see Section 5.10.4.3.2).

OP resistance has never been linked with αE7 in *D. melanogaster* and a possible reason is that the enzyme in this species tends to show lower rather than higher affinities for OPs when compared with its endogenous AChE (Parker *et al*., 1991, 1996; Chen *et al*., 2001). It is therefore suggested that little benefit would arise from mutations that might amplify the gene or enhance its turnover of OPs.

5.10.5.3. Nonmicrosomal Esterases

Although a relatively derived clade compared to others in **Figure 2**, this clade (A) contains sequences from both holo- and hemimetabolan orders, and it shows greater diversity in respect of cellular/subcellular localization than do any other clades. It contains a substantial proportion of the presumptively cytosolic enzymes in the phylogeny, plus the only presumptively mitochondrial enzymes and also three with good consensus secretion signals.

Little is yet known of the functions of clade A enzymes. We previously suggested one *D. melanogaster* member (9) may correspond to the developmental gene *cricklet* (Claudianos *et al*., 2001), but it is now clear that it does not (http://flybase.bio.indiana.edu/). The only specific function now established for a clade A enzyme is the high level of malathion-specific resistance attributed to a mutant form of a cytosolic esterase (17) in the parasitoid *A. calandrae* (Baker and Weaver, 1993; Baker *et al*., 1998a, 1998b; Zhu *et al*., 1999a, 1999b) (see Section 5.10.5.2).

Resistant strains of *A. calandrae* have a Trp to Gly substitution at a position equivalent to the Trp251Leu/Ser substitutions conferring malathion-specific resistance in *L. cuprina* and *M. domestica*. The effect is to improve the MCE kinetics of the enzyme. Heidari *et al*. (2004a) have since made a Trp251Gly change in the *L. cuprina* enzyme *in vitro* and expressed it in a baculovirus system, finding that it confers significantly greater benefits in respect of MCE activity than do the Trp251Leu/Ser mutations in this enzyme. The *A. calandrae* mutant thus provides strong support from a case of malathion-specific resistance in the field supporting the contention of Heidari *et al*. (2004a) that substitution of the Trp with any of several small residues might confer malathion-specific resistance.

Baker *et al*. (1998a) also found that the mutant *A. calandrae* enzyme is relatively unstable, at least *in vitro*. This is reminiscent of similar evidence for the Trp251Leu mutant in the blowfly enzyme (Smyth *et al*., unpublished data). Interestingly, there is also 30-fold upregulation of the parasitoid enzyme in resistant strains (Zhu *et al*., 1999b). This might compensate for any instability of the enzyme *in vivo*, or simply augment the resistance due to the structural mutation. There is at least some evidence for upregulation of the blowfly mutant as well (Whyard and Walker, 1994).

5.10.6. Other Esterases Implicated in Insecticide Resistance

As seen in the earlier sections that molecular/genomic approaches have yielded enormous insights into the mechanisms underlying certain cases of esterase-based insecticide resistance. However, these clearly cover just a small proportion of the evergrowing list of esterase-based resistance. Now attention can be turned to the great majority of these for which there is as yet no molecular information. Their biochemistry and (classical) genetics are summarized in an attempt to discern recurring similarities and differences compared to those now elucidated at a molecular level.

5.10.6.1. Resistance against Organophosphates and Carbamates

Table 3 lists over 20 cases involving insect species from six orders and three acarines in which changes in esterase activity have been associated with nonmalathion specific OP resistance and/or carbamate resistance. About one-third of the cases involve

hemipterans. Most involve OP resistance alone or OP plus carbamate resistance; only a few involve carbamate resistance alone. The most common finding is an association of resistance with increased esterase activity as measured spectrophotometrically or electrophoretically with artificial substrates like naphthyl acetate.

Only three cases of a decrease are found, all involving OP resistance, outside the higher dipteran cases (see Section 5.10.5.2). These involve the codling moth *Cydia pomonella*, the western flower thrip *Frankliniella occidentalis*, and the predacious mite *Amblyseius potentillae*. However, only the *A. potentillae* case has been characterized in any detail biochemically and in this case the esterase seems unlikely to be the major cause of resistance (Oppenoorth, 1990). This suggests that other instances of the mutant aliesterase mechanism may occur outside the higher Diptera, but are relatively uncommon.

The fact that the great majority of cases involve increases in esterase activity might suggest that sequestration as exemplified in the *Myzus* and *Culex* cases is the predominant mechanism for esterase-mediated metabolic resistance to OPs and carbamates. The data for several of the cases are indeed at least consistent with these paradigms but it is equally clear that others are not. Some that may involve sequestration are not readily interpreted in terms of the sort of gene amplification events seen in the *Myzus* and *Culex* cases. A few are most easily explained in terms of a hydrolytic mechanism, albeit not the mutant ali-esterase mechanism.

Clearly one key requirement of a sequestration mechanism is that the esterase involved has high binding affinity for the insecticide. This is demonstrated directly in terms of the inhibition of the esterase activity by OPs *in vitro* in a few of the cases tabulated (the cockcroach *Blattella germanica*, the beetles *Leptinotarsa decemlineata* and *Oryzaephilus surinamensis*, and the mosquito *A. aegypti*). There are also several others where it can reasonably be inferred because the resistance is suppressed *in vivo* in bioassays including OP reagents like *S,S,S*-tributylphosphorotrithioate (DEF). Most of these cases cover OP resistance but they do include a case of carbamate resistance, involving *H. virescens*. Such *in vitro* or *in vivo* inhibition is generally taken as evidence for involvement of a member of the carboxyl/cholinesterases, although it is worth noting that an esterase from the serine protease family would probably yield similar results.

Sequestration as seen in the earlier aphid and culicine examples relies principally on mutations enabling massive overexpression of the relevant enzymes. In a few of the cases in **Table 3**, most notably the green rice leafhopper *Nephotettix cincticeps*, saw-toothed grain beetle *O. surinamensis*, and *B. microplus*, there is direct evidence for increased enzyme amounts. In a couple of others, it is indirectly inferred from the lack of difference in K_m or k_i estimates with various substrates or inhibitors between the relevant esterases from susceptible and resistant strains. In most cases, however, there is no evidence on this point and in one case, involving carbamate resistance in *H. virescens*, it actually appears not to be the case (see below).

In a significant proportion of the cases potentially involving sequestration which have been investigated electrophoretically, the greater level of spectrophotometric esterase activity in resistant lines appears to be largely due to the greater intensity of a single esterase isozyme. Cases like this include the currant lettuce aphid *Nasonovia ribisnigri*, the beetles *L. decemlineata* and *O. surinamensis*, and the tufted apple bud moth *Platynota idaeusalis*. However, there are in fact more cases where multiple isozymes show more intense staining in resistant strains. Some of the latter are probably just post-translationally modified variants of single gene products, while others involving just a small number of isozymes could reflect coamplification and overexpression of a small cluster of esterase-encoding genes. However, there are some cases, like *E. postvittana, H. virescens*, and *B. microplus*, where four to ten very different esterase isozymes are more intense in some resistant strains (Armstrong and Suckling, 1988; Rosario-Cruz *et al*., 1997; Harold and Ottea, 2000). It is not obvious what the genetic basis for this resistance could be, although there have been suggestions that *trans*-acting regulatory "supergenes" (Sabourault *et al*., 2001) could have such an effect.

For a few of the species in **Table 3** one or more of the elevated esterases associated with resistance has been purified and characterized to some degree biochemically. For the cases involving *B. germanica* (Prabhakaran and Kamble, 1995), *N. cincticeps* (Chiang and Sun, 1996), *L. decemlineata* (Anspaugh *et al*., 1995), and *Anopheles albimanus* (Brogdon and Barber, 1990), soluble esterases with molecular masses (~50–60 kDa), pH optima, pI values, and inhibitor sensitivities typical of carboxylesterases have been described. Limited comparisons between the enzymes from susceptible and resistant strains have failed to find any differences in properties suggestive of catalytic or other structural differences, and tentative conclusions about sequestration mechanisms based on increased enzyme amounts have therefore been drawn. However, the following cases, involving *O. surinamensis*, the western corn

rootworm *Diabrotica virgifera*, and *H. virescens*, all involve novel features suggestive of variously different mechanisms.

Two elevated esterase phenotypes are associated with OP resistance in *O. surinamensis*. One (HH) gives high level resistance to both chlorpyrifos-methyl and fenitrothion (both dimethyl thion OPs) (**Figure 11**), while the other (MH) gives high resistance to chlorpyrifos-methyl, but only moderate protection against fenitrothion. Isoelectric focusing resolves intense zones containing three and two isozymes, respectively, in HH and MH strains that are not apparent in susceptible individuals. None of these intense bands have the same mobility in HH and MH strains but all five have the same N-terminal sequence. It is therefore thought that the variation within each of the two phenotypes is posttranslational in origin, while the differences between phenotypes could be genetic, possibly due to allelic substitutions downstream of the sequenced N-terminal region.

The five isozymes all behave as conventional carboxylesterases: about 71 kDa in molecular mass, readily inhibitable by OPs, and without detectable OP hydrolase activity. Significantly, however, there are large quantitative differences in their sensitivities to OP inhibition. The isozymes in both HH and MH are more susceptible to chlorpyrifos-methyl and fenitrothion inhibition than extracts from susceptible strains. However, the HH isozymes are highly sensitive to inhibition by both OPs, whereas the MH isozymes are significantly less sensitive to fenitrothion. Given the consistency with the resistance data, the parsimonious interpretation is that there are structural differences between the HH and MH isozymes affecting the avidity of their binding to fenitrothion and hence their ability to sequester it. These structural differences may also be responsible for the greater naphthyl acetate staining intensities of the isozmyes compared to susceptible forms or, alternatively, the intensity differences could be due to a different mutation(s), involving gene amplification or upregulation of expression.

Parathion resistance in some populations of *D. virgifera* is associated with greatly increased intensities of (principally) two esterase isozymes (Scharf *et al*., 1999a, 1999b; Zhou *et al*., 2002). Little is known about the biochemistries of these isozymes, but the strong correlation in their intensities across individuals suggests that they are either posttranslational variants of a single gene product or that they are coamplified or coregulated. The fact that the resistance is partially suppressible by DEF suggests that they are carboxylesterases. The paradox is that there is also very good evidence that resistance is associated with *in vivo* hydrolysis of OPs (Miota *et al*., 1998), whereas the mutant carboxylesterases conferring resistance through OP hydrolysis as per the mutant ali-esterase mechanism are associated with a loss, not a gain in carboxylesterase activity. Either the isozyme intensities and OP hydrolysis both reflect a single as yet undescribed mechanism, or they reflect two distinct mechanisms, one involving sequestration by the isozymes and the other involving hydrolysis by other, apparently electrophoretically cryptic enzymes. Significantly there are three other species where OP resistance is also both substantively suppressed by DEF and associated with OP hydrolytic activity *in vivo* (*P. idaeusalis* and two simulid species) (Hemingway *et al*., 1989; Karoly *et al*., 1996); all these cases might reflect a novel carboxylesterase mechanism involving enhanced hydrolysis for both OPs and the conventional staining substrates. Alternatively, there are at least two instances (*H. virescens* and the hemipteran *Triatoma infestans*; see below) where esteratic OP hydrolysis is clearly not related to carboxylesterases.

The biochemistries of two independent cases of OP resistance and one of carbamate resistance have been studied in *H. virescens*. In the case of the carbamate resistance three esterase isozymes resolvable by isoelectric focusing were found to be elevated in intensity in a thiodicarb-selected strain (Goh *et al*., 1995; Zhao *et al*., 1996). Two of these were unreactive against antibodies raised against either the amplified *M. persicae* esterase or the *M. domestica* αE7 esterase, but the third reacted to both these antibodies and amino terminal sequencing confirmed its similarity with these and other carboxylesterases. Similarity was greatest against the *Drosophila* and hemipteran β-esterases, which might suggest it belongs in clade E. Notably, immunoblotting did not show a clear difference in the amount of this isozyme between susceptible and resistant strains, suggesting that structural rather than expression differences could underlie its elevated esterase activity in the resistant strain. Unfortunately little information was obtained about the biochemistries of the other two isozymes showing elevated staining intensities in this strain. At this point neither sequestration nor hydrolysis can be discounted as the mechanism underlying this resistance.

Profenofos resistance in *H. virescens* has also been associated with increased staining intensities of multiple naphthyl acetate staining esterase isozymes (Harold and Ottea, 1997, 2000). Several different isozymes are involved and some are not always elevated in intensity. However, the intensity of one

isozyme is always elevated in resistant individuals from both the field and laboratory populations analyzed, and the intensity of this band is negatively correlated with that of another, suggesting that the two may be allelic alternatives. This would argue for a structural difference between the two forms. It is not clear whether any of the isozymes implicated in OP resistance in this work correspond with those associated with carbamate resistance above; Harold and Ottea (2000) used native PAGE whereas the latter were resolved by isoelectric focusing. However it is notable that the carbamate selected line did also show substantial DEF-suppressible cross-resistance to OPs (Zhao *et al.*, 1996), which clearly supports the possibility of some overlap.

The other case of OP resistance in *H. virescens* does not involve carboxylesterases. It involves a parathion resistant line in which an arylesterase isozyme has been associated with OP hydrolysis both *in vitro* and *in vivo* (Konno *et al.*, 1990; Kasai *et al.*, 1992). The 120 kDa enzyme is concentrated in the soluble fraction, is activated by some divalent metal ions (Co^{2+} and Mn^{2+} but not Ca^{2+}) and has a pH optimum between 8 and 9. It has relatively low affinity for methyl paraoxon (K_m over 700 μM) but apparently good turnover rate (V_{max} ~0.01 μM min^{-1} mg^{-1} semipure protein), which contrasts directly with the mutant ali-esterases of *L. cuprina* and *M. domestica* (see Section 5.10.5.2). It is apparently inactive against parathion, but shows activity for paraoxon and a range of other oxon OPs. Some aspects of its biochemistry seem reminiscent of mammalian paraoxonases, but the latter are much smaller molecules (~45 kDa) that are preferentially activated by Ca^{2+} (Primo-Parmo *et al.*, 1996; La Du *et al.*, 1999; Claudianos *et al.*, 2001). Its activity was found to be many-fold higher in the resistant strain, compared to the susceptible control strain, but there was no evidence as to whether this reflected a difference in amount or activity of the molecule.

Further insights into OP hydrolytic activities not associated with carboxylesterases come from earlier work on OP hydrolysis by a strain of the kissing bug *Triatoma infestans* (Casabé and Zerba, 1981; De Malkenson *et al.*, 1984). The resistance status of this strain is not clear. However, analysis of the hydrolytic activity of native gel slices for various radiolabeled OPs found three distinct zones of activity from extracts of this strain. None corresponded with slices containing carboxylesterase isozymes although, as expected, some of these sequestered significant amounts of the OPs. One zone containing an aryl esterase isozyme could hydrolyze both oxon and thion OPs (**Figure 11**), another containing an acetylesterase isozyme could hydrolyze a thion OP, and a third containing no detectable esterase isozyme could also hydrolyze the thion OP. The aryl esterase has some parallels with the *H. virescens* case elucidated by Konno *et al.* (1990) and Kasai *et al.* (1992), although the activity against the thion OP is a notable difference. More generally these data clearly indicate the potential for several esterase-based hydrolytic resistance mechanisms that do not involve carboxylesterases, or even detectable esterase isozymes.

5.10.6.2. The Special Case of Malathion Carboxylesterase

Malathion is unusual among OP insecticides in having two carboxyl ester linkages in addition to the phosphoester linkage common to all OPs (**Figure 11**). As well as the hydrolysis of the latter as with other OPs, malathion can also be detoxified by hydrolysis of either or both of its (α- and β-) carboxylester linkages (Matsumura and Hogendijk, 1964; Eto, 1974; Welling *et al.*, 1974; Raftos, 1986). We outlined above (see Sections 5.10.5.2 and 5.10.5.3) three specific cases, involving dipteran microsomal α-carboxylesterases and a cytosolic wasp carboxylesterase, where substitutions to smaller amino acids at a particular residue in their presumptive acyl pocket created an MCE capable of effective *in vivo* detoxification and high levels of malathion-specific resistance. In the case of the wasp, the amount of its mutant cytosolic MCE was also elevated, further boosting resistance. In this section the biochemistry of several other cases of resistance-conferring MCEs, which have not yet been elucidated at a molecular level is summarized.

However, it is first worth noting some particular features of the chemistry of the malathion molecule. One is that it has an asymmetric carbon in its diethyl succinate group (**Figure 11**) and commercial malathion insecticides are racemic mixes of the two stereo isomers generated (Talley *et al.*, 1998). Almost all the biochemistry of MCEs to date is likewise based on unresolved racemates. Also, malathion differs from most other commonly researched carboxylester substrates, like acetylcholine or naphthyl acetate, etc., which have simple acyl groups and more complex alcohol moieties. Malathion has simple alcohol moieties (both ethyl) and bulkier acyl groups (ethyl succinate linked to the organophosphorus moiety). In this it is reminiscent of juvenile hormone (**Figure 7**) (see Section 5.10.4.3). It also resembles the pyrethroids (see **Figure 12**, Section 5.10.6.3) in having the bulky acyl groups, albeit the latter have bulky alcohol moieties as well. This may explain occasional cases of esterase-mediated

malathion and pyrethroid cross-resistance outlined below.

Reports of so-called malathion-specific resistance range across several insect orders, although about half involve the Diptera (**Table 4**). High levels of resistance, 50- to thousands-fold, are commonplace. With a few significant caveats, the resistance also shows a high level of specificity for malathion. One caveat is that in the few cases where it has been tested it also covers a small number of other OP insecticides like phenthoate, which also have carboxylester bonds in their acyl groups (Beeman and Schmidt, 1982; Scott and Georghiou, 1986; Raftos, 1986). Another is that while most relevant studies clearly show a lack of high levels of cross-resistance to noncarboxylester OPs, they could not preclude the possibility of low level resistance to such compounds, as seen occurs in the intensively characterized *L. cuprina* and *M. domestica* cases (see Section 5.10.5.2). Finally, there is some evidence for a degree of cross-resistance to pyrethroids, at least in the hemipterans *N. lugens* and *N. cincticeps* (Motoyama *et al*., 1984; Chen and Sun, 1994; Karunaratne *et al*., 1999).

Because the phenotype is generally so clear-cut, malathion-specific resistance has proven relatively amenable to classical genetic analysis. Essentially single-locus control has been reported for the higher dipterans *M. domestica*, *L. cuprina*, and *Chrysomya putoria* (Townsend and Busvine, 1969; Shono, 1983; Raftos and Hughes, 1986), the mosquitoes *A. stephensi, A. culicifacies, A. arabiensis, A. subpictus* (Hemingway, 1983, 1985; Malcolm and Boddington, 1989; Karunaratne and Hemingway, 2001) and *C. tarsalis* (Matsumura and Brown, 1963), the Indian meal moth *Plodia interpunctella* (Beeman and Schmidt, 1982), and the beetles *Tribolium cataneum* and *Cryptolestes ferrugineus* (White and Bell, 1988; Spencer *et al*., 1998), amongst others. However, there can be two or more resistance alleles at the locus, including both multiple malathion-specific alleles (Picollo de Villar *et al*., 1983), or also including one or more broad-spectrum OP resistance alleles (Campbell *et al*., 1998c; Karunaratne *et al*., 1999; Smyth *et al*., 2000; Vontas *et al*., 2000; and see below).

It has generally been found that malathion-specific resistance can be supressed by the use of the OP triphenyl phosphate (TPP) as a synergist (**Table 4**). This is often regarded as diagnostic of malathion-specific resistance and strongly implicates a carboxylesterase-based mechanism. Thin layer chromatography (TLC) indeed shows that malathion-specific resistance is generally associated with esteratic degradation at both the α- and β-carboxylester bonds of malathion (**Figure 11**), although the α-monoacid is generally the majority product and the diacid is generally less abundant than either monoacid (Matsumura and Voss, 1964; Kao *et al*., 1985; Raftos, 1986; Malcolm and Boddington, 1989, and references therein). Quantitation of MCE activity as a V_{max} of whole body homogenates (as determined from an endpoint radiometric partition assay) also generally shows MCE activity to be elevated in malathion-specific resistant strains. Elevations of 50-fold or greater are commonly recorded, although notably they are often significantly less than the corresponding resistance factors (e.g., Beeman and Schmidt, 1982; Ziegler *et al*., 1987; Smyth *et al*., 1996; Spencer *et al*., 1998). Characteristically the elevated MCE activities are potently inhibited by OPs, particularly TPP (e.g., Plapp and Eddy, 1961; Dyte and Rowlands, 1968; Townsend and Busvine, 1969; Hemingway, 1985; Spencer *et al*., 1998).

However, there is a very variable relationship between elevated MCE activity and general carboxylesterase activity in malathion-specific resistance. As well as the well-characterized *L. cuprina* and *M. domestica* cases (see Section 5.10.5.2), those involving the blowfly *C. putoria,* the moth *P. interpunctella*, and the mite *Tetranychus urticae* are also associated with a reduced level of "general" esterase activity as assessed using methyl butyrate or various naphthyl esters as substrates. However, there are cases where such general esterase activities are essentially unchanged (e.g., in some of the anophelines) or substantially enhanced (e.g., *C. tarsalis* and some planthoppers and leafhoppers) in resistant strains. A similar range of results is found across the various isozyme studies. Elevated MCE activity is associated with reduced staining intensities of particular isozymes in *M. domestica* and *L. cuprina*, but with elevated staining intensities of particular isozymes in *N. cincticeps* and the brown planthopper *Laodelphax striatellus*. In *C. tarsalis* the majority of MCE is associated with a zymogram region lacking any detectable general esterase isozyme at all. The same is true of the bug *T. infestans*, although malathion resistance status was not reported in this case (Wood *et al*., 1985).

Importantly it is clear that even susceptible strains often have significant levels of MCE activity. Notwithstanding large quantitative differences, at least some MCE is found to be widely distributed across tissues, life stages and subcellular fractions in both susceptible and resistant strains (Townsend and Busvine, 1969; Beeman and Schmidt, 1982; Motoyama *et al*., 1984; Wood *et al*., 1985) (**Table 4**). Studies of *N. lugens* and *N. cincticeps* found

Table 4 Summary of cases of esterases implicated in malathion-specific metabolic resistance

Species	*Biochemistry*	*Reference*
Hemiptera		
Laodelphax striatellus (brown planthopper)	Some immunologically related esterase isozymes with *in vitro* malathion carboxylesterase (MCE) activity and identical amino terminal sequences are elevated in amounts in malathion-resistant strains	Miyata and Saito (1976), Sakata and Miyata (1994)
Nephotettix cincticeps	Four isozymes with high esterase activity, three of which had malathion hydrolytic activity in three strains showing moderate levels of resistance to malathion albeit also several other OPs and some SPs	Miyata and Saito (1976), Motoyama *et al.* (1984), Chiang and Sun (1996)
Nilaparvata lugens	An isozyme with high MCE activity (and some SP hydrolytic activity) is more intense in strains with low level resistance to malathion (and some SPs) but not most OPs	Chang and Whalon (1987), Chen and Sun (1994)
Coleoptera		
Cryptolestes ferrugineus (rust red grain beetle)	Slightly lower general esterase activity but increased MCE activity *in vivo* and *in vitro* in a strain showing a high level of triphenyl phosphate (TPP)-suppressible malathion resistance	Spencer *et al.* (1998)
Tribolium castaneum (red flour beetle)	TPP-suppressible malathion-specific resistance	White and Bell (1988)
Lepidoptera		
Plodia interpunctella (Indian meal moth)	General esterase activity reduced but MCE activity elevated 33-fold in a strain showing high TPP-suppressible resistance to malathion and cross-resistance to phenthoate	Beeman and Schmidt (1982)
Hymenoptera		
Anisopteromalus calandrae	General esterase activity unchanged but (cytosolic) MCE activity 10–30-fold higher in a malathion resistant strain; W to G mutation at the same site as the W251L MCE mutation in *L. cuprina* and *M. domestica* contributes to malathion resistance, as does upregulation of expression	Baker *et al.* (1998a, 1998b), Zhu *et al.* (1999a, 1999b)
Diptera		
Anopheles arabiensis	General esterase activity unchanged and no elevated esterase isozymes but kinetically efficient MCE in strains with high levels of TPP-suppressible malathion specific resistance	Hemingway (1985)
Anopheles culicifacies	General esterase activity essentially unchanged and no elevated esterase isozyme but high levels of MCE activity and *in vivo* malathion metabolism in strains with high levels of TPP-suppressible malathion specific resistance	Herath *et al.* (1987), Malcolm and Boddington (1989), Karunaratne and Hemingway (2001)
Anopheles stephensi	General esterase activity essentially unchanged and no elevated esterase isozymes but three isozymes have MCE activity in strains resistant to malathion and phenthoate	Hemingway (1982, 1983), Scott and Georghiou (1986)
Anopheles subpictus	High levels of MCE activity and monoacid and diacid metabolites produced by mass homogenates of resistant field strain	Karunaratne and Hemingway (2001)
Chrysomya putoria (green blowfly)	General esterase activity is reduced in TPP-suppressible malathion-specific resistance; the alkyloxy methyl group of malathion is important for high level resistance	Townsend and Busvine (1969)
Culex tarsalis	General esterase activity enhanced in a strain with 150-fold resistance specifically to malathion that is synergised by TPP; MCE activity is associated with a zymogram region lacking esterase activity	Matsumura and Brown (1963), Ziegler *et al.* (1987), Whyard *et al.* (1994)
Lucilia cuprina	Reduced levels of general esterase activity, slightly higher levels of MCE activity and significant OP hydrolase activity associated with Ser/Leu251 variants of the LcαE7 (E3) isozyme in strains with high levels of TPP-suppressible resistance to malathion and phenthoate (see Section 5.10.5.2)	Hughes *et al.* (1984), Raftos (1986), Raftos and Hughes (1986), Smyth *et al.* (1994, 1996, 2000), Whyard and Walker (1994), Campbell *et al.* (1998a, 1998c), Newcomb *et al.* (2004)
Lucilia sericata	Ser/Leu251 variants found in LcαE7 ortholog in populations known to segregate for malathion specific resistance (see Section 5.10.5.2)	R.D. Newcomb, C.G. Young, and J.R. Stevens, unpublished data

Continued

Table 4 Continued

Species	*Biochemistry*	*Reference*
Musca domestica	Reduced levels of general esterase activity, slightly higher levels of MCE activity and Ser/Leu251 variants of the MdαE7 (Ali) isozyme in strains with high levels of TPP-suppressible resistance to malathion (see Section 5.10.5.2)	Plapp and Eddy (1961), Picollo de Villar *et al.* (1983), Shono (1983), Kao *et al.* (1984, 1985), Claudianos *et al.* (1999, 2001)
Acarina		
Tetranychus urticae	Reduced levels of general esterase activity, increased MCE activity and increased phosphatase activity in a strain with 60-fold malathion resistance and 10-fold parathion resistance	Matsumura and Voss (1964)

measurable levels of MCE activity associated with a majority of the esterase isozymes in both susceptible and resistant strains (Chang and Whalon, 1987; Chen and Sun, 1994; Chiang and Sun, 1996). Together with the cases where MCE is associated with a nonstaining area of general esterase zymograms, this suggests that a range of MCEs is at least theoretically available from which mutants with improved activities might be selected to confer resistance.

As described above (see Section 5.10.5.2) one MCE mutation found in orthologous microsomal carboxylesterases from clade B (**Figure 2**) in both the higher dipterans *L. cuprina* and *M. domestica*. This active site mutation improves MCE kinetics very slightly (although with a specificity constant around $10^6\,M^{-1}\,s^{-1}$ it is already high) but also confers significant OP hydrolase activity, so the MCE enzyme escapes from otherwise essentially irreversible inhibition if it binds at the phospho end of malaoxon (the activated form of malathion) rather than the carboxylester end of malaoxon or malathion. The mutant enzyme also has reduced activity for several of the conventional artificial substrates used to measure general esterase activity. There is molecular evidence that a similar MCE mutation confers malathion specific resistance on the hymenopteran *A. calandrae*, albeit in this case it involves a soluble cytosolic esterase from clade A in **Figure 2**, and also appears to involve some upregulation in the amount of the esterase (see Section 5.10.5.3). Precise parallels in the biochemistry and toxicology of the phenotype have also led to suggestions that the malathion-specific resistance in another higher dipteran *C. putoria* and in the moth *P. interpunctella* would be due to the same mutation in a microsomal clade B esterase (Campbell *et al.*, 1997, 1998c; Smyth *et al.*, 2000). Some of the better-characterized other cases of resistance to see if they also have biochemistries matching these cases are now considered.

Several cases of malathion-specific resistance in anopheline mosquitoes have been characterized to some degree biochemically, and none has proven associated with elevated staining of any esterase isozymes although all show the characteristic TPP-suppressible, MCE-based mechanism (Hemingway, 1985; Herath *et al.*, 1987; Malcolm and Boddington, 1989; Hemingway *et al.*, 1998; Karunaratne and Hemingway, 2001). Kinetic evidence in several cases indicates the presence of a highly efficient MCE enzyme in resistant strains that is apparently absent in susceptible strains (Hemingway, 1985; Hemingway *et al.*, 1998). *Anopheles stephensi* in Pakistan express at least three esterase isozymes with MCE activity but none of them is overexpressed in resistant strains and indeed they are all inabundant in both susceptible and resistant strains (Jayawardena and Hemingway, cited in Hemingway *et al.*, 1998). All these data imply that a qualitative rather than quantitative change in an MCE confers malathion-specific resistance among these anophelines. The *A. gambiae* genome does not contain any sequences in clade B (although culicines do), but the biochemistry available for the anopheline MCEs does not yet suggest which clade they do belong to.

In the culicine mosquito *C. tarsalis*, malathion-specific resistant lines express in the mitochondria of their gut cells a kinetically efficient MCE, which is not detectable in susceptible strains (Ziegler *et al.*, 1987; Whyard *et al.*, 1994). There is also a cytosolic MCE in a broad range of tissues, but this is less efficient kinetically and equally expressed in both susceptible and resistant strains. It is thus suspected that the effect of the resistance mutation is to substantially elevate the expression of a previously inabundant enzyme that is otherwise appropriate in its kinetics and expression profile for *in vivo* detoxification of malathion. The resistance-associated enzyme is not an ortholog of the clade B esterase amplified in broad-spectrum OP resistance in other culicines (Tittiger and Walker, 1997). The only clade in **Figure 2** containing sequences with mitochondrial targeting signals is clade A, although not all clade A enzymes have such signals. There are many precedents for mitochondrially located enzymes

performing detoxification functions in other organisms, including for pesticides like malathion (Bachurin *et al.*, 2003 and references therein).

An unusual variant of the secreted clade E esterase associated with broad-spectrum OP resistance in the planthopper *N. lugens* (see Section 5.10.4.3.2) has been described from Japan and the Philippines. This esterase provides at least a low level of resistance to malathion and certain synthetic pyrethroids but not to most OPs (Chang and Whalon, 1987; Chen and Sun, 1994) (see Section 5.10.6.3). While the variant associated with the broad-spectrum OP resistance has been shown to involve a three- to sevenfold amplification of the encoding gene, nothing has yet been reported of the molecular nature of the malathion/pyrethroid resistant variant (Karunaratne *et al.*, 1999; Small and Hemingway, 2000a, 2000b; Vontas *et al.*, 2000). While as many as eight different esterase isozymes have MCE activity in *N. lugens*, it is the E1 isozyme, which is more intense in the malathion/pyrethroid resistant strain, that appears to have the best MCE activity.

At least four esterase isozymes are strongly overexpressed in field strains of the leafhopper *N. cincticeps* showing varying levels of resistance to many OPs, including moderate resistance to malathion, and also some resistance to pyrethroids (Miyata and Saito, 1976; Motoyama *et al.*, 1984). The net effect is over 40-fold higher carboxylesterase activity in the resistant strains. At least three of the isozymes have some MCE and pyrethroid hydrolytic activities. It has been proposed these isozymes provide resistance to malathion and pyrethroids by hydrolytic detoxification, and to the other OPs by sequestration (Motoyama *et al.*, 1984) (see Section 5.10.6.1). Whilst not discounting this possibility, the latest data suggest that the contribution to malathion resistance due to the MCE activities of these enzymes may be relatively minor (Chiang and Sun, 1996). Even without this *N. cincticeps* case, it is apparent that the structural mutations described in *L. cuprina* and *M. domestica*, and inferred in *C. putoria* and *P. interpunctella*, are just one mechanism conferring MCE based malathion-specific resistance. Although not yet resolved at the molecular level there are clearly other mechanisms, involving different mutations, nonorthologous enzymes, and possibly different clades, which could confer MCE based resistance.

5.10.6.3. Resistance against Synthetic Pyrethroids

Most commercial synthetic pyrethroid (SP) insecticides are carboxylesters, with relatively large and highly hydrophobic acid and alcohol groups (Casida *et al.*, 1983) (**Figure 12**). The early, type 1, SPs are smaller than the more modern type 2 compounds, which differ in having an α-cyano substituent on their alcohol group and, in many cases, dibromo instead of dichloro substituents on their acyl groups. Most SPs also show high levels of racemic complexity, with as many as three chiral centers, one around the carbon to which the cyano moiety attaches in the alcohol group and two across the cyclopropane ring in the acyl group. The type 2 SPs generally have greater potency, in part because their greater bulk makes them less susceptible to hydrolytic detoxification by carboxylesterases (Elliott, 1977; Soderlund and Casida, 1977a, 1977b; Casida *et al.*, 1983). The various isomers also differ in potency against many insects, albeit not always in the same way across species. For example, it is generally but not always true that the *cis* isomers across the cyclopropane ring are more potent insecticides than their *trans* alternatives and, again, this is at least partly because they appear to be less susceptible to hydrolysis by carboxylesterases (see, e.g., Casida *et al.*, 1983; Ruigt, 1985; Chang and Whalon, 1986; Byrne *et al.*, 2000).

Table 5 summarizes about a dozen cases where elevated esterase levels have been associated with metabolic resistance to SPs. The cases tabulated range across several orders of insects and two acarines, although lepidopterans account for about half the cases. None of the cases tabulated has yet been fully elucidated at a molecular genetic or even biochemical level. The problems in studying SP resistance at a biochemical level stem from several refractory properties of the compounds themselves, including their isomeric complexity, difficulties in separating some isomers, and their very limited (low μM) aqueous solubilities. These difficulties have been compounded until recently by the unavailability of sensitive and convenient fluorometric or colorimetric assays, so kinetic analyses had to be carried out with expensive radiometric reagents in tedious partition assays. Fortunately Wheelock *et al.* (2003) have recently developed fluorometric analogs of some SPs, which should now greatly expedite progress in resolving the biochemistry of SP resistance.

At a phenotypic level, esterase based metabolic resistance to SPs is often reported in association with P450-based resistance. The contribution that the esterase mechanism makes to the overall metabolic resistance can be readily demonstated experimentally by the use of respective inhibitors for the two enzyme systems, and the reliance of the P450 mechanism on NADP as a cofactor; however, it is difficult to quantify the relative contributions of the two mechanisms (Liu *et al.*, 1984; Ottea *et al.*, 1995;

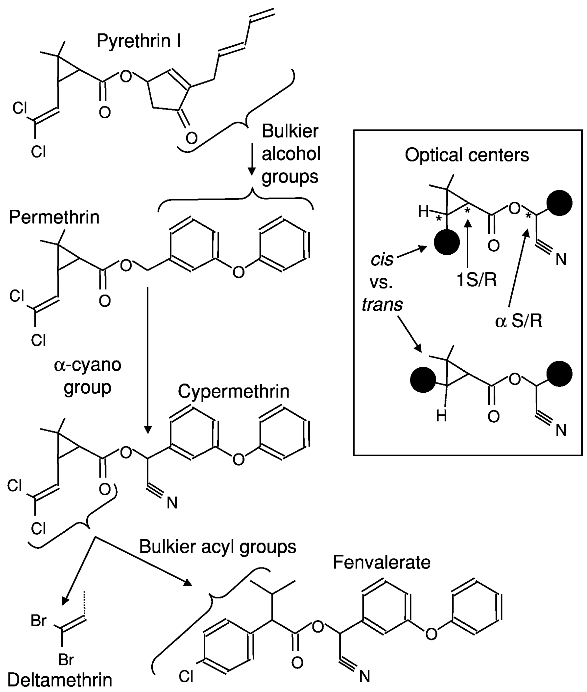

Figure 12 Pyrethroid structures. Pyrethrin I is shown first as an example of a natural pyrethroid. Synthetic pyrethroids (SPs) have shown increasing resistance to hydrolysis by esterases as the alcohol groups were made bulkier (e.g., permethrin), an α-cyano group was added (e.g., cypermethrin) and the acyl group was also made bulkier (e.g., fenvalerate), often by the replacement of the chlorine atoms with bromines (e.g., deltamethrin). Type 2 SPs contain the α-cyano moiety and often also the dibromo moiety. Pyrethroids generally have at least two and often three optical centers, one around the carbon to which the cyano moiety attaches and two across the cyclopropane ring, resulting in four or eight possible stereoisomers. Naming conventions describe stereoisomers as α R or S with respect to the carbon to which the cyano group attaches and 1R or S for the optical center on the cylcopropane ring closer to the carboxylester linkage. However, the alternatives at the other optical center on the cyclopropane ring are not described directly. Instead the combined effect of the two optical centers either side of the cyclopropane ring is then described as *cis* or *trans* for whether the bulkier moieties either side of the cyclopropane ring are placed closer together or further from each other.

Shan *et al.*, 1997; Shan and Ottea, 1998). Cross-resistance of the esterase component beyond SPs is unusual, although it has been reported for malathion in a small number of cases, e.g., *N. cincticeps* and *N. lugens* (Table 5), plus possibly also see *C. pipiens* (Bisset *et al.*, 1997). In these cases resistance may be mediated by a shared carboxylesterase-based mechanism. There is one report, involving *A. albimanus*, of cross-resistance to other OPs. The mechanism here is unknown but may involve amplification of an esterase that binds and sequesters both classes of compound (Brogdon and Barber, 1990). In a few cases multiple SPs have been tested; cross-resistance among SPs seems the rule, although (consistent with their heterogeneity in size and shape) resistance factors can vary substantially (Gunning *et al.*, 1999).

At a biochemical level, the usual finding is of elevated levels of esterase activity in *in vitro* assays of whole body extracts with compounds like naphthyl acetate as substrates. The increase at this level is generally not large, around two- to tenfold, although increases exceeding 50-fold have been reported, for example, in the cotton bollworm *Heliothis armigera*. However, the staining intensity of individual isozymes may be elevated over 100-fold in resistant strains, or in some cases they may be apparent in resistant strains but undetectable in susceptible strains. In some cases, like *Bemisia tabaci* and *B. microplus*, it essentially involves just a single band. More commonly it involves several bands; cases of this include *H. armigera*, the native budworm *Helicoverpa punctigera*, *H. virescens* and the tick *A. fallacis*. In *A. albimanus* the elevated intensity was resolved as a single band by native PAGE but separate bands by isoelectric focusing. There are no cases of SP resistance to our knowledge associated with reductions in staining intensity of esterase isozymes or the replacement of one isozyme band with another.

It is generally assumed that increased staining intensities of esterase isozymes associated with resistance are due to increases in the amounts of

Table 5 Summary of cases of esterases implicated in metabolic resistance to synthetic pyrethroids

Species	*Biochemistry*	*Reference*
Hemiptera		
Bemisia tabaci	Increased molar amount of the esterase isozyme $E_{0.14}$ is strongly associated with a marked increase in *in vivo* permethrin hydrolysis	Costa and Brown (1991), Byrne and Devonshire (1996), Byrne *et al.* (2000)
Nephotettix cincticeps	Increased amounts of four esterase isozymes with some SP (and malathion) hydrolytic activity tentatively associated with SP (and malathion) resistance; one isozyme with activity essentially only for fenvalerate. Activity greatest for *cis*-permethrin, then cypermethrin, then *trans*-permethrin (and then malathion)	Motoyama *et al.* (1984), Chiang and Sun (1996)
Nilaparvata lugens	Increased amount of the E1 isozyme in an SP and malathion resistant strain has more activity for *trans*-permethrin (and malathion) than *cis*-permethrin and cypermethrin. Several other isozymes also hydrolyse *cis*- and *trans*-permethrin (*trans* better than *cis)* and malathion	Chang and Whalon (1987), Chen and Sun (1994)
Coleoptera		
Leptinotarsa decemlineata	Increased *trans*-permethrin hydrolytic activity and general esterase activity in whole body homogenates of resistant individuals	Argentine *et al.* (1995)
Lepidoptera		
Helicoverpa armigera	Increased *in vivo* SP hydrolysis, general esterase activity and more intense staining of several esterase isozymes in strains whose resistance to multiple SPs is partially suppressible by nontoxic doses of OPs; increased staining intensity due to increased amount of enzyme	Gunning *et al.* (1996b, 1998, 1999), Campbell (2001)
Helicoverpa punctigera (native budworm)	Increased *in vivo* SP (fenvalerate) hydrolysis and more intense staining of several esterase isozymes in strains whose resistance is suppressible by DEF and propenofos	Gunning *et al.* (1997)
Helicoverpa zea (corn earworm)	Increased general esterase activity in resistant strains (not inducible by diet)	Muehleisen *et al.* (1989)
Heliothis virescens	Increased *in vivo* SP hydrolytic activity and general esterase activity and more intense staining of several esterase isozymes in resistant strains; increased staining intensity due to increased amount of enzyme; *trans*-permethrin hydrolyzed more rapidly than *cis*-permethrin	Dowd *et al.* (1987), Goh *et al.* (1995), Ottea *et al.* (1995), Shan and Ottea (1998)
Plutella xylostella (diamondback moth)	Esterase activity towards permethrin found in resistant strain	Liu *et al.* (1984)
Spodoptera exigua (beet armyworm)	Increased *in vivo* deltamethrin hydrolytic activity and general esterase activity in resistance strains	Delorme *et al.* (1988)
Spodoptera littoralis (Egyptian cotton leafworm)	Increased esterase activity associated with TPP-suppressible SP resistance	Riskallah (1983)
Diptera		
Anopheles albimanus	Increased intensity of an esterase isozyme zone in strains and individuals showing *S,S,S*-tributylphosphorotrithioate (DEF)-suppressible resistance to fenitrothion and deltamethrin	Brogdon and Barber (1990)
Acarina		
Amblyseius fallacis (predatory mite)	Many esterase isozymes in susceptible insects have some SP hydrolytic activity (preferentially *trans*- over *cis*-permethrin) but certain esterase isozymes from resistant strain have higher rates of SP hydrolysis	Chang and Whalon (1986)
Boophilus microplus	Increased *in vivo* SP hydrolytic activity and at least one unique esterase isozyme detected in strains whose SP resistance is at least partially suppressed by TPP	de Jersey *et al.* (1985), Jamroz *et al.* (2000)

the enzymes, and in some cases (*B. tabaci*, *N. cincticeps*, *N. lugens*, *H. armigera*, and *H. virescens*) immunochemical, tritium-labeling or other techniques have been used to validate this assumption. In *H. armigera* and the corn earworm *H. zea* it has been found that the elevated activity phenotype is stably expressed across a range of dietary conditions and is not the result of increased inducibility of the enzymes by the pyrethroids.

Although there may also be some protective effect due to the esterases binding and sequestering the pesticide (Goh *et al*., 1995; Gunning *et al*., 1999), there is good evidence from many studies indicating metabolism of SP by the esterases. In particular, increases in SP hydrolytic activity in whole body homogenates of resistant individuals have been recurrently reported. Examples of this include *B. tabaci*, *L. decemlineata, H. armigera*, *H. punctigera*, *H. virescens*, the beet armyworm *Spodoptera exigua*, *M. domestica*, and *B. microplus*. The generalities of greater hydrolytic activity for smaller compounds and *trans* isomers hold up in these extracts, but exceptions to both these generalities are also documented (Ishaaya and Casida, 1981) (**Table 5**).

As with malathion above, it appears that a substantial proportion of the esterase isozymes even in susceptible insects have some SP hydrolytic activity, at least *in vitro*. This has been mostly clearly demonstrated by Chang and Whalon (1986, 1987) who found that a substantial proportion of the esterase isozymes which they could resolve in *N. lugens* and *A. fallacis* had some SP hydrolytic activity; some of these were elevated in resistant strains but others were not. Evidence from other species is also consistent with these results (Abdel-Aal and Soderlund, 1980; Ishaaya and Casida, 1980; Yu, 1991) (**Table 5**).

Esterase isozymes with some SP hydrolytic activity have been purified and characterized to varying degrees from several species. Except for *B. tabaci*, evidence to implicate the particular enzymes studied in SP resistance is generally lacking (Byrne *et al*., 2000). It is clear that isozymes with SP hydrolytic activity can be found from many tissues and developmental stages, and from both soluble and micrososmal fractions (Abdel-Aal and Soderlund, 1980; Ishaaya and Casida, 1980; Motoyama *et al*., 1984). Evidence on inhibition by OPs, molecular mass, isoelectric points, pH optima, and immunological cross-reactivity are all consistent with the isozymes being in the carboxyl/cholinesterase family, without being sufficiently definitive to identify particular clades within the family (Abdel-Aal and Soderlund, 1980; Ishaaya and Casida, 1980; Motoyama *et al*., 1984; de Jersey *et al*., 1985; Chen and Sun, 1994; Goh *et al*., 1995; Chiang and Sun, 1996; Byrne *et al*., 2000). K_m estimates with SPs are generally in the low–mid μM range, with k_{cat} data generally lacking (Jao and Casida, 1974; Abdel-Aal and Soderlund, 1980; Yu, 1991). Interestingly, Abdel-Aal and Soderlund (1980) found quantitative differences in tissue distributions and inhibitor sensitivities between *cis* and *trans* permethrin preferring activities and therefore suggested that esterase-mediated metabolic resistance to SPs would accrue through the combined effect of several different esterases of differing substrate preferences.

The most detailed kinetic analyses of SP hydrolysis by insect esterases have recently been carried out by Heidari *et al*. (unpublished data) for *in vitro* expressed forms of the *L. cuprina* αE7/E3 enzyme and various natural and synthetic mutants of it. LcαE7 is not involved in SP resistance but the wild-type enzyme shows high SP hydrolytic activity, including preferences for type 1 compounds, dichloro substituents, and *cis*/*trans* isomers across the cycopropane ring, with relatively little stereospecificity with respect to the α-cyano group. However, a few variants of the enzyme with substitutions in its presumptive acyl pocket were variously found to have reversed the *cis*/*trans* and *R*/*S* stereospecificities, and at least quantitatively altered preferences for the other structural features. These results support the earlier studies above indicating that most esterase isozymes are individually quite specific for the variable structural features of SP insecticides, and they further show that good hydrolytic activities against a variety of SP structures can be achieved across different (even very closely related) esterases. They also caution against the assumption that the changes in esterase biochemistry conferring SP resistance will always affect isozyme amounts; clearly there is scope for point mutations affecting enzyme structures to improve the suite of SP hydrolytic activities of the organism.

Two predictions can be made about the genetics of esterase-based SP resistance from the biochemical findings to date: they might differ considerably between species and sometimes can be polygenic. Whilst accepting the possibility of some structural changes in relevant enzymes, most of the data to date suggest that the changes will generally affect isozyme amounts. Gene amplification has been suggested as one possible mechanism for this (Gunning *et al*., 1999) although it would probably need to involve multiple amplifications, or amplifications of multiple (closely linked) genes, to account for some of the cases of resistance involving increased staining of multiple isozymes. Regulatory changes are an alternative explanation, and certainly there is abundant evidence for regulatory variation affecting the amounts of esterase isozymes (Game and Oakeshott, 1990; Holloway *et al*., 1997; Odgers *et al*., 2002). Notably the best evidence for the coincident upregulation of multiple esterases appears to involve inducible systems (Salama *et al*., 1992; Callaghan *et al*., 1998; Campbell, 2001), which does not appear to apply to the esterases involved in SP resistance. It is therefore suspected that polygenic inheritance will sometimes be the case.

5.10.7. Concluding Remarks

The carboxyl/cholinesterase gene family has radiated extensively in the higher eukaryotes. Small numbers are found in a minority of prokaryotes and only a few occur in lower eukaryote genomes, but 30 or more have been found in each of the higher eukaryotic genomes annotated. In insects, it appears that this expansion corresponds at least in part with their recruitment to functions in neurodevelopmental processes and the transduction of hormonal and other signals, albeit the precise physiological functions of most remain largely, if not completely, unknown. The radiation in physiological function is paralleled at a biochemical level. Where known, the kinetics of individual enzymes for their particular physiological substrates can be highly efficient. However, the substrates for different members of the family differ quite widely in structure and, remarkably, a significant proportion of the family has moved into noncatalytic functions.

While a significant proportion of the major catalytic and noncatalytic clades appear to have origins as old as the Insecta, it is also clear from cases like glutactin, the noncatalytic β-esterases, and the evolution of insecticide resistance, that new radiations moving the family into new functions are still arising. In this respect it will be interesting to see the constitution of the family in the silkmoth *Bombyx mori* and honeybee *Apis mellifera,* whose genome sequences should be released before this article appears in print. Both species are clearly much more distantly related than *D. melanogaster* and *A. gambiae*, and an enormous diversity of esterase isozymes have been reported from several Lepidoptera – as many as 60 isozymes compared to just 20–30 in *D. melanogaster* (Campbell, 2001; Campbell *et al*., 2003).

Notwithstanding the expansion of the carboxyl/cholinesterase family in higher eukaryotes, it is also clear that other protein families contribute significantly to the complement of esteratic activities of higher organisms. Vertebrate and prokaryote precedents suggest that insect aryl and acetyl esterases will derive from other families (Oakeshott *et al*., 1993). There are also other insect esterase activities like the ortholog of vertebrate neuropathy target esterase (Borrás *et al*., 2003) that clearly have other, nonserine dependent reaction mechanisms. And there are several vertebrate precedents for other enzyme families with serine based reaction mechanisms like the serine proteases that have generated good esteratic activities (Zschunke *et al*., 1991). The carboxyl/cholinesterases probably contribute the majority of insect carboxylic ester hydrolase activities, but the contributions of other protein families are as yet very poorly understood.

We will not understand why the carboxyl/cholinesterase family has been such a versatile platform for the evolution of new functions until we know a great deal more about structure, function, and structure–function relationships within the family. Fortunately, use of the modern tools of functional genomics and metabolomics could greatly improve our knowledge of their physiological and biochemical functions in the near term. The structural information, however, will be more difficult to expand. AChE is the only insect member of the family whose structure is currently known, albeit with a structure for a lepidopteran JHE also imminent. Even the modeled structure of JHE has suggested some qualitative differences from AChE directly concerned with catalysis, like the reverse orientation of the acyl and leaving group pockets. There is also particular priority to solve structures in some of the clades with noncatalytic functions and those from which the various metabolic resistances arise. In both cases ligand-bound structures will be of particular interest.

Perhaps the most spectacular demonstration of the evolutionary adaptability of the carboxyl/cholinesterases is their likely involvement in well over 50 cases of resistance to chemical insecticides over the last 50 years. Many involve the older OP and carbamate compounds where mutations of major biochemical effect are required to achieve either target site or metabolic resistance. Several also now involve the SPs although none of these has as yet been resolved at a molecular level. Esterase based SP resistance is also a notable feat of molecular evolution given the bulk and chiral complexity of SP insecticides. Nor are the more recent insecticides immune from esterase based resistance mechanisms – there are already reports of esterase involvement in resistance to various insect growth regulators (Ishaaya and Degheele, 1988; El Saidy *et al*., 1989; Ishaaya and Klein, 1990) where at least one can rationalize a hydrolytic basis for detoxification. Intriguingly there are also reports of possible esterase involvement in metabolic resistance to imidacloprid (Wang *et al*., 2002) and even the proteinaceous crystal toxins of *Bacillus thuringiensis* (Dang and Gunning, 2002), where a mechanism is at this time much less readily rationalized biochemically.

This chapter has taken a genomics perspective to the cases of esterase mediated resistance that have been resolved at a molecular level and then analyzed the biochemistries of about 70 cases of such resistances that have not yet been resolved at a molecular level. These analyses generally support the contention that the options for evolving resistance are

limited. However, the biochemistry clearly indicates the existence of several more that have yet to be resolved at a molecular level in any species. Involvement of multiple clades of carboxyl/cholinesterases has already been observed, and it is clear that a few cases involve other protein families.

It has recently been suggested that there may be two broad classes of AChE insensitivity mutations conferring target site resistance to OPs and carbamates, one skewed towards OP resistance and the other to carbamate resistance. It also appears that there may be at least two subclasses within the carbamate resistant class, with one specific for dimethyl carbamates and possibly restricted to hemipterans. The validity of these classifications will only be tested by molecular work on several more independent cases of target site resistance. It also appears from biochemical analyses of synthetic mutants that there could be many more substitutional options available for conferring resistance than have been reported from natural populations to date. Understanding which are real options, and how they relate to the different patterns of insensitivity phenotype, will also require AChE structural data for additional taxa. Also important to our understanding of the evolution of AChE and its role in resistance will be much greater knowledge at a biochemical and molecular level of both the noncatalytic functions of AChE and of the partitioning of the catalytic and noncatalytic functions among the two AChE proteins found in most insects.

It appears that the gene amplification/sequestration mechanism, and possibly also the mutant aliesterase mechanism, found in the cases of metabolic resistance to OPs resolved at a molecular level so far will indeed recur in some other cases. However, the biochemistry clearly points to some significant variations on these themes, as well as some completely different mechanisms. The involvement of the metal activated aryl esterases in general OP resistance in *H. virescens* obviously constitutes at least one completely different mechanism. Whilst it seems that insects do not have homologs of the vertebrate paraoxonase subfamily of aryl esterases (Sorenson *et al*., 1995), they appear to have homologs of at least some prokaryote OP hydrolytic enzymes (Hou *et al*., 1996; Claudianos *et al*., 2001; Horne *et al*., 2002a, 2002b). Insect homologs of one of these, the metal-activated OPH (Pfam 02126), have been identified (Hou *et al*., 1996; Claudianos *et al*., 2001). *Spodoptera frugiperda* larvae infected with recombinant baculoviruses expressing high levels of a bacterial OPH show nearly 300-fold greater resistance to paraoxon than uninfected controls (Dumas *et al*., 1990) while *D. melanogaster* genetically transformed with this gene show over 20-fold greater paraoxon resistance than untransformed controls (Phillips *et al*., 1990; Benedict *et al*., 1994).

There are also diverse esterase biochemistries underlying malathion-specifc resistance, with the molecular biology only as yet resolved for the Leu/Ser251 versions of the mutant αE7/aliesterase mechanism.

Regulatory changes are clearly suggested by the increased staining intensities and abundances of some isozymes seen for general OP, malathion-specific and pyrethroid resistance. Some of these could be relatively straightforward changes to the promoters of the relevant esterase genes, as seems to be the case for at least one *C. pipiens* amplicon. However, one paradox is the finding of greater intensities for multiple isozymes in several cases of resistance. Some of these appear beyond the scope of explanations based on posttranslational enzyme modification or adjacent gene coamplifications. Alternative explanations involving *trans*-acting regulatory factors remain to be investigated.

With the notable exception of the carbamate–OP cross-resistance due to E4/FE4 sequestration in *M. persicae*, none of the esterase based metabolic resistances to carbamates and SPs have as yet been elucidated at a molecular level. A sequestration mechanism similar to the E4/FE4 model may underlie some of the many other cases of OP–carbamate cross-resistance reported. Some variant of it might also account for the occasional case of OP–SP cross-resistance. However hydrolysis could well underlie more of the cases not involving cross-resistance to OPs, which are now numerous for the SPs at least. It is clear that many insect esterases have significant hydrolytic activity against the carboxylester bonds in SPs *in vitro*. Little is known about hydrolysis of carbamates in insects but bacterial enzymes are known which have good hydrolytic activities against either the amide or carboxylester bonds in these compounds (Pohlenz *et al*., 1992). The nature of the chemistry involved in hydrolysis of the carbamates and SPs is so different, both from that for OPs and from each other, that we would not expect hydrolytic mechanisms to confer cross-resistance among the three classes of compound.

One final perspective on resistance is that what is known at the moment is a snapshot of the "first generation" of insect responses to the insecticides. There is little insight as to what preceded resistance or what will follow the first generation response. What were the predisposing features of the relevant esterase systems? Did the mutations pre-date the use of the pesticides or has the breakdown of

control waited on the occurrence of new mutations? Can insects develop "second generation" responses that substantively enhance their resistance or cross-resistance or avoid the costs of resistance? Has the repeated use of ester pesticides so depleted some insects' store of genetic variability in detoxifying enzymes that they will struggle to respond to new compounds? One is just beginning to see the power of modern genomic and other biotechnologies to reconstruct the past and predict the future. Recently genotyping of preserved specimens by PCR has in fact suggested that some resistance mutations did predate insecticide use (Newcomb *et al.*, 2004). Likewise the tools of *in vitro* evolution, already used to predict resistance futures in the field of antibiotic resistant microorganisms, might also be useful in plotting possible futures for some key pesticide resistance enzymes.

Acknowledgments

The authors thank Thom Boyce, Bronwyn, Campbell, Chris Coppin, Erica Crone, Alan Devonshire, Peter East, Carol Hartley, Irene Horne, Kerrie-Anne Smyth, Tara Sutherland, and David Tattersall for sharing their insights into various topics covered in this review. They are also indebted to the tireless work of Narelle Dryden in compiling the literature. Undoubtedly, some significant relevant papers have been missed here, for which JGO takes full responsibility; the authors apologise to those authors whose work has been missed or inadvertently misrepresented.

5.11 Glutathione Transferases

H Ranson and J Hemingway, Liverpool School of Tropical Medicine, Liverpool, UK

5.11.1. Introduction

Glutathione transferases (GSTs) are found ubiquitously in aerobic organisms. They were first discovered in animals in 1961 where they were postulated to play a role in the detoxification of drugs (Booth *et al*., 1961). Their central role in detoxification and drug resistance pathways in mammals has now been established but additional functions are continually being attributed to this complex enzyme family. For example, GSTs are important mediators in oxidative stress responses, are involved in the synthesis of prostaglandins, and facilitate intracellular transport of hydrophobic compounds. Mammalian GSTs are particularly well studied due to their role in cancer epidemiology and treatment. Several GSTs can metabolize environmentally derived carcinogens and polymorphisms in these genes are linked to cancer risk. In addition, the overexpression of GSTs in tumor cells can contribute to drug resistance (Landi, 2000).

The vast majority of GSTs are cytosolic dimeric proteins with typical molecular masses of around 50 kDa. A small subset of trimeric microsomal GSTs that are very distantly related to the cytosolic GSTs occur in mammals and insects. Most organisms contain multiple forms of GSTs with both specific and overlapping substrate preferences.

In 1985, GSTs had only been identified in a limited number of insect species including the grass grub, greater wax moth, housefly, and American cockroach (Mannervik, 1985). The importance of this enzyme family in many different types of insecticide resistance had been demonstrated and multiple forms were known to exist in individual insects. That GSTs have now been studied in over 30 different insect species is testimony to the importance of this enzyme family. This review describes the diversity of the GSTs family in insects and highlights some of the diverse functions of this complex enzyme family.

5.11.2. Methods Used to Study Insect GSTs

Although a wide range of biochemical techniques have been exhaustively applied to the isolation of

GSTs from numerous insect species, relatively few enzymes have been purified to homogeneity. Frequently, after several purification steps, multiple bands were still visible after sodium dodecyl sulfate (SDS) electrophoresis and, moreover, given our current knowledge of the extent of certain insect GST classes, a single band on an SDS gel may not always be indicative of a homogeneous enzyme preparation. The choice of purification techniques also led to a systematic bias in the classes of GSTs identified with some GST classes being more amenable to purification. The methods employed have now been shown to capture only a relatively small subset of the total GST population. Thus, it is no surprise that advances in gene cloning and recombinant protein expression techniques were seized upon by those studying the role of individual GST enzymes in insects. However, early molecular biology approaches to the isolation of insect GSTs were also biased towards the isolation of certain subsets of GSTs and it was not until the era of large-scale genome sequencing projects that the full extent of this enzyme family was appreciated (see Section 5.11.3). Some of the various approaches that have been used to isolate and characterize insect GSTs are outlined below.

5.11.2.1. Isolation of Insect GSTs

5.11.2.1.1. Biochemical purification Early purification approaches used conventional column chromatographic methods such as ion exchangers, gel filtration, and hydroxyapatite chromatography to isolate GSTs. These approaches were very time consuming and often ineffective, and purification of many individual isoenzymes was really only feasible after the introduction of affinity chromatography (Yu, 1996). Original affinity chromatography columns used the glutathione conjugate of sulfobromophthalein immobilized to an agarose matrix as a ligand (e.g., Clark and Dauterman, 1982; Clark and Shamaan, 1984). Problems sometimes arose when recovering the bound enzyme from this matrix and most purification methods now use glutathione coupled via the sulfur atom or *S*-hexyl glutathione coupled via the α-amino group of the glutamyl residue as ligands (e.g., Grant *et al.*, 1991; Prapanthadara *et al.*, 1993). Enzymes that bind to the columns are usually eluted using glutathione and the GST activity of different fractions determined with the "general substrate" for all GSTs, i.e., 1-chloro-2,4-dinitrobenzene (CDNB). Once eluted, the multiple enzymes are sometimes further separated by nondenaturing polyacrylamide gel electrophoresis (PAGE), isoelectrofocusing, or chromatofocusing.

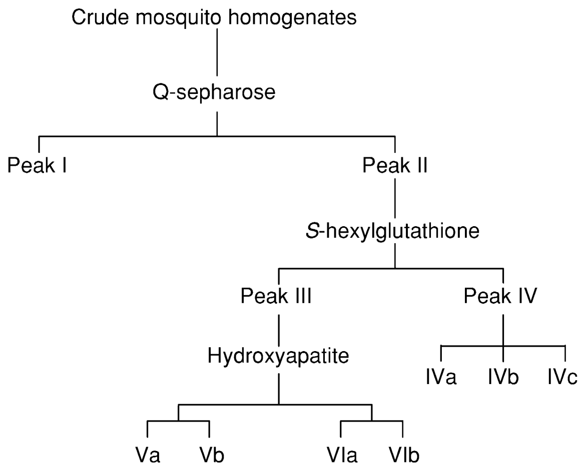

Figure 1 Partial purification of GSTs from the mosquito *A. gambiae* by column chromatography. Bound enzymes are shown on the right arm of the branch. (Adapted from Prapanthadara, L., Hemingway, J., Ketterman, A.J., **1995**. DDT-resistance in *Anopheles gambiae* (Diptera: culicidae) from Zanzibar, Tanzania, based on increased DDT-deyhdrochlorinase activity of glutathione *S*-transferases. *Bull. Ent. Res. 85*, 267–274.

There are two major limiting factors associated with the purification approaches outlined above. First, many GSTs do not bind to any of these affinity columns. It is generally reported that theta class GSTs are not retained by GSH-based affinity matrices (Meyer *et al.*, 1991) but, even within a particular GST class, individual enzymes can sometimes be divided into bound and unbound fractions (Sawicki *et al.*, 2003; Ortelli *et al.*, 2004). Second, CDNB is not a good substrate for all GSTs. Several GSTs have now been characterized that have low or undetectable activity with this substrate (e.g., Singh *et al.*, 2001; Sawicki *et al.*, 2003).

Nevertheless, despite these limitations, the application of biochemical purification techniques provided the first indications of the diversity, in terms of both physical properties and substrate range, of this enzyme family in insects. For example, using the purification scheme outlined in **Figure 1**, eight different fractions with CDNB conjugation activity, each containing multiple isozymes, were obtained from the mosquito *Anopheles gambiae* (Prapanthadara *et al.*, 1993).

A summary of the GSTs isolated biochemically from insects is given in **Table 1**. A review of the purification procedures used to isolate many of these enzymes is provided by Clark (1989).

5.11.2.1.2. Cloning of insect GSTs The approaches that have led to the successful cloning of insect GSTs can be broadly divided into five categories: (1) use

Table 1 Examples of glutathione transferases isolated from insects by biochemical or molecular cloning techniques

Insect order	*Species name*	*Common name*	*Number of enzymes isolated by biochemical techniques*[a]	*Number of genes cloned*	*Reference*
Coleoptera	*Costelytra zealandica*	New Zealand grass grub	3		Clark *et al.* (1985)
Dictyoptera	*Periplaneta Americana*	American cockroach	5	1	Arruda *et al.* (1995)
Diptera	*Aedes aegypti*	Yellow fever mosquito	2, 3	1	Grant *et al.* (1991), Grant and Hammock (1992)
	Anopheles gambiae	African malaria mosquito	7	28	Prapanthadara *et al.* (1993), Reiss and James (1993), Ranson *et al.* (1997, 1998, 2001), Ding *et al.* (2003)
	Culicoides variipennis sonorensis	Biting midge		1	Abdallah *et al.* (2000)
	Drosophila melanogaster	Fruit fly	1, 2	13	Toung *et al.* (1990, 1993), Sawicki *et al.* (2003), Beall *et al.* (1992)
	Lucilia cuprina	Sheep blowfly	1	1	Board *et al.* (1994)
	Musca domestica	Housefly	4, 2, 9	7	Clark *et al.* (1986), Chien *et al.* (1995), Wei *et al.* (2001)
Hemiptera	*Nilaparvata lugens*	Rice brown planthopper	1	1	Vontas *et al.* (2002)
	Triatoma infestans	Kissing bug	1		Wood *et al.* (1986)
Lepidoptera	*Choristoneura fumiferana*	Spruce budworm		1	Feng *et al.* (1999)
	Diatraea saccharalis	Sugar borer	2		Tiwari *et al.* (1991)
	Eoreuma loftni	Mexican rice borer	3		Tiwari *et al.* (1991)
	Galleria mellonella	Greater wax moth	1, 4		Clark *et al.* (1977), Baker *et al.* (1994)
	Helicoverpa zea	Corn earworm	3, 1		Chien and Dauterman (1991)
	Manduca sexta	Tobacco hornworm	2	3	Snyder *et al.* (1995), Rogers *et al.* (1999)
	Orthosia gothica	Hebrew character moth	4		Egaas *et al.* (1995)
	Plutella xylostella	Diamondback moth	1, 4, 3	1	Chiang and Sun (1993), Huang *et al.* (1998)
	Spodoptera frugiperda	Fall armyworm	4		Kirby and Ottea (1995)

[a]In species with more than one report of the isolation of GST enzymes, where it can be difficult to determine the relationship between the enzymes described in each study, multiple entries are given. Note also that the figures given do not distinguish between homodimers and heterodimers.

of GST-specific antibodies to screen cDNA expression libraries; (2) PCR using degenerate primers; (3) screening of cDNA or gDNA libraries with GST nucleotide probes; (4) searching nucleotide sequence databases; and (5) fortuitous discovery. Of these, the latter approach accounted for a surprising proportion of the early insect GST gene sequences determined and is still a valuable source of new sequences for species without large volumes of sequence data. Since many GST classes are encoded by closely related multigene families (and these are often clustered in the genome; see Section 5.11.5.1), the identification of the first gene within a family has often had a cascade effect with multiple additional members of the gene family being identified in quick succession. The difficult step is isolating the first member of a particular gene class. In *Drosophila melanogaster* and *Musca domestica*,

two of the first insect GSTs to be isolated were obtained by raising antibodies against GSTs purified by affinity chromatography from these species and using these to screen expression libraries (Toung *et al*., 1990; Fournier *et al*., 1992). A similar approach was used to isolate GSTs from the spruce budworm *Choristoneura fumiferana* (Feng *et al*., 1999) and the biting midge *Culicoides variipennis* (Abdallah *et al*., 2000), although in both of these cases, the antibodies were raised against unknown proteins rather than purified GSTs.

The degenerate PCR approach, using primers designed by homology to other known insect GSTs, was successfully employed to identify the first GST gene from the brown planthopper *Nilaparvata lugens* (Vontas *et al*., 2002) and the diamondback moth *Plutella xylostella* (Huang *et al*., 1998). *DmGST2* the first of a new class of GSTs to be identified in insects (now classified as the sigma class) was amplified as a secondary PCR product obtained during an unrelated project (Beall *et al*., 1992) and the orthologous gene from *A. gambiae* was also fortuitously isolated during a library screen using the coding region of a salivary gland-specific gene as a probe (Reiss and James, 1993). The recurrent isolation of GST clones using antibodies or DNA probes designed to bind to other protein or gene families may partly reflect the relatively high frequency with which some members of the GST family are expressed. For example, the accidentally amplified *DmGST2* described above has now been shown to account for about 2% of the total soluble protein in *Drosophila* (Singh *et al*., 2001).

Searching EST databases and partial or full genome sequence databases has led to the detection of fragments of GST-like sequence that have been used as a starting point for obtaining full-length gene sequences by PCR-based techniques (Snyder *et al*., 1995; Ranson *et al*., 2001; Sawicki *et al*., 2003).

Several insect GST genes have been expressed *in vitro* in order to characterize the recombinant proteins. The absence of posttranslational modification and their location in the cytosol make GST proteins amenable to expression in *Escherichia coli* (e.g., Ranson *et al*., 1997; Huang *et al*., 1998; Wei *et al*., 2001) although baculovirus expression systems have also been used (Feng *et al*., 1999). One of the potential limitations of using recombinant proteins to characterize GST activity is the absence of heterodimers. This problem has been elegantly addressed in plants by coexpressing two GST subunits and separating the recombinant proteins into homodimers and heterodimers by chromatofocusing or anion exchange chromatography. By constructing tandem expression systems, the transcription and translation of both subunits are coordinated helping to ensure that they are expressed at the same level (Dixon *et al*., 1999).

5.11.2.2. Characterization of Substrate Specificity

A number of model substrates are widely used to characterize the substrate specificity of GSTs, the most common of which is the conjugation of reduced glutathione (GSH) to CDNB. This assay is simple to conduct and the rate of conjugation can be monitored by measuring the change in optical density at 340 nm. The conjugation of GSH to 1,2-dichloro-4-nitrobenzene (DCNB) can also be measured under similar assay conditions although the activity of most insect GST enzymes is higher with CDNB than DCNB. Other model substrates used to characterize GST activity include *p*-nitrophenol acetate (*p*-NPA), *p*-nitrophenyl bromide (*p*-NPB), and ethacrynic acid. The selenium independent peroxidase activity of GSTs is usually detected using cumene hydroperoxide or *t*-butyl hydroperoxide (*t*-BHP).

A vast array of GST inhibitors have been described (Mannervik and Danielson, 1988) and the effects of these on GST enzymes can be useful in distinguishing between different enzymes. Those commonly used to study insect GSTs include bromosulfophthalein, cibacron blue, and glutathione derivatives (Vontas *et al*., 2002). Quinones can also have strong inhibitory effects on GSTs and this can be problematic in purification of insect GSTs (Grant *et al*., 1991).

These model substrates and inhibitors have been proved very valuable for characterizing and comparing the various GST enzymes, and many early approaches to the classification of insect GSTs relied heavily on data generated from such experiments (see below). More recent studies on insect GSTs have focused mainly on their role in the detoxification of xenobiotics or in protection against oxidative stress, and assays have now been developed to assess the role of individual enzymes in these physiological processes. For example, spectrophotometric, chromatographic, and radiolabeling techniques can detect products generated by the GST catalyzed metabolism of many insecticides and products of lipid peroxidation reactions (Clark *et al*., 1986; Prapanthadara *et al*., 1995; Singh *et al*., 2001).

5.11.3. Classification and Nomenclature

Mammalian GST nomenclature was originally based on substrate specificities. Five GST enzyme types

were recognized and referred to as glutathione-*S*-aryltransferase, glutathione-*S*-epoxidetransferase, glutathione-*S*-alkyltransferase, glutathione-*S*-aralkyltransferase, and glutathione-*S*-alkenetransferase. However, later studies on GSTs isolated from rat livers found that each enzyme recognized a broad and overlapping range of substrates and thus this nomenclature was abandoned in favor of the use of roman letters reflecting the order of elution from a CM-cellulose ion exchanger (Habig *et al.*, 1974). Subsequently, the realization that GSTs existed as both homo- and heterodimers led to a further change in nomenclature to reflect that subunit composition and individual subunits of GSTs were numbered in the order in which they were discovered and classified. These GSTs were divided into three distinct groups on the basis of their isoelectric points: the basic (α-ε), near neutral (μ), and acidic (π) groups (Mannervik, 1985). These groups were later designated as classes and assigned the Greek letters alpha, mu, and pi (Mannervik and Danielson, 1988).

In early studies on insect GSTs, where multiple enzymes were isolated from a species they were generally assigned numbers according to their order of elution from the various purification procedures employed or isoelectric points (Clark *et al.*, 1985; Prapanthadara *et al.*, 1993). Two immunologically distinct classes of GSTs were later recognized in houseflies and designated class I and class II (Fournier *et al.*, 1992). The first insect GST to be cloned was *Dm*GST1 from *D. melanogaster* (Toung *et al.*, 1990). The ortholog of this gene was later cloned from *M. domestica* and proposed to be the sole member of the class I GST gene family in this species (Fournier *et al.*, 1992). However, soon after, a cluster of eight GST genes (termed the *gstD* genes and including the original class I *DmGST1* gene) were identified in *D. melanogaster* (Toung *et al.*, 1993). Representatives of the class II family were also cloned from *D. melanogaster* and *A. gambiae* and in each species, the class II family was reported to be encoded by a single gene (Beall *et al.*, 1992; Reiss and James, 1993). As predicted by their immunological properties, these class II GSTs had very low levels of sequence identity to the class I genes and were proposed to have a different physiological function. This was supported by immunohistology studies on houseflies, which located the class I GSTs to the hemolymph and the class II GSTs predominately to the indirect flight muscles in the thorax (Franciosa and Berge, 1995).

The advent of large-scale EST and full genome sequencing data has led to a marked increase in the number of GST classes recognized in insects, plants, and mammals. A total of nine different classes of cytosolic GSTs have now been described (**Table 2**). In insects, it became clear that the existing classification of insect GSTs into class I and class II was inadequate and new guidelines were proposed for the naming of insect GSTs along the lines of the mammalian classification system (Chelvanayagam *et al.*, 2001).

Table 2 Classes of cytosolic glutathione transferases and their representation in insects

Class	*Lineage*	*Putative number in* A. gambiae	*Putative number in* D. melanogaster
Alpha	Mammals		
Beta	Bacteria		
Delta	Insects	15	11
Epsilon	Insects	8	14
Kappa	Mammals		
Lambda	Plants		
Mu	Mammals		
Omega	Mammals, insects, nematodes	1	5
Pi	Mammals		
Phi	Plant		
Tau	Plant		
Theta	Mammals, insects, plants	2	4
Sigma	Molluscs, helminths, nematodes, insects, mammals	1	1
Zeta	Plants, nematodes, mammals, insects	1	2

5.11.3.1. Nomenclature Guidelines for Insect GSTs

As a general rule, GST sequences that share over 40% amino acid sequence identity are assigned to the same class. A robust nomenclature requires a degree of flexibility in class assignments, however, and ideally other properties such as phylogenetic relationships, immunological properties, tertiary structure, and ability to form heterodimers should be employed in classification decisions. As in mammals, kinetic characteristics have proven a poor criterion for classification with several GSTs from different insect classes catalyzing similar reactions. At least six classes of insect GSTs have been identified in both *A. gambiae* and *D. melanogaster* (**Table 2**) (Ranson *et al.*, 2002). Despite the availability of full genome sequences for two insect species, the possibility that further insect GST classes

exist cannot be discounted. In particular, several of the assignments to the delta and epsilon classes are weakly supported by phylogenetic analysis and may be more correctly placed in a separate class (Ding *et al*., 2003).

Individual GST subunits are assigned names indicating the species they were isolated from and the GST class. They are also given a number that may either reflect the order of discovery or the genomic organization. Thus, *AgGSTd12* is the twelfth member of the *A. gambiae* delta class of GSTs to be identified. The proteins, represented by capital letters, are nonitalicized and contain information on the composition of the dimer. So the designation AgGSTD12-12 represents a homodimer of two AgGSTD12 subunits, whereas AgGSTD11-12 would be a heterodimer made up of a subunit of AgGSTD11 and a subunit of AgGSTD12. In practice, except where ambiguity may arise, the species prefix is usually omitted.

5.11.3.2. Classes of Insect GSTs

5.11.3.2.1. Delta class The delta class is one of the two largest classes of insect GSTs (**Table 2**). GSTs originally classified as belonging to insect class I have mostly been reclassified as delta GSTs. There are 15 delta GST genes in *A. gambiae* and 11 in *D. melanogaster* (Ranson *et al*., 2002). GSTs from this class are found uniquely in insects and have been cloned from many species including *Lucilia cuprina* (Board *et al*., 1994), *M. domestica* (Fournier *et al*., 1992), *N. lugens* (Vontas *et al*., 2002), and *C. variipennis* (Abdallah *et al*., 2000). Multiple recombinant delta GST homodimers have been produced *in vitro* and biochemically characterized. Most, but not all, have activity with CDNB and the majority bind to glutathione or *S*-hexylglutathione columns. Delta class GSTs have been implicated in resistance to all the major classes of insecticide (Wang *et al*., 1991; Tang and Tu, 1994; Vontas *et al*., 2002).

5.11.3.2.2. Epsilon class The epsilon class is also a large, insect-specific class. Members of this class have been cloned from *P. xylostella*, *M. domestica, Manduca sexta, A. gambiae*, and *D. melanogaster* (Snyder *et al*., 1995; Huang *et al*., 1998; Singh *et al*., 2000; Ranson *et al*., 2001; Wei *et al*., 2001). The majority of epsilon GSTs that have been characterized have low levels of activity with CDNB and are often not retained by glutathione affinity matrices. Both these factors may explain the relatively recent discovery of this class. As with the delta class, epsilon GSTs play an important role in the detoxification of insecticides (Huang *et al*., 1998; Wei *et al*., 2001; Ortelli *et al*., 2004).

5.11.3.2.3. Omega class The omega GST class was first identified in humans by bioinformatic techniques (Board *et al*., 2000). Members of the omega class have also been found in the mouse, rat, *Caenorhabditis elegans, Schistosoma mansoni, D. melanogaster*, and *A. gambiae* (Board *et al*., 2000; Ranson *et al*., 2002). In most species, the omega GSTs appear to be encoded by a single gene but five putative omega GST genes have been identified in *D. melanogaster* (Ranson *et al*., 2002). The human recombinant GSTO1-1 has low levels of activity with most typical GST substrates but high thiol transferase activity. Its physiological function is unclear but one suggestion is that it may play a housekeeping role in protecting against oxidative stress by removing *S*-thiol adducts from proteins (Board *et al*., 2000).

5.11.3.2.4. Sigma class The sigma class GSTs are related to the catalytically inactive cephalopod *S*-crystallin, a major component of eye lens (Ji *et al*., 1995). A structural role has also been suggested for the insect sigma GSTs (formally known as the insect class II GSTs), as in both *D. melanogaster* and *M. domestica* these proteins are found predominately in the indirect flight muscles in close association with troponin-H. Both of these enzymes also possess a proline/alanine rich N-terminal extension, which may aid attachment to the flight muscle. Recently, however, insect sigma GSTs (with or without the N-terminal extension) have been shown to be catalytically active (Singh *et al*., 2001). This class of proteins has low levels of activity with typical GST substrates but a high affinity for the lipid peroxidation product 4-hydroxynonenal (4-HNE). A means of reducing the levels of reactive oxygen species in highly metabolically active tissues such as flight muscles is essential and it is postulated that the high levels of GSTS1-1 found in this tissue may protect the flight muscle against by-products of oxidative stress (Singh *et al*., 2001). Sigma GSTs are found in all major eukaryotic taxonomic groups except plants. In addition to the housefly and *Drosophila* sigma GSTs described above, members of this class lacking the N-terminal extension have been cloned or purified from *M. sexta, Blattella germanica*, *A. gambiae*, and *C. fumiferana* (Reiss and James, 1993; Snyder *et al*., 1995; Arruda *et al*., 1997; Feng *et al*., 1999). In all cases to date, the sigma GSTs are encoded by a single gene, although in *A. gambiae*, two alternative transcripts from this gene have been detected (see Section 5.11.5.3.1).

5.11.3.2.5. Theta class Theta GST were first purified from mammalian livers. The first theta GSTs to be studied were unusual amongst the mammalian GSTs in that they had very low levels of activity with CDNB and were not retained by glutathione affinity matrices (Meyer *et al.*, 1991). Theta GSTs also occur in bacteria, plants, and insects and initially the theta GSTs were proposed to be the progenitor of all GST classes (Pemble and Taylor, 1992). However, as more GSTs were identified it became apparent that many GSTs, including the insect delta class, were inappropriately assigned to this class and proposals for the evolutionary pathway of GSTs were revised (see Section 5.11.8). Insects do possess several GST genes whose sequence identity and phylogeny warrant their inclusion in the theta class. These putative insect theta GSTs have not yet been biochemically characterized and their physiological role is unknown.

5.11.3.2.6. Zeta class The zeta class of GSTs was first identified by bioinformatic approaches. Zeta GSTs occur in many different species and their sequence is highly conserved, particularly at the N-terminus of the proteins where the SSCXWRVIAL motif is conserved in plants, insects, and mammals (Board *et al.*, 1997). The highly conserved structure of this protein suggests it plays an essential housekeeping role and in this regard, GSTZ1-1 catalyzes an important step in the tyrosine degradation pathway. Two putative zeta class GSTs have been identified in *D. melanogaster*, while a single zeta GST gene is found in *A. gambiae* (Ranson *et al.*, 2002).

5.11.3.2.7. Microsomal GSTs The microsomal GSTs have a different structure and genetic origin to the cytosolic GSTs but perform similar functions. The microsomal GST class is encoded by a single gene in *D. melanogaster*. Mutants that have this gene disrupted have reduced life spans but are still viable (Toba and Aigaki, 2000). Humans possess multiple microsomal GSTs some of which detoxify xenobiotic and lipid-derived products of reactive oxygen but other members of this class are involved in the synthesis of prostaglandins. Microsomal GSTs are sometimes referred to as membrane associated proteins in eicosanoid and glutathione metabolism (MAPEG) (Jakobsson *et al.*, 1999).

5.11.4. Protein Structure

There are two types of GST with very differing structures. The majority of insect GSTs are soluble dimeric proteins found in the cytosol. The second type, the microsomal class, are trimeric membrane associated proteins. At present, the three-dimensional structure has only been elucidated for four insect GSTs, three from the delta class and a single sigma class GST and much of our knowledge of the structure of insect GST proteins is extrapolated from knowledge of mammalian GSTs. Posttranslational modification of GSTs appears to be a very rare phenomenon and has not been reported in insects.

5.11.4.1. Cytosolic GSTs

Each soluble GST is a dimer of subunits ranging from 24 to 28 kDa in size. Each subunit has two binding sites, the G site and the H site. The highly conserved G site binds the tripeptide glutathione and is largely composed of amino acid residues found in the N-terminal of the protein. The H site or substrate binding site is more variable in structure and is largely formed from residues in the C-terminal (Mannervik, 1985). An alignment of amino acid sequences of representative insect GSTs from different classes is shown in **Figure 2**. The active site residue at the N-termini of the protein is shown in bold. This residue interacts with and activates the sulfhydryl group of glutathione to generate the catalytically active thiolate anion (Armstrong, 1991). This nucleophilic thiolate anion is then capable of attacking substrates bound to the H site. In most mammalian GSTs and in all sigma GSTs, the active site residue is a tyrosine (Wilce and Parker, 1994; Agianian *et al.*, 2003). In the delta, epsilon, theta, and zeta classes this role is performed by a serine residue while in the omega class, cysteine is the active site residue (review: Sheehan *et al.*, 2001). Generally, mutation of the active site residue results in reductions in GST activity of up to 90% (Rushmore and Pickett, 1993; Caccuri *et al.*, 1997). However, it is noteworthy that GSTD3-3 in *D. melanogaster* lacks the 15 N-terminal amino acids and yet is still catalytically active (Sawicki *et al.*, 2003). The determination of the three-dimensional structures of GST subunits have identified additional residues that interact with glutathione (Wilce *et al.*, 1995; Agianian *et al.*, 2003) (**Figure 2**) and perhaps an alternative residue substitutes for the active site tyrosine in GSTD3-3. The *cis*-proline at residue 53 is conserved in all GSTs and appears to be critical for the correct formation of the GSH binding site.

The H site, which binds the hydrophobic substrate, is more variable in structure and contributes to the substrate specificity of the enzyme. The H site of the *Drosophila* sigma GST, GSTS1-1, is polar and unusually open in structure (Agianian *et al.*, 2003) whereas the delta class GSTs from *A. gambiae* have

Figure 2 Alignment of representative amino acid sequence from each insect GST class: delta GST = *L. cuprina* (Acc. No. P42860], epsilon GST = *P. xylostella* (Acc. No. U66342], sigma GST = *D. melanogaster* (Acc. No. M95198], theta GST = *A. gambiae* (Acc. No. AF15526], zeta GST = *A. gambiae* (Acc. No. AF15522], omega GST = *A. gambiae* (Acc. No. AY255856]. The active site residues are shown in bold and the conserved proline necessary for maintaining the GST fold is marked with an asterisk. The extent of the N and C domains is indicated by an arrow below the alignment. The two GSTs in this alignment for which three-dimensional structures have been resolved (Wilce *et al.*, 1995; Agianian *et al.*, 2003) are annotated as follows. Residues putatively involved in the binding of glutathione are underlined, those involved in substrate binding are shown in italics. Beta sheets are highlighted in blue, alpha helices in pink.

a mixture of polar and hydrophobic pockets (Oakley *et al.*, 2001). Again, elucidation of three-dimensional structures has predicted a number of residues involved in substrate binding (Wilce *et al.*, 1995; Oakley *et al.*, 2001; Agianian *et al.*, 2003). The putative H site residues in the *D. melanogaster* sigma GST and the delta class GST1 from *L. cuprina* are shown in **Figure 2**.

Representative crystal structures of vertebrate GSTs are available for all the cytosolic GST classes found in insects. The general structure is the same for all classes with the major differences occurring at the active site and at the intersubunit interface. The unique structural features of the different GST classes were recently comprehensively reviewed (Sheehan *et al.*, 2001) and will only be covered briefly here.

Each monomer consists of two distinct domains joined by a variable linker region. The N-terminal domain consists of four beta sheets and three flanking alpha helices and adopts a conformation similar to the thioredoxin domain found in many proteins that bind GSH or cysteine (Sheehan *et al.*, 2001). A conserved proline in the *cis* conformation (marked with an asterisk in **Figure 2**) is found in all GST sequences and appears to be important in maintaining the protein in a catalytically competent structure (Wilce *et al.*, 1995). The C-terminal domain is larger and consists of a variable number of alpha helices. The omega GST class is unusual in possessing an N-terminal extension that forms a unique structural unit with the C-terminal domain in human omega GSTs (Board *et al.*, 2000). Aligning the putative insect omega GSTs with the mammalian GST sequence suggests this may be a general characteristic of the omega GST structure. A 45 amino acid residue N-terminal extension is present in some sigma class GSTs (**Figure 2**) but, unlike the

omega extension, this region of the protein is not essential for catalytic activity (Singh *et al.*, 2001; see Section 5.11.3.2.4).

The interface between the two subunits can be hydrophobic or hydrophilic and interactions between residues in both subunits are essential for dimer stability. Many GST classes have a V-shaped dimer interface with a "lock and key" motif linking the dimers. The "key," which can be aliphatic (zeta class and *D. melanogaster* sigma class) or aromatic (mammalian alpha, mu, and pi classes), from one subunit interacts with a hydrophobic pocket on the other subunit. The lock and key mechanism appears to be absent from the omega and theta classes of GSTs (Sheehan *et al.*, 2001).

Incompatibility in interfacial residues prevents heterodimers forming between two GST subunits from different classes. However, within a class, the formation of heterodimers can expand the range of functional proteins produced. The prevalence of GST heterodimers has not been widely studied in insects. However, an elegant series of experiments in plants, in which two GST subunits were consecutively expressed *in vitro*, found that even within a class not all GSTs will dimerize with each other to form heterodimers (Dixon *et al.*, 1999).

5.11.4.2. Microsomal GSTs

The microsomal GSTs are trimeric proteins with a molecular mass of approximately 50 kDa. The human MGST1 is a homotrimer found in the membranes of the endoplasmic reticulum and mitochondria. The three-dimensional structure of this protein has been resolved and is markedly different to the soluble GST classes. Each subunit consists of four transmembrane alpha helices. The homotrimer contains a single active site with the hydrophobic substrate binding site facing the cytosol (Schmidt-Krey *et al.*, 1999). The *D. melanogaster* microsomal GST class is encoded by a single gene and hence only homotrimeric proteins can be formed in this species (Toba and Aigaki, 2000). In contrast three distinct microsomal gene GSTs are transcribed in *A. gambiae* but their tertiary structure *in vivo* has not been resolved.

5.11.5. GST Gene Organization

The wide range of functions performed by GSTs is aided by the broad substrate specificities of individual enzymes and by the extensive nature of the GST supergene family in insects. Multiple gene duplications provide a degree of genetic security enabling individual GST genes to evolve to occupy new biochemical niches while still ensuring that essential functions are covered. The insect-specific GST classes in particular are characterized by paralogous clusters of genes, indicating that expansion has occurred by local gene duplications (see below). The permissiveness of GSTs to alterations in their primary structure has also facilitated the diversification of this enzyme family. Very dramatic changes in substrate specificity can be achieved by a small number of amino acid substitutions (Ortelli *et al.*, 2004). In addition, several genetic mechanisms have been described in insects that contribute further levels of heterogeneity to the GST supergene family. In this section, we discuss current knowledge of the genomic organization of the GST supergene family in insects and describe some specific examples of alternative splicing, gene conversion, and allelic variation.

5.11.5.1. Clustering of Paralogous Genes

The physical location of GST genes in the genomes of *A. gambiae* and *D. melanogaster* is shown in **Figure 3**. In both species, the genes are found on all three chromosomes but several large clusters exist. In fact, of the total 69 putative GST genes present in these two species only 17 are present as singletons. In both species, the majority of epsilon class GSTs are found sequentially on both chromosome strands of a single polytene division and there is evidence of recent internal duplications within these gene clusters (Ding *et al.*, 2003; Sawicki *et al.*, 2003). The 11 *D. melanogaster* delta GSTs are sequentially arranged on chromosome 3R, division 87B. The orthologous class in *A. gambiae* is larger and individual members are scattered over all chromosomes, but two closely linked clusters each consisting of six genes are found on chromosome 2R. These two paralogous *A. gambiae* delta class GST clusters may be a result of a segmental duplication (Ding *et al.*, 2003).

5.11.5.2. Intron Size and Position

The frequency of introns in the insect GST supergene family varies widely between species, particularly within the insect-specific delta and epsilon classes. In the *D. melanogaster* delta and epsilon GSTs and the *M. domestica* delta GSTs, the majority of the genes are uninterrupted by introns within the coding sequence (Zhou and Syvanen, 1997; Sawicki *et al.*, 2003) although some have introns in their 5′UTRs (Lougarre *et al.*, 1999). In contrast, the coding sequence of all but one of the *A. gambiae* GSTs is interrupted by at least one intron. The intron size in *A. gambiae* ranges from 64 to 13 937 bp (Ding *et al.*, 2003). A common intron is found in the N-terminal

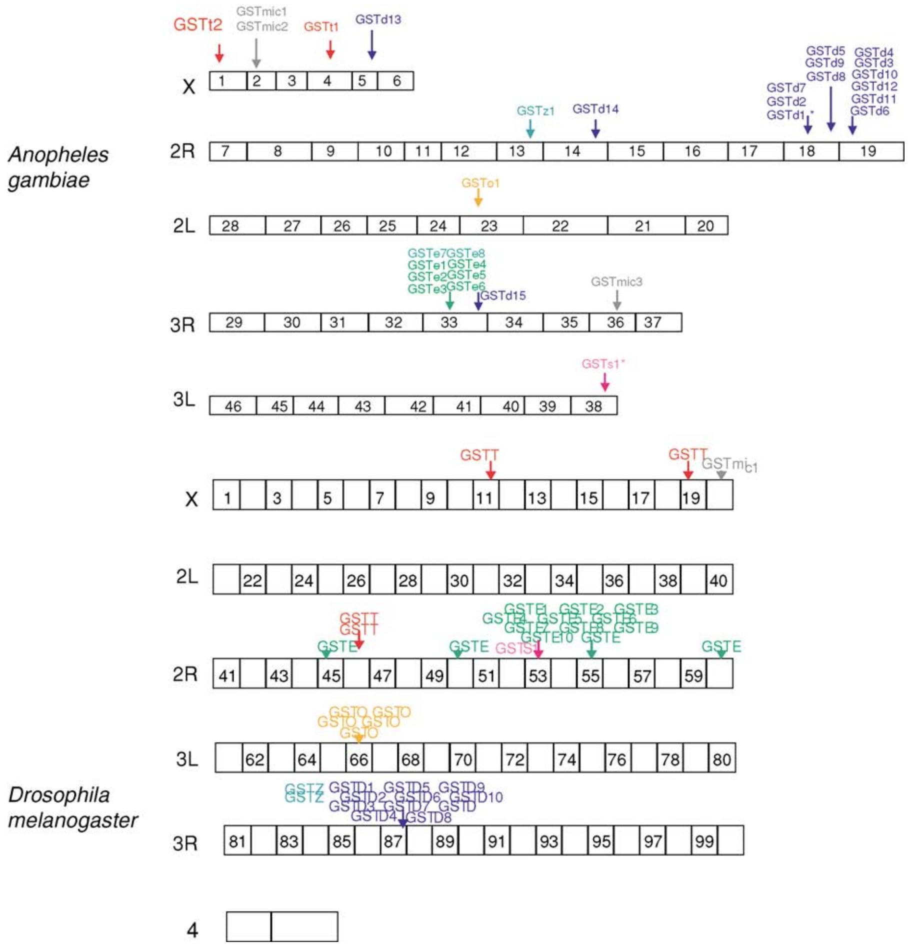

Figure 3 Chromosomal location of GST genes in two species of *Diptera*.

of 16 of the 28 cytosolic GST genes in this species (Ding *et al*., 2003).

5.11.5.3. Mechanisms for Generating Additional Heterogeneity

5.11.5.3.1. Alternative splicing of GSTs Alternative splicing of an RNA transcript can result in the production of different mRNAs, and thereby different proteins, from the same DNA segment. To date, alternative splicing of insect GST genes has only been reported in the *Anopheles* genus. A delta class GST *GSTd1* from *A. gambiae* (and its ortholog from *A. dirus*) is alternatively spliced to produce four distinct mature transcripts each encoding subunits with different biochemical properties (Ranson *et al*., 1998; Jirajaroenrat *et al*., 2001). In *A. gambiae*, the single sigma class GST gene is also alternatively spliced to produce two transcripts, both of which have been detected by RT-PCR (Ding *et al*., 2003). In both of these cases, the mature transcripts share a common 5′ exon (constitutive exon) but differ in their use of 3′ exons (Figure 4). The constitutive

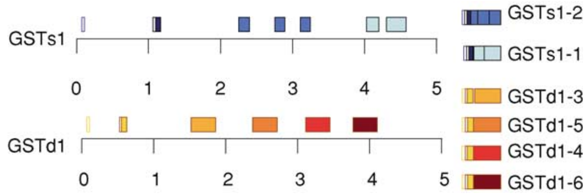

Figure 4 Alternative splicing of two *A. gambiae* GST genes. A schematic of the two genes is shown on the left and the mRNA transcripts on the right. The sigma class gene, *GSTs1*, produces two transcripts, *GSTs1-1* and *GSTs1-2*. The delta class *GSTd1* gene produces four distinct transcripts, *GSTd1-3* to *GSTd1-6*. Coding exons are shown by colored rectangles, 5′UTRs are shown by empty rectangles. The scale bar is in kilobases.

exon in each gene comprises the majority of the residues in the N-terminal domain whereas the variable exons encode the C-termini. As the carboxyl region of the GST subunit contains the majority of the residues involved in substrate binding (the H site), this form of alternative splicing is an efficient means of broadening the substrate recognition patterns of the GSTs with a minimal addition to the genome.

The factors governing choice of splice site in the *Anopheles* GSTs are unknown. For the delta GST at least, all four alternative transcripts are expressed throughout mosquito development and in both sexes. The expression pattern of this GST gene in different tissues has not yet been reported however, and it is possible that the choice of 3′ splice site is tissue dependent (Ranson *et al*., 1998).

5.11.5.3.2. GST fusion genes The delta class GSTs in *M. domestica* have an unusual genomic organization. Transcripts encoding five members of this class (*MdGST-1–MdGST-5)* have been detected in adult flies (Syvanen *et al*., 1994; Zhou and Syvanen, 1997). Screening a genomic library for clones containing these GST genes identified a complex array of loci encoding MdGST-3 and MdGST-4. At least three genomic loci encoding MdGST-3 and two encoding MdGST-4 were found, although none of these were identical to the sequence of the corresponding cDNA clones. Furthermore, several loci that appear to have resulted from the fusion of the 5′ end of one of these genes with the 3′ of another were identified in two different strains of *M. domestica* (Zhou and Syvanen, 1997). The open reading frame (ORF) is preserved in all of these fusion genes but, surprisingly, the breakpoints are not conserved and there are no introns at fusion sites, or elsewhere in the coding sequence. The genetic mechanism that produces these fusion genes is unclear and it is not known whether or not these fusion genes encode functional GSTs. Nevertheless, it is possible that a special recombination mechanism associated with the delta class GST family in *M. domestica* may contribute additional potential for functional diversity (Zhou and Syvanen, 1997).

5.11.5.3.3. Allelic variation Small numbers of amino acid substitutions can have dramatic effects on the substrate specificities of GST homodimers (Ketterman *et al*., 2001) and thus the maintenance of allelic variation in a population can provide further functional diversification. In *A. gambiae*, two alleles of the epsilon class GST *GSTe1*, differing at 12 amino acid residues, are found in laboratory and field populations. One of these encodes a protein with very high levels of peroxidase activity and it has been proposed that this may provide a fitness advantage in the presence of insecticide exposure, thus explaining its frequency in *A. gambiae* populations (Ortelli *et al*., 2003).

In addition to allelic variation, the formation of heterodimers can expand the range of functional proteins (see Section 5.11.4). The prevalence of GST heterodimers has not been widely studied in insects and it is often difficult to distinguish between genuine heterodimers and mixed populations of homodimers when characterizing GSTs isolated from insect tissues. An *in vitro* approach, similar to that adopted in plants (Dixon *et al*., 1999), may help reveal the importance of heterodimers in generating diversity in the insect GST family.

5.11.5.4. GST Pseudogenes

Pseudogenes can be produced by deleterious mutations, which result in the silencing of a gene. This type of pseudogene, known as an unprocessed pseudogene, normally occurs in a duplicate gene and frequently pseudogenes are found proximal to the genes from which they are derived. Unprocessed pseudogenes are rarely transcribed although some are transcribed and not translated or, occasionally, translated into nonfunctional proteins. Two possible unprocessed pseudogenes have been described in the GST delta class of *A. gambiae*. One of these is untranscribed and the second is transcribed but predicted to encode a nonfunctional protein (Ding *et al*., 2003). Both genes are located within the GST delta cluster on chromosome 2R. Originally, two of the *D. melanogaster* delta GSTs, *GSTD7* and *GSTD3*, were reported to be pseudogenes on the basis of abnormalities in their putative transcript lengths (Toung *et al*., 1993). However, transcripts for both of these have since been detected by real-time polymerase chain reaction (RT-PCR) and recombinant proteins derived from these cDNAs encode catalytically active proteins (Sawicki *et al*., 2003).

A different type of pseudogene, known as a processed pseudogene, is found in the GST supergene family in *D. melanogaster. Mgst1-psi* is a putative pseudogene of the single microsomal GST gene found in this species. This pseudogene contains a poly-A tail towards the 3′ end, has no introns, a premature stop codon, and a direct repeat at both ends. Presumably, it was derived from the reverse transcription and subsequent integration of *Mgst1* mRNA into the genome (Toba and Aigaki, 2000).

5.11.6. Functions of Insect GSTs

The primary function of GSTs is generally considered to be in the detoxification of both endogenous and xenobiotic compounds either by acting directly on these compounds or by catalyzing the secondary metabolism of a vast array of compounds that are oxidized by the cytochrome P450 family. Perhaps of equal importance is the role of GSTs in stress physiology. In addition, members of this enzyme family have been implicated in various biosynthetic

pathways and may be involved in the intracellular transport of ligands. In insects, the majority of studies have focused on their role in the detoxification of foreign compounds, in particular insecticides and plant allelochemicals, and in many cases the endogenous substrates of insect GSTs are unknown. The application of functional genomic approaches to this enzyme family will hopefully redress this balance and enable the housekeeping functions of these enzymes to be fully elucidated.

5.11.6.1. Endogenous Substrates

The little that is known about the endogenous substrates of insect GSTs is generally inferred from functions that have been attributed to mammalian enzymes. An exception to this is the antennae-specific GST identified in *M. sexta*, which is proposed to play a vital role in olfactory function both by detoxifying compounds that can interfere with sex pheromone detection and, more specifically, by conjugating GSH to aldehyde pheromones thereby terminating signals from sex-pheromone odorants (Rogers *et al*., 1999).

The wide range of substrates recognized by GSTs suggests they play a central role in cellular processes. One of these processes, GSH conjugation, is a key stage in the conversion of lipophilic compounds to water soluble metabolites that are more readily exported from the cell. GSTs are also important in the biosynthesis of prostaglandins (Meyer and Thomas, 1995). They can act as intracellular transporters of various nonsubstrate hydrophobic compounds in mammals and may be involved in similar processes in insects (Wilce and Parker, 1994). The zeta class of GST is one of the few enzymes with a clearly defined role in biosynthetic pathways in the cell. It catalyzes the isomerization of maleylacetoacetate to fumarylacetoacetate, an essential step in the catabolism of tyrosine (Blackburn *et al*., 1998).

5.11.6.2. Protection against Oxidative Stress

GSTs play a vital role in the inactivation of toxic products of oxygen metabolism. Reactive oxygen species (ROS), including hydrogen peroxide, superoxide anions, and hydroxyl radicals, are generated during aerobic respiration. These ROS trigger a cascade of reactions that can be highly damaging to the cells. The generation of ROS initiates the conversion of polyunsaturated fatty acids to lipid hydroperoxides. These in turn can give rise to highly reactive α,β-unsaturated aldehydes, e.g., 4-HNE. 4-HNE is toxic at high concentrations but at low concentrations it has important signaling functions affecting cell proliferation, apoptosis, and differentiation (Sawicki *et al*., 2003). GSTs have a protective effect at several different stages in this pathway. Peroxidase activity has been detected in insect GSTs from the delta, epsilon, and sigma classes using the model substrate cumene hydroperoxide (Vontas *et al*., 2001; Singh *et al*., 2001; Ortelli *et al*., 2004). Other delta and sigma insect GSTs can detoxify 4-HNE by conjugation with glutathione (Singh *et al*., 2001; Sawicki *et al*., 2003).

5.11.6.3. Detoxification of Xenobiotics

Insects, like all organisms, are continually being exposed to foreign chemical species. Some of these, such as insecticides, are in evolutionary terms relatively new threats, but other environmental pollutants, such as plant degradation products, have existed over a much longer timespan. GSTs can protect against these toxins by sequestration or, more commonly, by converting them to less toxic metabolites or conjugates that are tagged for export from the cell. Much attention has been focused on the role of insect GSTs in insecticide resistance because of the significant economic and public health problems associated with resistance. Insecticide resistance will be used to illustrate some of the different pathways of GST catalyzed detoxification.

5.11.6.3.1. Metabolism of insecticides Elevated GST activity has been implicated in resistance to at least four classes of insecticides. Higher enzyme activity is usually due to an increase in the amount of one or more GST enzymes, either as a result of gene amplification or, more commonly, through increases in transcriptional rate, rather than qualitative changes in individual enzymes (review: Hemingway and Ranson, 2000). An overview of GST involvement in insecticide resistance is shown in **Figure 5**.

5.11.6.3.1.1. Organophosphates This was the first insecticide class in which resistance due to increases in GST activity was detected. GSTs have been implicated in organophosphate resistance in many insect species (Hayes and Wolf, 1988). Recombinant GST enzymes from the diamondback moth and housefly have verified the role of these enzymes in the metabolism of organophosphate insecticides (Huang *et al*., 1998; Wei *et al*., 2001). Detoxification occurs via an *O*-dealkylation or *O*-dearylation reaction. In O-dealkylation, glutathione is conjugated with the alkyl portion of the insecticide, e.g., the demethylation of tetrachlorvinphos in resistant houseflies (Oppenoorth *et al*., 1979), whereas the reaction of glutathione with the leaving group, important in the detoxification of parathion and methyl parathion in

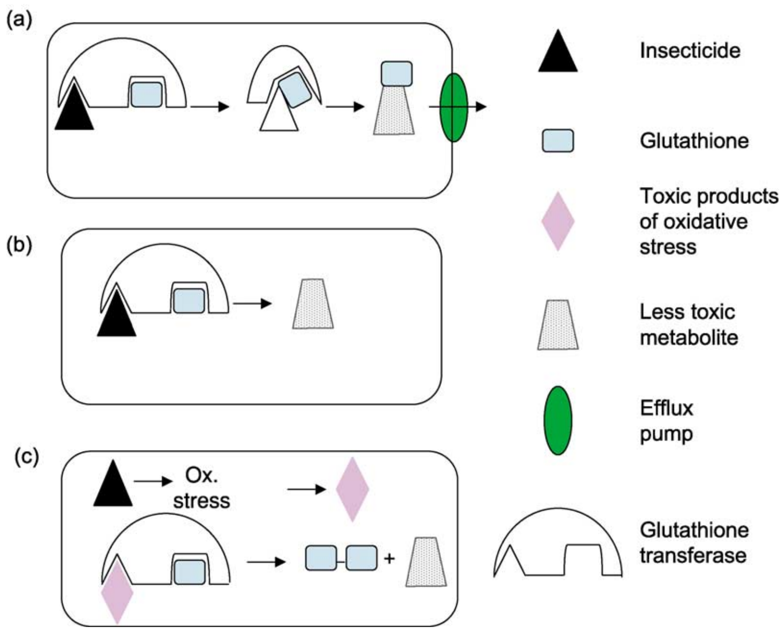

Figure 5 Overview of known GST involvement in insecticide resistance. (a) GSTs can detoxify insecticides via glutathione conjugation; the conjugates are then exported from the cell, e.g., demethylation of tetrachlorovinphos to demethyltetrachlorovinphos). (b) GSTs can detoxify the insecticide DDT via an elimination reaction. Glutathione acts as a proton source but no glutathione conjugate is produced (e.g., the dehydrochlorination of DDT to DDE). (c) GSTs with glutathione peroxidase activity can protect against insecticide induced oxidative stress.

the diamondback moth (Chiang and Sun, 1993), is an *O*-dearylation reaction.

GSTs can also catalyze the secondary metabolism of organophosphate insecticides. This insecticide class is usually applied in its noninsecticidal phosphorothionate form and activated to the insecticidal form by the action of cytochrome P450s in the insect. GSTs that can detoxify the active oxon analog have been described in mosquitoes and elevated activity of these enzymes is a cause of organophosphate resistance in *Anopheles subpictus* (Hemingway *et al*., 1991).

5.11.6.3.1.2. Organochlorines DDT dehydrochlorination is a major route of detoxification in insects. The enzyme catalyzing this reaction was not initially recognized as a member of the GST family partly due to the inability to detect even a transient GSH conjugate and also because of the lack of DDT dehydrochlorinase activity in some purified GSTs. Evidence that DDT dehydrochlorinase is a GST was finally provided in the housefly. Three enzymes with CDNB conjugating activity were isolated from a DDT resistant strain of housefly and two of these were also active with DDT as a substrate (Clark and Shamaan, 1984). The DDT dehydrochlorinase reaction proceeds via a base abstraction of hydrogen, catalyzed by the thiolate anion generated in the active site of the GST, leading to elimination of chlorine from DDT to generate DDE.

In addition to the housefly, an increased rate of DDT dehydrochlorination confers resistance to DDT in the mosquito *A. aegypti* (Grant *et al*., 1991) and *A. gambiae* (Prapanthadara *et al*., 1993).

5.11.6.3.2. Pyrethroids GSTs have not yet been shown to be involved in the direct metabolism of pyrethroid insecticides. Nevertheless, they play a very important role in conferring resistance to this insecticide class by detoxifying lipid peroxidation products induced by pyrethroids (Vontas *et al*., 2001). A delta class GST present in elevated quantities in a pyrethroid resistant strain of *N. lugens* was expressed *in vitro*. The recombinant protein had high peroxidase activity and a role for this enzyme in the prevention or repair of oxidative damage was proposed (Vontas *et al*., 2002). Elevated GSTs in other resistant insects may play a similar role. GSTs have also been suggested to protect against pyrethroid toxicity in insects by sequestering the insecticide (Kostaropoulos *et al*., 2001).

5.11.6.3.3. Plant chemicals Plants produce a wide variety of allelochemicals to protect themselves from pathogens and herbivores. The detoxification of these compounds presents a major challenge for

herbivorous insects and one consequence of this is that many insects feed on a very limited range of host plants. Many polyphagous species have highly evolved detoxification systems. Most studies on the metabolism of plant allelochemicals have focused on the role of cytochrome P450s (Fogleman *et al.*, 1998). However, GSTs can also metabolize many allelochemicals (review: Yu, 1996) and in some cases, the allelochemical acts as a regulator, inducing its own metabolism.

5.11.7. Regulation and Induction of GST Expression

In noninsect species, many GSTs are differentially regulated in response to various inducers or environmental signals or in a tissue developmental-specific manner. A similar complex pattern of expression is gradually being elucidated within the insect GST family. A detailed account of the effect of dietary compounds, insecticides, and laboratory inducers on GST expression is provided in two review articles (Clark, 1989; Yu, 1996). The main purpose of the following discussion is to outline some of the recent results from molecular studies on expression of individual GST genes and to highlight gaps in our knowledge.

5.11.7.1. Tissue and Life Stage Specificity of Expression

The majority of individual insect GSTs whose expression profiles have been determined are expressed constitutively in all life stages. Of course, the caveat here is that GSTs with a very restricted window of expression may have escaped detection in earlier studies. Nevertheless, in recent experiments looking at the global expression of the insect GSTs it was found that in *A. gambiae*, transcripts for all but one of the GST supergene family were detectable in 1-day-old adult mosquitoes by RT-PCR (Ding *et al.*, 2003). In these preliminary experiments no attempt was made to quantify the expression level in different developmental stages and it is apparent from several studies in other insects that the levels of individual enzymes can fluctuate widely during the life span of an insect. For example, using the less sensitive technique of Northern blotting, four delta class GSTs were undetectable in *D. melanogaster* adults (Toung *et al.*, 1993) and in the spruce budworm, *C. fumiferana,* a sigma GST was found at very low levels in feeding larvae but at high levels in diapausing larvae (Feng *et al.*, 1999).

Variations in the level of GST activity in different insect tissues have been reported in several species. In cases where the variation in activity is attributed to individual enzymes, such studies can provide valuable insights into the functions of different GSTs. Thus, the finding that sigma GSTs from housefly and *Drosophila* were predominately located in the indirect flight muscles in association with troponin H suggested that the role of this GST class was structural rather than catalytic (subsequently, however, these GSTs have been found to play a very important role in the protection against oxidative stress; Franciosa and Berge, 1995; Clayton *et al.*, 1998). Very high levels of GST activity have been reported in the fat body and midguts of insects. Both these tissues are important sites for the detoxification of xenobiotics and further studies characterizing the individual enzymes present in these tissues are needed.

5.11.7.2. Induction of GSTs

In a number of studies, insects have been exposed to various xenobiotics to determine the effect of these chemicals on GST expression levels (Ottea and Plapp, 1984; Yu, 1984). In the majority of cases, a model substrate, such as CDNB, is used to assay GST activity from crude insect homogenates and hence the results are general measurements of the activity of a large subset of GSTs and do not reveal much about fluctuations in the level of individual enzymes. A more complete picture of factors governing GST expression is available for the plant GST family. By studying the expression profile of 10 different *Arabidopsis* GSTs in response to a variety of inducers and stress treatments different signaling mechanisms were demonstrated to regulate the expression of individual GSTs in response to different stimuli (Wagner *et al.*, 2002). Although not resolved at the level of individual enzymes, a study in the fall armyworm, *Spodoptera frugiperda,* showed that different enzyme fractions were induced to varying extents by treatment with different inducers (Kirby and Ottea, 1995). Injection of larvae with 8-methoxypsoralen enhanced the activity of GSTs active against DCNB, but not those active against CDNB, whereas injection with pentamethylbenzene had the opposite effect. Coadministration of the inducers prevented some of these induction effects leading the authors to conclude that multiple mechanisms are involved in the regulation of these enzymes.

Other chemicals that induce GSTs include insecticides, fumigants, barbiturates, and plant allelochemicals (review: Yu, 1996). Several of these, e.g., paraquat and pyrethroid insecticides, are also inducers of oxidative stress. Repressors of insect GST activity have also been identified in the diet of

some insects. For example, GST activity in the tobacco budworm, *Heliothis virescens*, is decreased by a diet of wild tomato leaves (Clark, 1989).

5.11.7.3. Regulation of GST Expression

Most studies of the response of GSTs to environmental or artificial inducers suggest that regulation occurs at the transcriptional level. Several regulatory elements have been identified in the promoter regions of mammalian GSTs that may mediate their induction. These include xenobiotic response elements (XREs) and antioxidant or electrophile response elements (AREs/EpREs) (Rushmore and Pickett, 1993). Analysis of the promoters of the delta class GSTs from *D. melanogaster* identified several putative transcription factor binding sites including 12-*O*-tetradecanoylphorbol-13-acetate (TPA) responsive elements (Toung *et al*., 1993). Other putative binding sites for transcription factors involved in developmental regulation were identified upstream of an epsilon GST in *A. dirus* (Udomsinprasert and Ketterman, 2002). In the absence of functional studies, the significance of these findings are unclear.

Genetic mechanisms responsible for the elevation in GST expression observed in many insecticide resistant strains have been the subject of many studies. In both the housefly and yellow fever mosquito (*Ae. aegypti*), modifications in *trans*-acting regulators have been implicated in increased GST expression. In *Ae. aegypti*, a mutation in a *trans*-acting repressor element is the proposed mechanism for the enhanced expression of a delta class GST in a DDT resistant strain (Grant and Hammock, 1992). A major regulatory gene on chromosome II of *M. domestica* has been proposed to regulate both GST and monooxygenase expression in insecticide resistant strains of houseflies (Plapp, 1984). Neither of these postulated regulators have been identified, although candidates have been proposed (Sabourault *et al*., 2001). Genetic mapping of the major genes controlling GST-based DDT resistance in *A. gambiae* also provided tentative evidence for a *trans*-acting regulator (Ranson *et al*., 2000) although in this species, mutations in promoter elements of the epsilon GST cluster are also associated with resistance (Ranson *et al*., 2001).

The significance of alternative splicing in regulating GST expression has not been fully investigated. Four alternative transcripts of a delta class gene and two of a sigma GST have been detected in *A. gambiae* (see Section 5.11.5.3.1) and it is possible that different inducers or stress treatments may affect the choice of splice site.

Regulation of GST enzyme levels may also occur by alterations in the stability of mRNA transcripts. Most studies on gene regulation rely on the detection of steady state mRNA levels and the role of differential stability of transcripts is often overlooked. An exception to this was a comprehensive study in *D. melanogaster* in which factors responsible for the observed difference in the protein levels of two delta GSTs, GSTD1 and GSTD21, were investigated (Tang and Tu, 1995). Although the transcription rate of *GSTD2* (previously known as *GSTD21*) was higher than that of the neighboring gene *GSTD1*, the steady state level of *GSTD1* mRNA was over 20-fold higher than that of *GSTD2*, suggesting that the *GSTD2* mRNA is unstable. Treatment with pentobarbital (PB) enhanced the stability of *GSTD2* mRNA, but also may have prevented its efficient translation, as no corresponding increase in the levels of GSTD2 protein was observed after PB treatment.

In general, posttranslational modification has not been widely reported in the GST family and there have been no confirmed reports in the insect GSTs. A glycosylated form of a GST from the human filarial parasite *Onchocerca volvulus* has been detected. This GST is unusual as it is located in the parasite cuticle at the host–parasite interface and hence is speculated to be involved in protecting the parasite from reactive oxygen produced during the host's immune response (Sommer *et al*., 2001). The detection of multiple forms of immunologically related GSTs during purification of housefly GSTs was initially interpreted as being suggestive of posttranslational modification (Fournier *et al*., 1992). However, the extent of the insect GST family, and the presence of multiple members within both the delta and epsilon classes, suggests that these multiple forms actually represented unique GST subunits.

5.11.8. Evolution of GSTs

GSTs are thought to have evolved from a thioredoxin-like ancestor to protect cells from oxygen toxicity (Hayes and McLellan, 1999). Multiple rounds of gene duplication and subsequent diversification have led to the range of GST proteins found in eukaryotes. The thioredoxin-like fold found in the N-terminal domain of GSTs occurs in many other glutathione binding proteins, including glutathione reductase, chloride intracellular channels (CLICs), and glutaredoxin (Bushweller *et al*., 1994; Xia *et al*., 2001; Cromer *et al*., 2002). The low levels of sequence identity between these proteins and GSTs led to the conclusion that the structural similarity was due to convergent rather than

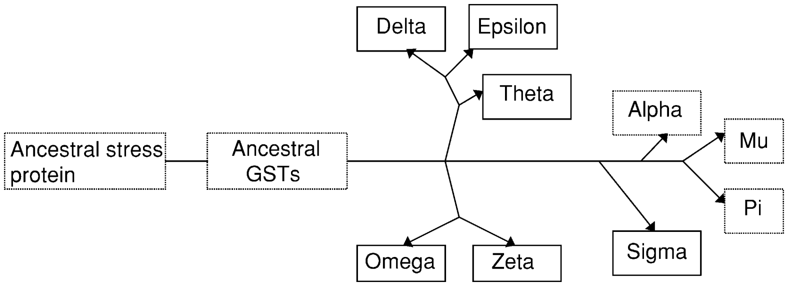

Figure 6 Suggested phylogenetic relationship between selected GST classes (those not present in insects are shown by dashed boxes). Schematic was modified from Sheehan *et al.* (2001) based on alignments of insect and mammalian GSTs in Ding *et al.* (2003).

divergent evolution (Wilce and Parker, 1994). However, the discovery of additional GST classes, in particular the omega class, warrants a reassessment of the relationship between these glutathione binding proteins and GSTs. For example, the CLIC1 sequence shows approximately 15% sequence identity with an omega class GST and structural similarity in both the N- and C-terminal domains suggesting that, despite the very different functions of these proteins, they have a common ancestor and belong in the same superfamily (Cromer *et al.*, 2002).

A schematic diagram showing the probable phylogenetic relationships between different GST classes is shown in **Figure 6**. The insect specific delta and epsilon GSTs have a common ancestor and are most closely related to the theta class to which they were originally assigned (Pemble and Taylor, 1992). The omega and zeta classes are also derived from a common ancestor and both of these classes are represented in a range of phylogenetic groups.

A comparative genomic analysis of the GSTs of the two Diptera, *A. gambiae* and *D. melanogaster*, found remarkably few clear orthologs between the two species (Ranson *et al.*, 2002). The orthologs that can be unambiguously identified were generally found within the noninsect-specific classes and these GSTs are presumably involved in essential steps in conserved physiological pathways, with subsequent constraints on their evolution. The two insect-specific classes, delta and epsilon, have independently radiated in *D. melanogaster* and *A. gambiae* suggesting that these GST classes play important roles in the adaptation of these insects to their specific biological niches rather than fulfilling general housekeeping functions. The majority of the delta and epsilon genes are tightly clustered in both species and the expanse of these GST classes is a result of local duplications of individual genes or blocks of genes (Holt *et al.*, 2002; Sawicki *et al.*, 2003).

5.11.9. Conclusions

Advances in genetics and biochemistry have unveiled a surprising complexity in the variety of the insect GST genes and enzymes in insects. The sequencing of insect genomes has been invaluable in unveiling the extent of the GST supergene family but clearly sequence analysis alone is not sufficient to uncover the *in vivo* function of individual enzymes. Furthermore, presently, full genome sequences are only publicly available for two Dipteran species. Extensive comparisons between the GST supergene family in these two species have enabled testable hypotheses about the broad roles of different GST classes to be formulated, but clearly the power of these comparative genomic approaches will be enhanced by expanding this analysis to other insect orders.

The role of GSTs in the detoxification of xenobiotics and, in particular insecticide detoxification, is rapidly being elucidated. However, much still remains to be learnt about the endogenous substrates of insect GSTs. Overexpression of individual GST genes via transient or stable transfection in insect cell lines or under expression via RNA interference or gene knockout studies will enable the role of GSTs in protecting cells against various external stimuli or chemical treatments to be studied. However, one of the biggest challenges for GST research is characterizing their roles in endogenous metabolic pathways. Deciphering the precise tissue and developmental expression profile of individual GST genes may provide some clues to their function and this type of data can now be more readily obtained for entire gene families via microarray-based experiments. Putative GST substrates are more readily assayed in an *in vitro* system, but frequently recombinant insect GSTs expressed in *E. coli* are sequestered in insoluble inclusion bodies. Overcoming this obstacle is a major priority for GST research.

5.12 Insect Transformation for Use in Control

P W Atkinson, University of California, Riverside, CA, USA
D A O'Brochta, University of Maryland Biotechnology Institute, College Park, MD, USA
A S Robinson, FAO/IAEA Agriculture and Biotechnology Laboratory, Seibersdorf, Austria

5.12.1. Introduction

In the previous series of *Comprehensive Insect Physiology, Biochemistry, and Pharmacology*, the corresponding article by Whitten (1985) dealing, briefly, with insect transformation technology raised two points about the problems that the extension of this technology into the field would most likely face. The prescience of these forecasts is even more remarkable given that it was written shortly after the development of a genetic transformation technology for *Drosophila melanogaster* and so was authored some 10 years before the repeatable transposable element-mediated transformation of nondrosophilid pest insect species.

In writing this review we have chosen not to regurgitate information already presented in recent reviews on the subject (Robinson and Franz, 2000; Atkinson, 2002; Handler, 2002; Robinson, 2002; Wimmer, 2003; Robinson *et al*., 2004), and we will not discuss the issue of the development of a regulatory framework for the use of this technology. Two recent reports on the regulation of the release of transgenic arthropods have recently been published and the reader is referred to these for illumination as to the state of this issue (National Research Council, 2002; Pew Initiative on Food and Biotechnology, 2004). It would also be difficult to improve on Whitten's (1985) review, which comprehensively examined the history, conceptual basis, and application of genetic control in insects. Rather, under examination are two points raised by Whitten as a means to assess critically the current status of the application of genetically engineered insects to help solve problems in medicine and agriculture.

It must first be said that, some 20 years after the publication of Whitten's review, there is not one single example of the use of genetically engineered pest insects in the field. This is despite the first report of the transformation of an anopheline mosquito by Miller *et al*. (1987), and then, 8 years later, the first of several published reports ultimately describing five new transposable elements used to transform a range of nondrosophilid insect species, e.g., the Mediterranean fruit fly, *Ceratitis capitata*, and the yellow fever mosquito, *Aedes aegypti* (review: Robinson *et al*., 2004).

In his 1985 review, Whitten stated:

> Clearly it is unlikely that our technical ability to transform a species will prove lacking: rather, it is our uncertainty concerning what genetic modifications are desirable that will usually prove to be the major impediment.

The current state of the field supports this prediction. Repeatable genetic transformation technologies for nondrosophilid insects have now existed for 9 years. While the development of these did prove to be more problematic than expected and awaited the discovery of new transposable elements such as *Minos* (Franz *et al*., 1994), *Mos1* (Medhora *et al*., 1991), *piggyBac* (Cary *et al*., 1989), and *Hermes* (Warren *et al*., 1994), the application of these technologies to practical problems in medical, veterinary, and economic entomology has not occurred. Several reasons exist for this, the most important one being the difficulty in discovering genetic and biochemical systems that might prove to be effective genetic control strategies in the field. Even as recently as 2001, the most elegant examples of using genetic-based strategies to selectively eliminate females (e.g., for the augmentation of a sterile insect technology) occurred in *D. melanogaster* and with experimental population sizes several orders

of magnitude smaller than those required for the mass-rearing of insects in sterile insect technique (SIT) programs (Heinrich and Scott, 2000; Thomas *et al*., 2000). Both experiments utilized conventional *P* element-mediated genetic transformation of *Drosophila*. As discussed, research into the manipulation of genetic and biochemical systems has produced interesting advances to prevent the transmission of pathogens through mosquitoes and, using model systems, proof of principle tha transmission of pathogens can be diminished in genetically modified mosquitoes has been demonstrated (Ito *et al*., 2002; Moreira *et al*., 2002). While significant for the control of mosquitoes and the human diseases they vector, these experiments have little bearing on the development of corresponding technology in agriculturally important insect species, such as *C. capitata* and the many lepidopteran species that feed on crops. Strategies for introducing and testing genetic markers, such as the green fluorescent protein (GFP), into an SIT strain for the purpose of allowing easy identification of this strain from the field strain, have been discussed and such strains have been generated in the Caribbean fruit fly, *Anastrapha suspensa*, in which the green fluorescence has been found to be detectable up to 4 weeks postmortem (Handler, 2002). Strains having similar properties have also been developed in *C. capitata* (Franz, personal communication). The stability of this protein, although very important for its use as a marker, has raised concerns about the transfer of the protein to nontarget organisms through predation. Significant effort has been expended towards unraveling the genetic basis of sexual development in *C. capitata* with the goal being to use these genes and their promoters as the basis of new genetic sexing strategies. Important genes such as *double-sex* and *transformer* have been isolated and characterized, allowing comparisons to be made of their function with their structural homologs in *D. melanogaster* (Saccone *et al*., 2002). Sex-specific promoters from *C. capitata* have also been isolated (Christophides *et al*., 2000). To date, however, no genetically engineered strains of *C. capitata* designed for a genetic sexing strategy have been generated or tested. In lepidopterans, the only progress in pest species has been the genetic transformation of *Pectinophora glossypiella* using the *piggyBac* element and the consequent application for permits to examine the robustness of this genetically engineered strain in outdoor cage experiments (Peloquin *et al*., 2000).

Another factor contributing to the slow development of the technology is that genetic transformation of nondrosophilid insects is still not a routine robust technology. In this regard Ashburner *et al*. (1998) defined robustness:

> by the property that anyone skilled in the art can carry out the procedure, as is the case with transformation of *Drosophila*, a technique that has been performed in hundreds of laboratories world-wide.

Indeed, one of the reasons that *C. capitata* and *A. aegypti* are most frequently the subject of transformation experiments is the relative ease with which their embryos can be handled and injected. Combined with this is the very small number of laboratories in which nondrosophilid transformation is practiced. This is compounded by, in the case of tephritid fruit flies, quarantine laws that prevent many pest species from being reared in regions where they are classified as being exotic, thereby ruling out many research groups from developing genetically engineered strains of tephritids. Some 9 years after the successful demonstration of *Minos* transposable element-mediated transformation of *C. capitata* by Loukeris *et al*. (1995), the comparison with the rapid spread of *D. melanogaster* transformation protocols through the *Drosophila* community following the publication of this technique in 1982 by Rubin and Spradling (1982) could not be more stark. By 1991, *Drosophila* transformation was a routine technique that permeated *Drosophila* genetics. This has not been achieved as yet with mosquitoes, let alone many tephritids, lepidopterans, or coleopterans.

Another reason concerns the nature of the transposable elements used to transform nondrosophilid species. As mentioned above, the identification of new transposable elements such as *Mos1*, *Minos*, *Hermes*, *piggyBac*, and *Tn5* (Rowan *et al*., 2004), was a major step in achieving genetic transformation of these species. With the exception of *Tn5*, which has been developed as a transformation agent of bacteria, we know little about the genetic and biochemical behavior of these elements, particularly with respect to their behavior in nonhost insect species. Possible problems about deploying transposable elements, and the transgenes contained within them, was forecast by Whitten (1985):

> Thus the selfishness of DNA is clearly subject to rather strict rules of etiquette, presumably imposed by evolutionary constraints on its host. These constraints may force those workers who see practical benefits flowing from the availability of transposable element vectors for genomic modification of particular plants or animals, to tailor a system suited to the special genetic constraints of their particular candidate species.

Recently, the behavior of *Hermes, piggyBac*, and *Mos1* elements in *A. aegypti* was described by O'Brochta *et al.* (2003) while the immobility of *Mos1* in transgenic lines of *A. aegypti* was reported by Wilson *et al.* (2003). These studies reveal that, while these transposable elements can be used to genetically transform this mosquito species, they are then rendered relatively immobile in following generations. Furthermore, the mechanism of *Hermes* element transposition appears to differ between germline nuclei and somatic nuclei of *A. aegypti*. Both mechanisms are transposase dependent, yet cut-and-paste transposition occurs in somatic nuclei while a mechanism that results in the transposition of both the transposable element and flanking sequences occur in the germline. This difference in mechanisms of *Hermes* element transposition has not been seen in any of the higher dipteran species – *D. melanogaster* (O'Brochta *et al*., 1996; Guimond *et al*., 2003), *C. capitata* (Michel *et al*., 2001), and *Stomoxys calcitrans* (Lehane *et al*., 2000) – in which *Hermes* has been used as a gene vector. It is clear we have a very limited knowledge of how any of these transposable elements function either in their original host species, or in species into which they are introduced. This lack of knowledge, combined with the problem of identifying genetic systems they would carry into a population so as to be used in genetic control programs, has contributed to the inability to bring these transgenic-based control programs to fruition. In particular, those who propose transposable element-based strategies for spreading beneficial transgenes through field populations of insects need to take into account that the ability of a given element to transform a species does not necessarily mean that it can also subsequently spread through this same species. That the *P* element of *D. melanogaster* can do this in this species is no guarantee that other elements can also do the same. Kidwell and Ribeiro (1992) specify three critical parameters needed for a transposable element to spread through a population. These are:

- the basic reproductive rate of the insects possessing the transposable element;
- the infectivity of the element (which is a function of its transposition frequency, its ability to undergo replicative transposition, and its propensity to transpose to loci unlinked to the original donor site); and
- the size of the target insect population.

In a subsequent article (Ribeiro and Kidwell, 1994), they proposed seven questions that needed to be resolved if one is to believe that a transposable element can spread genes through an insect population. These are: (1) the instability of chimeric transposable elements containing transgenes, (2) stabilization of these transgenes following their fixation in the target population (if, indeed, this is possible), (3) the biochemical properties of the transposase, (4) the possibility of repression systems becoming active as the copy number of the transposable element increases in the genome, (5) position effects, (6) the promoters chosen to control expression of the transgene, and (7) the length of the chimeric transposable element. It must be emphasized that none of these determines how well a given transposable element will function as a gene vector in achieving transformation in the first place. It is also poignant that we know next to nothing about the answers to any of these questions for the four "new" transposable elements used to transform pest insect species.

5.12.2. The Status of Transgenic-Based Insect Control Programs

What then, is the current status of programs in which transgenic insects have been proposed to utilize transgenic insects? They can be categorized into three broad categories:

1. Those that are designed to impose a genetic load on the target population in order to reduce population size.
2. Those that are designed to only eliminate the pest phenotype of the insects in a receiving population without altering population size.
3. Those that are designed to increase the fitness of biological control agents or increase the production of products excreted by insects, such as honey or silk.

5.12.2.1. Load Imposition on the Target Population

The sterile insect technique is the classic example of controlling insects through the imposition of a genetic load. The method was developed during the 1940s and 1950s and is now a mature and widely accepted method for insect population suppression and, in some cases, eradication. The pest species is mass-reared and irradiated to induce dominant lethal mutations and rearrangements at high frequencies in the germlines of these insects. The mass-reared insects, preferably only males, are released into the receiving, field population where they mate with wild fertile insects. Fertile females mating with released sterile males are nonproductive with a net reproductive rate (R_o) of zero. In many species a small

proportion of the females mate more than once so the net effect on R_o is a function of sperm competitiveness in multiple-mated females. Successive releases in multiple generations continues to drive R_o down until either the population size is below its economic threshold (at which point it does not impact upon the economy of the relevant commodity) or until it is eradicated. The advantages of using this method of control have been discussed elsewhere (Hendrichs, 2000) but clearly rest on the species specificity of the method and its low environmental impact. Nonetheless implementing this "clean" control method faces some constraints including fitness costs associated with the development of specific strains and the effects of mass rearing, radiation, handling, and release on many aspects of field behavior (Robinson and Franz, 2000). Transgenic technology has the potential to positively impact existing SIT programs by improving aspects of insect production and monitoring and also has the potential to increase the use of SIT to include species that have otherwise been intractable to this technology.

Perhaps the biggest impact transgenic insect technology could have on any SIT program is to create strains of insects that permit the removal or elimination of females. The most significant effect that this would have on an SIT program is the reduction of the costs of mass-rearing and release because fewer insects need to be reared and released. In other programs, for example those that might involve vectors of human disease, removal of females prior to release may be essential since females would still be capable of biting and transmitting disease. Transgenic technology offers numerous options for creating strains that permit the selective removal of females prior to release. Conceptually the problem is one of expressing genes in one sex or the other that can be easily selected for or against. Using transgenic technology specificity of expression can be achieved by a variety of ways. First, expression can be controlled through the use of sex-specific promoters in combination with genes resulting in lethality. Sex-specific promoters from the vitellogenin and yolk protein genes have been characterized, and are examples of female-specific promoters that have been tested in transgenic insects with respect to possible applications in insect control programs (Heinrich and Scott, 2000; Kokoza *et al.*, 2000; Thomas *et al.*, 2000). These promoters are active in adult stages and would have limited application in SIT programs. They would not be useful for eliminating females at the larval stage and so any cost savings resulting from rearing both sexes would still be accrued. For eliminating females prior to mass-rearing, the challenge remains to identify promoters or other regulatory sequences that selectively eliminate females during, or immediately following, embryogenesis.

5.12.2.2. Challenges of Long-Term Gene Introduction into Natural Populations

Transgenic strategies relying on load imposition to reduce or eliminate a population involve the short-term introduction of "effector" genes (usually dominant or conditionally dominant lethals) into the gene pool of native populations. As described above for the SIT, approaches relying on inundative releases of nongenetically engineered mass-reared insects carrying dominant lethal mutations have been successful. More subtle approaches have been proposed whereby deleterious genes can be transmitted over the course of a few generations before the load effects are encountered (Schliekelman and Gould, 2000a, 2000b). The most ambitious plans involve the permanent and stable alteration of the genotypes of wild insects. These ideas present enormous and novel challenges to insect geneticists. Introducing new laboratory-produced genotypes into populations is relatively simple (e.g., inundative releases of radiation-sterilized flies), but maintaining those genotypes in the population and, in fact, having them increase in frequency is an unprecedented undertaking in applied insect genetics.

An allele can increase in frequency in populations for a variety of reasons. For example, if there is a fitness advantage associated with a genotype then over time this allele is expected to become more abundant. If selection pressures are sufficiently high then the forces of natural selection can result in relatively rapid changes in allele frequencies. The global spread of insecticide resistance in *Culex* mosquitoes is one of many such examples of selection driven increase in gene frequencies (Raymond, 1991). The fitness costs associated with transgenic mosquitoes are largely unknown and is an area of research in need of attention. A few reports on the ability of transgenics to compete with wild conspecifics or on fitness estimates based on life table analyses, consistently indicate that the process of transgenesis decreases the fitness of the host insect (Catteruccia *et al.*, 2003; Irvin *et al.*, 2004). The sources of these fitness costs have not been precisely determined but are expected to be partitioned between costs associated with inbreeding during the process of creating a transgenic line of insects, transgene expression, and mutagenesis associated with transgene integration. It should be remembered, however, that genetic sexing strains generated through standard Mendelian genetics are less fit than

wild-type strains but are still successfully used in SIT programs. In *Drosophila* it has been estimated that transposing *P* elements results in a 1% reduction in viability per integration event, on average (Eanes *et al*., 1988). Thus, transgene integration is likely to result in fitness costs to the host organism. Expression of transgenes might also have effects on the fitness of the host organism. General costs associated with the metabolic load imposed by transgene expression are expected but have not been specifically measured (Billingsley, 2003). Individual transgenes, including marker genes, which have been generally considered to be "neutral," are likely to have costs associated with their expression. It is reasonable to assume, like others (Tiedje *et al*., 1989) that transgenic insects will be less fit relative to the nontransgenic host insect. Understanding the magnitude of fitness costs associated with transgenesis will permit insect geneticists to allow for any fitness costs in a given experiment. However, given that natural selection is unlikely to favor the increase in frequency of transgenes in populations, insect geneticists are still faced with the problem of driving a deleterious gene into populations quickly and effectively enough to alleviate the problem, economic or medical, caused by the target pest species.

Deleterious genes can be spread through populations by a number of mechanisms. For example, hitchhiking is a genetic phenomenon whereby genes closely linked to a particular gene under positive selection are also selected despite potentially negative fitness costs associated with them. Hitchhiking is a well-established phenomenon and insect geneticists could conceivably exploit it if a gene under strong positive selection could be identified and isolated. An alternative to hitchhiking is to link the deleterious transgene to a genetic element with transmission-skewing properties. Genetic segregation distorter systems and transposable elements have enhanced transmission potential under certain conditions. That is, organisms heterozygous for such elements give rise to a disproportionate number of gametes with the element or gene as compared to what would be expected based on simple Mendelian inheritance. A notable example of a transposable element with the ability to rapidly infiltrate populations of naive insects is the *P* element of *D. melanogaster.* Indeed, the natural history of *P* has been promoted to the status of a paradigm, and optimistic views by some vector biologists about the prospects of driving anti-*Plasmodium* genes into native populations of *Anopheles gambiae*, thereby eliminating malaria transmission, are based on exploiting the anticipated mobility properties of a *P*-like transposable element. It has been implicitly assumed that solution of the gene transformation problem in nondrosophilid insects through the development of transposable element based gene vectors would simultaneously solve the problem of gene drivers. This is an erroneous assumption.

Transposable elements differ in their abilities to spread through populations as illustrated by the differences observed between actively transposing *hobo* and *P* elements in *D. melanogaster.* The dynamics of movement and the final state achieved was element specific. A given element, such as the *P* element, may have drastically different drive potential in one species as compared to another. For example, while *P* elements effectively invade and spread in small laboratory cages of *D. melanogaster* they are relatively ineffective in *D. simulans* (Kimura and Kidwell, 1994).

There are a number of properties of a transposable element that are likely to influence its ability to spread through wild populations and these have already been listed based on previous studies (Kidwell and Ribeiro, 1992; Ribeiro and Kidwell, 1994). If we focus on the mechanism of transposition, then, clearly, activity of an element alone is not sufficient for an element to spread. Spread will require that transposition is associated with replication of the element to insure a net gain in allele frequency. Elements that transpose by a cut-and-paste mechanism are not expected to spread unless they are replicated in association with transposition. Class II transposable elements employ a number of mechanisms by which they can replicate. Element excision leaves a double-stranded break in the host DNA that is highly reactive and can initiate strand invasion and recombination using the sister chromatid as a template. Template-directed gap repair results in a copy of the moving element replacing the copy that has excised as a result of transposition. The frequency with which this type of repair takes place varies from element to element. The timing of transposition during the cell cycle is also a factor. Class II elements can also be replicated during the transposition process by timing their jumps to correspond to S phase of the cell cycle. If an element transposes after it has been replicated and targets an unreplicated region of a chromosome there will be a net gain of one element in the genome of one of the resulting mitotic products. The *Mos1* element of *D. mauritiana* appears to transpose during S phase in transgenic lines of *A. aegypti*; however, the stability of this element in these insects limits its use as a genetic drive mechanism in at least this species (O'Brochta *et al*., 2003). The proximity of the new

insertion sites relative to the donor site is also an important factor in determining the ability of the transposable element to spread. A highly active element that moves only, or even predominately, to tightly linked sites would not be a suitable agent to spread genes through an insect population, while an element with a reduced transposition rate that moved to unlinked loci either on the same or different chromosomes would be a viable spreading agent.

As mentioned above (see Section 5.12.1), at present little or no information exists as to the mobility properties of the four transposable elements used to genetically transform nondrosophilid insect species. Indeed, even for the relatively well-characterized *P* element of *D. melanogaster*, little is known about its mode of movement within and between chromosomes. This element does show a tendency to insert in or near the 5′ ends of genes, perhaps due to a relaxation of the DNA double helix during gene transcription. It has also been suggested that this element recognizes a structural feature at the insertion site rather than a strict canonical motif (Liao *et al*., 2000). This may well be true of other transposable elements and may well be an important factor in determining transposable element spread, but this remains an underexplored area of research.

5.12.2.3. Engineering of Beneficial Insects

Progress in this area has been limited to the stable introduction of genes, using the *piggyBac* transposable element, into the silkworm, *Bombyx mori* (Tamurua *et al*., 2000). Initially these experiments have been proof of principle experiments in which enchanced green fluorescent protein (EGFP) was used as a genetic marker to demonstrate that transformation could be achieved. Recently, Imamura *et al*. (2003) demonstrated that the GAL4/UAS system functions sufficiently in transgenic *B. mori* to enable tissue-specific expression of a reporter gene to occur. Transformation frequencies using the *piggyBac* transposable element as the gene vector were in the order of several percent. These experiments pave the way for gene identification using enhancer trapping in *Bombyx* which will further elevate the use of this species as a model system for other lepidopteran species. The extension of these techniques into practical benefits of silk production remains a challenge. While there have been reports of sperm-mediated transformation of the honeybee, *Apis mellifera* (Robinson *et al*., 2000), this technology has not yet been exploited by the honey industry and, since honey is a food, genetic engineering of its source may encounter public resistance. Similarly, the initial report of genetic transformation of the predatory mite *Metaseiulus occidentalis*, which is used as a biological control agent, has not been pursued in field applications (Presnail and Hoy, 1992).

5.12.3. Conclusion

Genetic transformation technologies have been successfully extended into selected nondrosophilid species using transposable elements. This significant and exciting success has, however, being confined to the laboratory where it has enabled novel genotypes to be constructed and tested. These technologies have yet to be extended to the field, despite many years elapsing since genetic transformation protocols were first established for key pest species such as *C. capitata* and *A. aegypti*. If the full potential and benefits of genetic modification of medically and agriculturally significant insect species is to be realized then there must be a stronger linkage between the formulation of ideas and the subsequent timely and safe testing of these in transgenic insect strains in the laboratory, and in the field. Key to this is improving the robustness of transgenic technology in these insect species. Alternatively, the wisdom of establishing a handful of insect transformation centers that would provide this service to the community needs to be explored. This may be particularly attractive for species, such as *A. gambiae*, that remain difficult to transform. Providing a central transformation center may encourage researchers to develop and test new concepts, confident that at least the transgenic insects containing the desired transgenes will be routinely produced in a timely manner. It is critical to demonstrate in the laboratory and then in field cage experiments clear and concrete examples of how transgenic insect technology is beneficial to the general public so that arguments about the benefits of these new approaches can be clearly made to this interested and undoubtedly concerned audience.

6.1 Pyrethroids

B P S Khambay and P J Jewess, Rothamsted Research, Harpenden, Hertfordshire, UK

6.1.1. Introduction

The introduction of synthetic pyrethroids in the 1970s signalled a new era for environmentally friendly, highly effective and selective insecticides. For example, deltamethrin when introduced was the most effective insecticide on the market, being over 100 times more active than DDT and with the benefit of not accumulating in the environment. More than 30 new pyrethroids, including several new structural types, have been commercialized in the past 20 years (Bryant, 1999; Tomlin, 2000). Despite the evolution of resistance to pyrethroids in many insect pests, pyrethroids continue to be an important class. Part of their success has been due to the implementation of resistance-management strategies and the exploitation of new applications.

Since the previous review in this series (Ruigt, 1985), research activity in the discovery of novel pyrethroids peaked in the early 1990s and has now largely ceased. Major advances have been made in understanding the mode of action, especially by the application of molecular biology techniques (see **Chapter 5.1**), and in the management of resistance in the field. This chapter will review the advances made in these areas with the emphasis on commercial compounds.

6.1.1.1. Pyrethrum Extract

Despite the introduction of a number of other natural insecticides, pyrethrum extract from the flowers of the pyrethrum daisy (*Tanacetum cinerariaefolium* Schulz –Bip.; syns *Chrysanthemum cinerariaefolium* Vis., *Pyrethrum cinerariaefolium* Trevir.) remains commercially the most important, with demand continually outstripping supply. Supplies from Kenya, the major producer, have been irregular for many years. A new pyrethrum industry has been established in Tasmania, Australia, which is currently the second biggest producer and is set to increase further. Their industry was founded on the basis of extensive research leading to the development of plant lines that flower simultaneously, thus allowing mechanical harvesting and thereby a significant saving in labor costs. In addition they produce a very high-quality product by further purification of the hexane extract with a new procedure based on partitioning with liquid carbon dioxide. Major applications of pyrethrum extract continue to center on control of flying insects (e.g., mosquitoes), pre-harvest clean-up, and human- and animal-health pests. With an increasing demand for organically grown produce, use of pyrethrum extract has also increased.

6.1.1.2. Synthetic Pyrethroids

The market share of synthetic pyrethroids remained for many years at around 20–25% of the global insecticide market but in the past few years has declined to around 17%. Cotton remains the biggest market for pyrethroid applications; however, due to resistance build-up, this market has steadily declined from nearly 50% to less than 40% of the total pyrethroid tonnage. With the exception of some Japanese and Chinese companies, most major agrochemical companies ceased research effort in the discovery of novel pyrethroids by the late 1990s.

Since 1985, major advances have been made in identifying novel pyrethroids that have substantially

increased the spectrum of activity to include control of mites, soil pests, rice pests (previously limited by the high fish toxicity of pyrethroids), and newer problem pests such as the cotton (also called the tobacco or sweet-potato) whitefly (*Bemisia tabaci*). In the past decade, commercial effort has been directed at introducing enriched isomer mixtures and the exploitation of niche markets including head-lice, termites, and bednets for the control of mosquitoes. Rather remarkably, sea-lice on salmonid fish are controlled by established pyrethroids (e.g., deltamethrin) which, despite their high fish toxicity, are being used at carefully selected doses. Another area of progress has been the development of novel formulations to extend the utility of established pyrethroids. For example, lambda-cyhalothrin formulated as micro-capsules allows slow release for public-health uses requiring long-term residual effects and when impregnated in plastic films controls termites with minimal operator exposure.

At the commercial level, global sales of pyrethroids in 2002 have been estimated at $1280M. Over 95% of the pyrethroid sales are accounted for by 12 active ingredients, of which deltamethrin continues to be the market leader with >16% share and sales exceeding $200M. Lamda-cyhalothrin is a close second with nearly 16% share; permethrin and cypermethrin account for 14% and 11% respectively, with all other pyrethroids contributing less than 7% each. Notably, although tefluthrin accounts for only 6% of the pyrethroid market, it is one of the most widely used soil insecticides in maize in the USA (Cheung and Sirur, 2002). The biggest concern in the sustained use of pyrethroids is the development of resistance. Though successful integrated pest-management strategies have been utilized, overall levels of resistance have continued to increase steadily. However, a greater understanding of the resistance mechanisms and the development of simple and high-throughput diagnostic procedures have aided the recognition of resistance mechanisms and hence facilitated the management of resistance.

6.1.2. Development of Commercial Pyrethroids

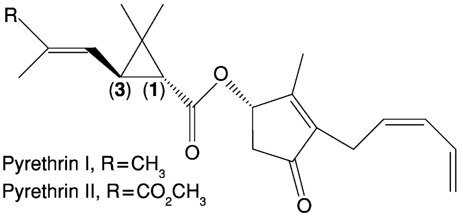
There are several reviews (Elliott, 1977, 1995, 1996; Davies, 1985; Henrick, 1995; Pap *et al*., 1996a; Matsuo and Miyamoto, 1997; Pachlatko, 1998; Bryant, 1999; Katsuda, 1999; Khambay, 2002; Soderlund *et al*., 2002) covering aspects of structure–activity relationships in pyrethroids. To appraise the advances made since 1985, it is useful to recollect the systematic approaches adopted earlier, in particular by Elliott, in the discovery of synthetic pyrethroids (see **Figure 1** for structures). The key to his success was the selection of pyrethrin I (**1**) over pyrethrin II (**2**) as the lead structure and the choice of test species (housefly *Musca domestica* and mustard beetle *Phaedon cochleariae*), which are model insects rather than agricultural pests. Pyrethrin I has superior insecticidal activity to pyrethrin II, though the latter gives better knockdown. This chapter will briefly review the progress in the development of pyrethroids using commercial pyrethroids as examples and for ease of readability these are not cited in chronological order.

Elliott's work culminated in the discovery of bioresmethrin (**3**) in 1967 followed by permethrin (**4**), cypermethrin (**5**), and deltamethrin (**6**) in 1977. These compounds have greater insecticidal activity than pyrethrin I, yet exhibit lower mammalian toxicity (**Table 1**) and initiated a major interest in pyrethroid research in agrochemical companies. These early synthetic compounds still account for a substantial share of the pyrethroid market despite the subsequent introduction of over 30 new pyrethroids. The majority of these compounds are closely related analogs. Replacement of the *E* (but not *Z*) vinyl chloride in cypermethrin with a CF_3 or a 4-chlorophenyl group retains activity and led to the discovery of cyhalothrin (**7**) and flumethrin (**8**), respectively. Both have good acaricidal activity and the latter is especially active against a range of tick species and is extensively used in animal health. Bromination of deltamethrin led to tralomethrin (**9**), a proinsecticide that breaks down to deltamethrin in the insect. Though most of the commercial pyrethroids are based on pyrethrin I, two have been developed using pyrethrin II as the lead structure. Kadethrin (**10**) emulates the high knockdown activity of pyrethrin II but acrinathrin (**11**) is more noted for its high activity against mites, ticks, lepidopteran, and sucking pests.

The other major influence in the development of pyrethroids came with the announcement of fenvalerate (**12**), a compound lacking the cyclopropane moiety. It was announced in 1976 by researchers at Sumitomo, around the same time as those disclosed by Elliott. Subsequently, many analogs were discovered, mainly with different substituents in the acyl moiety, especially at position 4. Examples include flucythrinate (**13**) and its derivative flubrocythrinate (**14**), also referred to as ZXI 8901) (Jin *et al*., 1996) with Br introduced at the 4″ position. Introduction of NH and optimization of substituents in the acyl moiety led to fluvalinate (**15**), which exhibits broad-spectrum insecticidal and miticidal

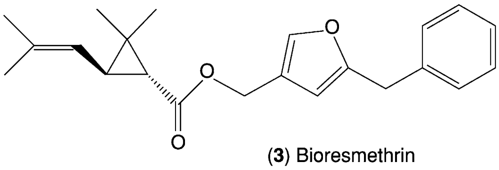
activity. In contrast to most other pyrethroids, it is essentially nontoxic to bees and is used to control mites in honeybee colonies and orchards.

Advances since 1985 in the development of new alcohol moieties have been limited. Recognition of the need for unsaturation in the side chain of the alcohol moiety of pyrethrin I had led to the development of the first commercial synthetic pyrethroid, allethrin (**16**). Substitution of the alkene with an alkyne group resulted in the more active analog prallethrin (**17**). Further systematic development resulted in the discovery of imiprothrin (**18**) and the more volatile, albeit only moderately insecticidal, empenthrin (**19**). The latter has low mammalian toxicity and is used in controlling insects that eat fabrics. Pyrethroids containing fluorinated benzyl alcohol moieties have long been recognized for their high vapor pressure but many exhibit high mammalian toxicity. An exception is transfluthrin (**20**) (acute $LD_{50} > 5000\,mg\,kg^{-1}$ to male rats), containing a tetrafluorobenzyl alcohol moiety, which has only recently been commercialised for domestic use. Although many pyrethroids exhibit high activity in contact assays against soil pests (e.g., the corn rootworm *Diabrotica balteata*), the majority are ineffective under field conditions because they do not possess the required physical properties, especially high volatility (Khambay *et al*., 1999). Tefluthrin (**21**), having a 4-methyltetrafluorobenzyl alcohol moiety, is sufficiently volatile and, despite its relatively high mammalian toxicity (acute LD_{50} $22\,mg\,kg^{-1}$ to male rats), is the only pyrethroid to have been commercialized as a soil insecticide. Two analogs of tefluthrin, metofluthrin (**22**) and profluthrin (**23**), have recently been developed for non-agricultural use by Sumitomo.



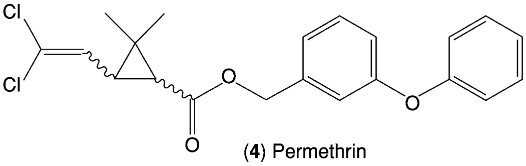
An interesting development has been the replacement of 3-phenoxybenzyl alcohol by 3-phenylbenzyl alcohol, which is sterically more restricted. Activity in this series is enhanced by the introduction of a CH_3 group at position 2 as in bifenthrin (**24**), which forces noncoplanarity of the phenyl rings presumably so matching the conformation of the target site. It has broad-spectrum activity and is particularly effective against some mite species. Although it is has one of the highest levels of mammalian and fish toxicity, it is commercially very successful.

The development of "hybrid" pyrethroids containing structural features both of DDT and of pyrethroids has been discussed previously (Ruigt, 1985). One compound, cycloprothrin (**25**), was eventually commercialized in 1987. Though it is much less insecticidal than deltamethrin, it has lower mammalian and fish toxicity and is therefore used to control pests in a range of applications including paddy rice, vegetables, tea, and cotton.



The most noteworthy advance in the past 20 years has been the discovery of the nonester pyrethroid etofenprox (**26**) in 1986. Further innovations led to silicon (e.g., silafluofen, (**27**)) and tin (e.g., (**28**)) analogs, the latter being nearly ten times more active than the corresponding carbon compounds. It had been a major objective of many researchers to replace the ester linkage in pyrethroids so as to achieve increased metabolic stability. A key feature of the nonester pyrethroids is their low toxicity to fish, and indeed etofenprox is used in rice paddy. However, it may be noted that even ester pyrethroids, despite having high intrinsic toxicity to fish, often manifest lower toxicity in the field than might be expected. This lower toxicity is observed because their concentration in water is limited by very low solubility, together with mitigation by strong sorption into organic matter such as pond sediments and river vegetation. However, the nonester pyrethroids have not yet made a significant commercial impact.

Of the many other variations, introduction of fluorine at the 4-position in the alcohol moiety has been the most significant. In general it leads to an appreciable enhancement of activity, albeit only to some species especially ticks (as in flumethrin (**8**)). Cyfluthrin (cypermethrin with a 4′-F) appears to have been introduced mainly on commercial considerations rather than on the grounds of efficacy. Furthermore, this substitution reduces metabolic attack at the 4′-position, thereby reducing the level of resistance in some insect species.



Commercial effort in the discovery of novel pyrethroids had all but ceased by the late 1990s, although efforts have continued to introduce single- or enriched-isomer mixtures (**Table 2**). Deltamethrin was the first pyrethroid to be commercialized as a single enantiomer by Rousell-Uclaf. This was followed by esfenvalerate (1*S*, α*S* component of fenvalerate) and acrinathrin. A single isomer of cyhalothrin, gamma-cyhalothrin (also called super-cyhalothrin), is currently under development. For cypermethrin, commercial production of a single isomer has not been possible; however, enriched isomer mixtures have been introduced to exploit specific properties and market opportunities. For example, the *trans* isomers of cypermethrin are known to be more readily metabolized in mammals than the *cis* isomers. Thus theta-cypermethrin, containing only the *trans* isomers, has a much higher safety margin than cypermethrin and, in addition to its use in agriculture, also has uses in veterinary and public health. Prallethrin also has potentially

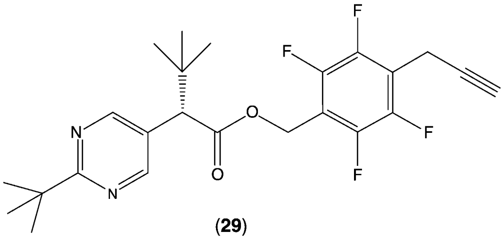
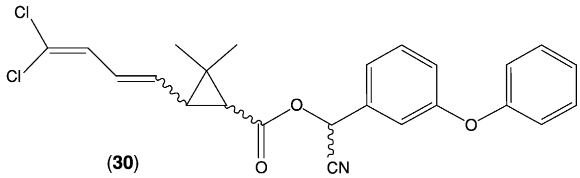
eight isomers but is sold as a mixture of two active *cis*/*trans* isomers, each with the 1*R* center at C1 and α*S* in the alcohol moiety.



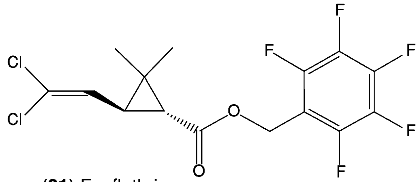
6.1.3. Structure–Activity Relationships in Pyrethroids

As described above, pyrethroids form a diverse class of insecticides highly effective against a broad spectrum of insect and acarine pests. The level of activity is determined by penetration, metabolism within the insect, and the requirements at the target site. As an illustration (see Figure 2 for structures), pyrethrin I has good activity against houseflies but poor activity against mites, whereas an experimental compound (**29**) has very high miticidal but poor insecticidal activity. Despite this diversity, it is possible to make some generalizations regarding structural requirements for high activity in pyrethroids. The seven-segment model (Figure 3) based on pyrethrin I, the lead structure originally adopted by Elliott (Elliott and Janes, 1978), serves as a good model to illustrate these general requirements and exceptions to them.



Segment A: Unsaturation generally leads to high activity. However, exceptions are known; for example fenpropathrin (**41**), containing the tetramethylcyclopropane acyl moiety (lacking in unsaturation), has high insecticidal and acaricidal activity. In general, large variations (steric and electronic) can be tolerated in this region. For example, (**30**) has an extended side-chain compared with cypermethrin and yet their activity is similar; flumethrin (**8**), possessing a bulky aromatic substituent, is highly active towards ticks.

Segment A + B: In ester pyrethroids, the gem-dimethyl group or its steric equivalent must be beta to the ester group. The required geometrical stereochemistry (*cis*/*trans*) across the cyclopropane ring (segment B) is influenced by the nature of the alcohol moiety, substituent at C3 and test species. In general, 1*R*-*trans*-chrysanthemates (as in bioresmethrin) are more active then the corresponding *cis* isomers. The vinyl dihalo substituents are generally more effective than the chrysanthemates; however, the relative activity of the *cis* and *trans* isomers varies considerably. For alcohols containing two rings (e.g., 3-phenoxybenzyl alcohol as in deltamethrin), the 1*R*-*cis* isomers are generally more active than the *trans* isomers, but with alcohol moieties that contain a single ring (e.g., pentafluorobenzyl as in fenfluthrin (**31**) and cyclopentenone as in allethrin) the converse is true, with the *trans* isomers being more active.



In pyrethrin II, the vinyl carbomethoxy group in the acid moiety has the *E* configuration. Its corresponding analogs, *cis* and *trans* esters of α-cyano-3-phenoxybenzyl alcohol, are equally active; the *Z* isomer of the nor homolog (e.g., (**32**)) of the *cis* (but not the *trans*) isomer was unexpectedly much more active. Acrinathrin incorporates these two features and, although only half as active as deltamethrin against houseflies, it is more active towards some species of mites, ticks, lepidopteran insects, and sucking pests. Furthermore, stereochemistry also influences species selectivity of pyrethroids, a process primarily determined by selective metabolism. For example, contrary to the above generalization for pyrethroids containing 3-phenoxybenzyl

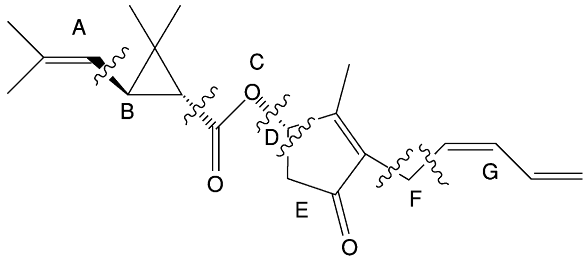

Figure 3 Schematic breakdown of the pyrethrin I molecule into seven segments.

alcohol, theta-cypermethrin (*trans* isomers) controls lepidopteran pests more effectively than α-cypermethrin (*cis* isomers), whereas the converse is true for dipterans.

When present, correct chirality at C1 of the acyl moiety (segment B) is crucial for activity. For both the esters of cyclopropane acids and for the fenvalerate series, activity requires the same spatial configuration at C1 (note that this is designated by *R* in the former and *S* in the latter by the nomenclature rules). Flufenprox (**33**), with an *R* configuration at C1, appears to contradict this generalization but apparently it is more similar to esfenvalerate than its corresponding *S* isomer.

Segment C: The ester linkage can be replaced by an isosteric group. However, changes are directly affected by the nature of segment B. For the cyclopropane esters, all isosteric replacements of the ester linkage substantially reduce activity. However, in the fenvalerate series, it can be replaced with retention of activity, for example (**34**) in which a ketoxime group replaces the ester linkage. The first such non-ester pyrethroid to be commercialized was etofenprox (**26**). Successful replacement of the ester group by an ether linkage was found to be largely dependent on the spatial arrangement of the gem-dimethyl group. In addition, the gem-dimethyl group could be replaced by cyclopropane and the ether link by other isosteric groups such as alkyl (MTI 800, (**35**)) and alkenyl (e.g., NRDC 199 (**36**) and NRDC 201 (**37**)). A subsequent important observation was that, in contrast to fenvalerate, replacement of the dimethyl with a cyclopropyl group in the nonester analogs (as in protrifenbute, (**38**)) resulted in a substantial (almost ×100) increase in activity.

Segments D and E: The carbon joined to the ester oxygen must be sp3 hybridized, with at least one proton attached to it and linked to an unsaturated center (e.g., an alkene). This can be a cyclic moiety (as in pyrethrin I) or substituted aromatic (as in permethrin). In the latter, introduction of an α-cyano group (e.g., deltamethrin) enhances activity only with benzyl alcohols with a 3-phenoxy or an equivalent cyclic substituent (e.g., 3-benzyl and 3-benzoyl). With other alcohols containing cyclic moieties (e.g., 5-benzyl-3-furylmethyl alcohol as in bioresmethrin and 3-phenyl as in bifenthrin), it reduces activity. With a single cyclic moiety (e.g., NRDC 196, (**39**)) containing an acyclic substituent, introduction of an α-cyano group has a negligible effect on activity. However, in the absence of a side-chain, introduction of a cyano group in such compounds leads to loss of activity (e.g., as with tefluthrin (**21**)). An ethynyl group is generally less effective, though in empenthrin it is more effective than a cyano group.

The chirality at the oxygenated carbon of the alcohol moiety (the α carbon) is also important for activity but, in contrast to the strict requirement at C1 of the acyl moiety, the required chirality appears to depend on the structure of the alcohol. For example, the orientation conferring high activity in the cyclopentanone (as in pyrethrin I) and acyclic (as in empenthrin) alcohol moieties is the opposite to that for the α-cyano-3-phenoxybenzyl alcohols (as in deltamethrin). Furthermore, the difference in the level of activity between the epimers at this center is much larger for the latter (see below). In addition, selectivity in pyrethroids between insect species can be due to selective metabolic processes. A good illustration is an elegant investigation by Pap *et al.* (1996b). They investigated the insecticidal activity of three structurally related series of pyrethroids (phenothrin (**40**), permethrin (**4**), and cypermethrin (**5**)) toward six insect species. The chirality requirement at C1 was as indicated above, and, as expected at the α-cyano center, the *S* isomer was more effective than *R* in all species; however, in the presence of metabolic inhibitors, the *R* isomer had comparable activity to the *S* towards mosquitoes but not the other species. Against houseflies, permethrin and phenothrin were less active than the corresponding α-cyano analogs. However, in the presence of the synergist piperonyl butoxide (PBO), the difference in the levels of activity was much lower. Both examples demonstrate that the α*R* isomer is more sensitive to metabolism and that in mosquitoes, but not the other species, unexpectedly binds to the sodium channel receptor in a comparable manner to the *S* isomer.

Segment F: The CH_2 group can be replaced by an oxygen or sulfur atom, or by an isosterically equivalent group such as carbonyl, with retention of variable levels of activity. In the case of benzyl alcohols, both cyclic and acyclic substituents can be attached either at position 3 or 4. However, cyclic substituents such as 3-phenoxybenzyl in the

4-position result in almost complete loss of activity, though a subsequent introduction of an α-cyano group enhances activity only for 3-substituted benzyl alcohols.

Segment G: Unsaturation in this region was initially considered essential for high activity. However, subsequent developments have indicated anomalies. Replacement of the diene in pyrethrin I with an alkene had led to the discovery of allethrin, the first synthetic pyrethroid to be commercialized. Although against houseflies it was as effective as pyrethrin I, it was significantly less effective against a range of other insect species. Indeed, this was the key observation made by Elliott that led to the development of bioresmethrin. However, since then many other highly effective alcohols have been discovered that contain unsaturated acyclic side-chains e.g., prallethrin and imiprothrin, both containing an alkynyl group. Two commercial compounds, transfluthrin (**20**) and empenthrin (**19**), both devoid of a side-chain, appear to contradict this generalization.

There are constraints in the overall shape, size, and the relative positioning of the various structural features within the pyrethroid molecule. Thus, despite the general belief, it is clear that the requirements for overall size are not stringent, though the alcohol moiety is limited to an overall size of no more than two benzene rings. The acid moiety can be varied substantially with retention of activity, for example flumethrin (**8**), fenpropathrin (**41**), and compound (**42**). In addition, although some of the regions of pyrethroid molecules can be varied independently of others, many require simultaneous modifications in adjacent regions (e.g., as in nonester pyrethroids). With regard to the relative positioning of the segments, compound (**43**), despite having the correct overall size, is nontoxic; this indicates that the relative positioning of the unsaturated center in the alcohol moiety to the ester linkage is crucial for activity. Thus, overall shape and size are both important for activity in pyrethroids.

Selectivity of pyrethroids is influenced by several factors, including rate of penetration, susceptibility to detoxification, and potency at the site of action. Finally, synergism in pyrethroids has been reported for a combination of active and inactive isomers, and between two structurally different pyrethroids (e.g., bioallethrin and bioresmethrin). Synergy is also known to arise with other classes of insecticides (e.g., organophosphates) that inhibit metabolic degradation (Naumann, 1990; Katsuda, 1999).

Quantitative structure–activity relationships (QSAR), using both *in vivo* and *in vitro* bioassay data with a range of pyrethroids, have been extensively investigated to gain a better understanding of structural/physical requirements for transport and binding of pyrethroids at the site of action (Ford *et al*., 1989; Ford and Livingstone, 1990; Hudson *et al*., 1992; Mathew *et al*., 1996; Chuman *et al*., 2000b). The most comprehensive QSAR studies with pyrethroids have been undertaken over the past 20 years by researchers at Kyoto University and collaborators (Nishimura *et al*., 1988, 1994; Matsuda *et al*., 1995; Nishimura and Okimoto, 1997, 2001; Akamatsu, 2002). For example, early studies (Nishimura *et al*., 1988 and references therein), using benzyl chrysanthemates and bioassays with the American cockroach *Periplaneta americana*, indicated that knockdown activity was strongly correlated with steric bulkiness (Van der Waals' volume) and both the hydrophobicity and position of substitution in the benzyl alcohol moiety. Thus, for *meta*-substituted derivatives, both hydrophobicity and steric factors were important, but for *para*-substituents activity varied parabolically with substituent volume. Both the rate of development of intoxication and the potency of the symptoms directly influenced knockdown activity and were dependent primarily on the pharmacokinetics of the transport process.

More recently, a direct relationship between changes in membrane potentials and physical properties of pyrethroids has been established (Matsuda *et al*., 1995). Using a diverse set of 39 ester pyrethroids, incorporating nine types of acyl and five types of alcohol moieties, they found a parabolic relationship between membrane potentials in crayfish (*Procambarus clarkii*) giant axons and the hydrophobicity of the compounds tested. They concluded that nonspecific penetration from outside the nerve membrane to the target site was the major factor influencing the rate of development of knockdown effects. The optimum lipophilicity for knockdown effect was calculated to be log K_{ow} 5.4 (where K_{ow} is the partition coefficient between 1-octanol/water). This was slightly higher than predicted values of about log K_{ow} 4.5 (Briggs *et al*., 1976; Kobayashi *et al*., 1988), indicating that other factors may also influence *in vivo* activity. Hence, less lipophilic pyrethroids can still exhibit high knockdown activity. Of particular note is imiprothrin, which gives high knockdown though having an exceptionally low log K_{ow} of 2.9. Interestingly, compounds of such low lipophilicity are expected to exhibit systemic movement in plants, though such activity has not been reported in pyrethroids. Given the complexity of structure–activity relationships in pyrethroids, it is not surprising that such QSAR studies have not led to the new commercial compounds.

It should be noted that commercial pyrethroids can exhibit significant phytotoxicity which can limit their application. For example, deltamethrin is too phytotoxic to be used on Sitka spruce (*Picea sitchensis*) transplants to control the large pine weevil (*Hylobius abietis*), and black pine beetles (*Hylastes* spp). Permethrin exhibits little phytotoxicity and cypermethrin is intermediate between the two (Straw *et al.*, 1996).

6.1.4. Mode of Action of Pyrethroids

6.1.4.1. Classification of Pyrethroids

Pyrethroids, which comprise a diverse range of structures, have historically been classified into two broad groups (Type I and Type II) on the basis of their biological responses (Table 3). Interpretation of most mode of action studies on insects has been predicated on this classification, though this is now considered to be an overly simplistic approach.

The two types of symptoms have been associated with the absence (Type I) or presence (Type II) of an α-cyano group. For example, permethrin exhibits Type I behavior; introduction of an α-cyano group gives cypermethrin which shows Type II behavior. This modification is accompanied by an increase in activity of an order of magnitude, and indeed all commercial Type II compounds have an α-cyano group in conjunction with a 3-phenoxybenzyl alcohol moiety. However, introduction of an α-cyano group does not always lead to an increase in activity. For example, in bioresmethrin it leads to a loss in activity and in NRDC 196 activity is only marginally increased. Furthermore, the level of activity is influenced by the choice of test species. Thus classification as Type I or II cannot be based solely on the presence/absence of an α-cyano group. It is most likely that Type I and Type II represent the extremes of a continuum, with many pyrethroids exhibiting intermediate properties.

Despite the uncertainty over such a classification, it has been suggested (Soderlund *et al.*, 2002; Vais *et al.*, 2003) that, on the basis of electrophysiological properties, there are two distinct binding sites for pyrethroids on the sodium channel. However, this would not explain why some pyrethroids (e.g., fluvalinate and bifenthrin, respectively with and without an α-cyano group) appear to manifest intermediate responses in insects, which behavior might indicate the presence of only a single binding site. The most likely explanation for the differential responses of Type I and Type II pyrethroids in *in vitro* assays lies in the occurrence of pharmacologically different voltage-gated sodium channels in insects (see below).

6.1.4.2. Site of Action

Pyrethroids are recognized for their rapid knockdown action on insects but are generally poor at killing them, a fact not fully appreciated for many years. Measurements of LD_{50} are usually made 24 and 48 h after treatment, at which times paralyzed insects are regarded as dead. However, insects often recover fully, even at higher doses (e.g., $5 \times LD_{50}$) (Bloomquist and Miller, 1985), over the following few days. In practice, such long-term recovery does not limit pyrethroid efficacy in the field, as death occurs by secondary processes including desiccation and predation.

Pyrethroids are nerve poisons that disrupt nerve conduction in both invertebrates and vertebrates

Table 3 Classification of pyrethroids

Response/action	*Type I*	*Type II*
Poisoning symptoms	• Rapid onset of symptoms even at sublethal levels • Hyperactivity often leading to knockdown • Low kill with high recovery • Inversely related to changes in temperature	• Slow onset of symptoms • Convulsion followed by paralysis • High kill with low recovery • Little effect of temperature change
Electrophysiological response in nerve tissue	• Repetitive discharges in axons	• Blockage of conduction at synapses
Action on sodium-channel function	• Monophasic and rapid decay of tail currents • Bind preferentially to closed channels	• Biphasic and very slow decay of tail currents • Bind preferentially to open channels
Level of resistance due to resistant houseflies with *super-kdr* mechanism	• Below 100-fold	• Over 200-fold

and their primary site of action is the voltage-gated sodium channels. However, there is controversy regarding the precise mode of action of pyrethroids and their binding site on the sodium channels (see **Chapter 5.1**).

Much of the work on the mode of action was reported during the 1980s but investigations on sodium channels have continued and a great deal of progress made. Many *in vitro* and *in vivo* investigations on mode of action and metabolism have been carried out on mammalian systems because of the interest in toxicology of these pesticides to mammals including humans and the expertise present in many laboratories for electrophysiology on mammalian neurons and muscles. Experiments have also used model systems such as squid and crustacean giant nerve fibers because of their large size and robustness. However, such studies may not be relevant to insects since there is considerable variation, not only in the metabolic capacities but also in the amino-acid sequences of the sodium channel proteins and thus their pharmacological properties. Another complication is that, in mammals, several genes express different sodium-channel isoforms, which exhibit differential responses to the two types of pyrethroids (Tatebayashi and Narahashi, 1994; Soderlund *et al*., 2002). Furthermore, each gene can express channels (splice variants) with varying pharmacological and biophysical properties (Tan *et al*., 2002). In insects, the voltage-gated sodium channels are encoded by only a single gene, which can also express splice-variants. Such channels, though having a common binding site, might nevertheless exhibit differences in their responses to pyrethroids. Such differences have been demonstrated in mammals but not yet in insects, though there is ample indirect evidence for this (see below).

These different factors give rise to the complex nature of pyrethroid action and therefore difficulty in defining in detail the mode of action. Early investigations into their mode of action were conducted on insect and mammalian nerve preparations but the interpretation of these measurements is somewhat controversial. Broad agreement has only been possible with measurements from sodium channels (see below) (Soderlund *et al*., 2002). Thus the summary presented below is a brief personal overview of the area.

6.1.4.2.1. Investigations based on nerve preparations Of the various symptoms induced by pyrethroids (hyperactivity, tremors, incoordination, convulsions followed by paralysis and death), only the initial toxicity symptoms can be linked to neurophysiological measurements and then only for Type I pyrethroids. They induce repetitive firing (short bursts of less than 5 s duration) in axonal nerve preparation in the sensory nerves accompanied by occasional large bursts of action potential in the ganglia (Nakagawa *et al*., 1982; Narahashi, 2002; Soderlund *et al*., 2002). Repetitive firing has been correlated to hyperactivity and uncoordinated movements leading to rapid knockdown in insects. This is also thought to stimulate the neurosecretory system causing an excessive release of diuretic hormones which eventually results in the disruption of the overall metabolic system in insects (Naumann, 1990 and references therein). The initial symptoms are manifested at very low concentrations ($0.1–0.001 \times LD_{50}$), it being estimated that less than 1% of the sodium channels need to be modified to induce repetitive firing (Song and Narahashi, 1996). In contrast, Type II pyrethroids, even at rather high concentrations, initially cause much less visible activity in insects, convulsions and rapid paralysis being the main symptoms. They cause slow depolarization of nerve membranes leading to block of nerve conduction. The concentration required ultimately to kill insects is much lower for Type II than for Type I compounds.

In general, Type I compounds have been viewed as more active than Type II in producing both visible symptoms and repetitive discharges in the peripheral nerves, though exceptions are known, especially when considering results from noninsect nerve preparations. For example, repetitive firing has been observed for both Type I and Type II pyrethroids in frog-nerve preparations (Vijverberg *et al*., 1986).

The first claimed correlation between a neurophysiological response and the poisoning action of pyrethroids related to the increased production of miniature excitatory postsynaptic potentials (MEPSPs) in response to depolarization of the nerve terminal caused by both Type I and Type II compounds (Salgado *et al*., 1983a, 1983b; Miller, 1998). This increase in MEPSPs results in depletion of neurotransmitter at the nerve-muscle synapses leading to nerve depolarization (paralysis) and also blockage of flight reflex responses. At low threshold concentrations, Type I pyrethroids induce repetitive firing and hyperactivity but not neurotransmitter release so that these processes are not linked to the toxic action of pyrethroids. These observations thus accounted for the apparent contradiction that though initial symptoms of Type I pyrethroids are positively correlated with temperature, the toxic action (release of neurotransmitter and conduction block) is negatively correlated with temperature. At high concentrations, Type I pyrethroids behave similarly to Type II pyrethroids and elicit toxic

symptoms in insects with neurotransmitter release and neuromuscular block. Thus, Type I pyrethroids affect the overall sensory nervous system but Type IIs affect only a specific part. This was elegantly demonstrated by Salgado *et al.* (1983a, 1983b), who showed that deltamethrin applied to the abdomen of houseflies took over an hour to reach the CNS, so that that the knockdown effect seen within 20 min could only be attributed to its action at the peripheral nervous system. Moreover, flies that had been knocked down by deltamethrin were able to fly when thrown in the air because communication along the CNS between the brain and the flight system had not yet been disrupted. In contrast, flies knocked down by Type I pyrethroids cannot fly when thrown in the air, indicating transmission block at the motor neurons. This effect can be reversed by increasing the temperature with Type I pyrethroids but not for Type II, in line with the observed *in vivo* toxicity symptoms.

6.1.4.2.2. Investigations based on sodium channels The most significant advances since 1985 in understanding pyrethroid action have been made by the application of molecular biological approaches to the functioning of voltage-gated channels (for a detailed review of this aspect, see **Chapter 5.1**). The ability to introduce specific mutations in the voltage-sensitive channels and to measure inter- and intra-cellular changes (by voltage- and patch-clamp experiments) has provided conclusive evidence that the primary target sites for pyrethroids are the voltage-gated sodium channels. In summary, pyrethroids interact with the voltage-gated sodium channels to produce tail currents, which can be used to quantify the potency of the insecticides, higher tail-current being associated with higher insecticidal activity (Nishimura and Okimoto, 2001). This action appears to account for symptoms of pyrethroid poisoning and actions on the peripheral and central neurons. The prolongation of these tail-currents is much longer and the effect is less reversible for Type II pyrethroids than Type I. The presumption that Type I and Type II pyrethroids represent the extremes of a continuum is supported by the observation that many pyrethroids exhibit an intermediate response. Thus, deltamethrin (Type II) and permethrin (Type I) exhibit Hill slopes (an indicator of the molar binding ratio) of $\sim$2 and $\sim$1, respectively but bifenthrin exhibits an intermediate slope of $\sim$1.4 (Khambay *et al.*, 2002). Finally, the link between single point mutations in sodium channels and resistance in insects has provided the most conclusive evidence that the voltage-gated sodium channels are the primary target for pyrethroids.

Other measurements on single sodium channels that confirm their being the primary target for pyrethroids include the negative temperature coefficient with toxicity being paralleled by a negative temperature dependence of channel depolarization. Furthermore, hyperactivity induced by Type I pyrethroids can be explained by the tail currents exceeding a certain threshold that then triggers repetitive firing and hyperactivity. Interestingly, it has recently (Motomura and Narahashi, 2001) been demonstrated that tetramethrin (**44**) (Type I) displaces fenvalerate (Type II) from mammalian sodium channels, implying that the former has a higher binding affinity. Also, tetramethrin displaces deltamethrin in single-channel studies. At first sight, this observation appears contradictory in that Type II pyrethroids are significantly more toxic than Type I pyrethroids in insects. However, the explanation may lie in the differences between sodium channels from insects and mammals.

6.1.4.3. Modeling Studies on Prediction of Putative Pharmacophores

Sodium channels are lipid-bound trans-membrane proteins and consequently it is difficult to obtain their crystal structure, especially with bound ligands. However, a recent publication (Jiang *et al.*, 2003) of the crystal structure of the voltage-gated potassium channel should aid progress. Indirect techniques involving binding of pyrethroids to the channel protein (e.g., with photo-reactive and radio-labelled pyrethroids) have been unsuccessful, primarily due to nonspecific binding to the channel and adjacent protein. Given these limitations, effort has been directed at modeling studies.

The "bioactive" conformation has been defined as that most probable at the binding site, and which is energetically stable and three-dimensionally similar to other compounds acting at the same site. Although ester pyrethroids such as deltamethrin have seven torsional axes, most conformational studies have focused on three axes (T2, T3, and T4 in **Figure 4**) around the ester linkage. Most studies have investigated common conformations of minimum energy and correlated them with toxicity/knockdown, overall electronic effects, geometric bulk, and partitioning coefficients (Naumann, 1990 and references therein; Chuman *et al.*, 2000a, 2000b). A "folded" form (**Figure 4**), also referred to as the "clamp" and "horseshoe", was identified as the active conformation.

As an example of the approaches used, Chuman *et al.* (2000a, 2000b) chose the nonester pyrethroid MTI 800 (representative of the most flexible series of pyrethroids) to identify the possible conformers. By comparison, they then deduced the likely

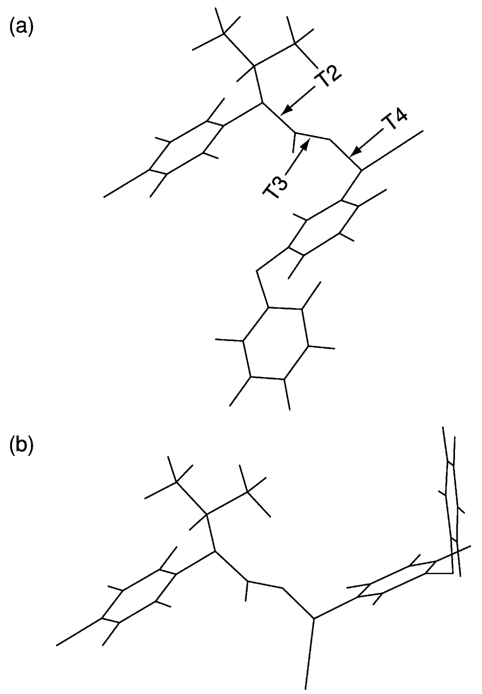

Figure 4 Folded and extended conformations of fenvalerate.

common conformations (within 10 kcal/mol of the ground energy) for the active isomers of pyrethrin I, deltamethrin, and fenvalerate (representatives of each of the three other main series of pyrethroids). To define the bioactive conformer, they also considered a further seven pyrethroid structures, both active and inactive. Similarity/dissimilarity searches using Cosine and Tanimoto coefficients together with superimposition considerations indicated the folded form as the common bioactive conformation for all four types of pyrethroids.

For deltamethrin (a cyclopropane ester), this bioactive folded conformation is close to minimum energy, and is similar to that both of the crystal structure and as observed in solution by NMR (under certain conditions). However, for fenvalerate (not containing a cyclopropane acid moiety), the extended form (**Figure 4**) has lower minimum energy than the bioactive folded conformation.

However, another recent study appears to contradict the above findings. Using new computational methodologies based on cluster analysis of molecular dynamics trajectories, Ford *et al.* (2002) proposed an "extended" conformation for the lethal action of both Type I and Type II pyrethroids, which would also account for the negative temperature coefficient. For knockdown activity (Type I compounds only), he proposed a different higher-energy conformation which is not accessible to Type II pyrethroids. Not being a minimum-energy conformation, this would be transient in nature, and would occur with a higher probability at elevated temperatures (i.e., positive temperature correlation with knockdown activity). Once again the key torsion angles, T2 and T4, lie around the ester bond, T3 being invariant throughout the dynamics simulations undertaken in this study.

6.1.5. Resistance to Pyrethroids

Under selection from repeated sprays of insecticides, individuals possessing biochemical mechanisms that can detoxify the insecticide more rapidly or are less sensitive to it are likely to be favoured. These resistant insects survive doses that would kill normally sensitive individuals. Genes encoding these mechanisms will then be passed on to the succeeding generations, resulting in pest populations that are not controlled effectively. This can lead to farmers increasing the rate or frequency of applications, imposing further selection pressure and ultimately leading to a situation whereby the pests become totally immune. Removal of selection pressure may result in the pest populations regaining some degree of sensitivity, particularly if there is a fitness cost to resistance such as longer development times or reduced over-wintering ability. Usually, however, the population never regains the degree of sensitivity of the naïve population, and often there appears to be little fitness cost so that high numbers of resistant pests remain in the population. Pesticide resistance has occurred with all insecticides; the existence of resistance mechanisms common to pyrethroids and other older insecticides meant that onset of resistance to the new compounds was quite rapid.

Many factors, in particular the type of crop and the history of insecticide use, can affect the selection and dominance of resistance mechanism(s) within an insect species. In addition, the relative importance of these mechanisms can change over time (Gunning *et al.*, 1991). Thus, management of resistance requires knowledge of the mechanism(s) present and ideally also their relative contribution. Though the nature of the resistance mechanisms can be identified relatively straightforwardly, there are, as yet, no established methods for predicting their relative importance in field strains of resistant insects. Such prediction requires a multidisciplinary approach based on both *in vivo* and *in vitro* assays. The concept of using novel selective inhibitors, designed using structure–activity investigations and ideally devoid of insecticidal activity, could prove particularly useful in determining the biochemical mechanism(s) responsible for resistance. The design of such inhibitors will need to take into consideration the variations in specificities of

metabolic enzymes amongst insect species. A greater input from chemists would be a key factor in such investigations.

There are three main mechanisms by which insects become less sensitive to pesticides: increased detoxification ("metabolic resistance"), reduced penetration, and target-site resistance. For many pests, the most important resistance mechanism for pyrethroids is considered to be site insensitivity, often referred to as knockdown resistance (*kdr*), caused by the inheritance of point mutations in the *para*-type sodium channel which is the target-site of the pyrethroids. The principal mechanisms of detoxification are esteratic cleavage of the ester bond and oxidative mechanisms catalysed by cytochrome P450. The other common mechanism of xenobiotic detoxification, dealkylation catalysed by glutathione-*S*-transferases (GSTs), is of lesser importance. Also, reduction in cuticular penetration and/or increased excretion has long been recognized as a resistance mechanism, though its contribution is likely to be as a modifier of metabolic or target-site resistance rather than as a major mechanism in its own right.

Advances in molecular techniques have led to the development of simple and efficient diagnostic kits for the detection of *kdr* resistance. Only a limited amount of work has been done to develop tests for resistance caused by metabolic enzyme(s), for which synergists are commonly used to detect their presence. The biggest problem currently is that the established inhibitors (e.g., piperonyl butoxide, PBO) are not specific and thus may give unreliable results. For example, PBO has been shown to inhibit both cytochrome P450 monooxygenases and esterases in Australian *H. armigera* (Gunning *et al*., 1998a).

When present, the site-insensitivity (*kdr* and especially *super-kdr*) mechanisms often predominate, although populations of pests frequently have multiple resistance mechanisms. The situation regarding the two principal metabolic mechanisms is much less clear and the relative importance of esterase or oxidative mechanisms may vary between species or even between populations of the same species.

Details of the resistance mechanisms and their management in the field are discussed in the following sections.

6.1.5.1. Resistance Mechanisms

6.1.5.1.1. Metabolic resistance

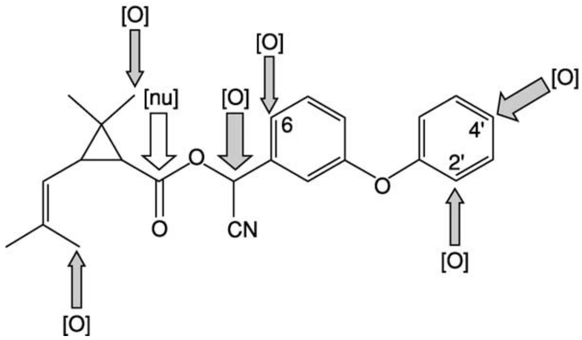
6.1.5.1.1.1. Metabolism of pyrethroids in insects

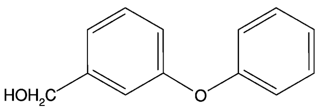
The principal metabolic pathways by which pyrethroids are degraded in insects were mostly evaluated prior to 1985 and are summarized in Roberts and Hutson (1999). Metabolism is conveniently divided into two phases: the initial biotransformation of a pesticide is referred to as Phase I metabolism, comprising mainly oxidative, reductive, and hydrolytic processes; Phase II metabolism is biotransformation, in which the pesticide or Phase I metabolite is conjugated with a naturally occurring compound such as a sugar, sugar acid, glutathione, or an amino acid. In general, the major Phase I degradative routes in insects and other animals (mostly mammals and birds) are similar. It is only in the details of their Phase II reactions whereby polar conjugates with sugars or amino acids are formed that there are major qualitative differences in the nature of the metabolites. As degradation studies on insects are not required for the registration of insecticides, such studies are usually only undertaken in order to understand specific questions concerning structure–activity relationships or to evaluate problems associated with resistance caused by enhanced metabolic breakdown. It is the latter reason that has seen the majority of insect metabolism studies performed.

Since 1985 there has been a vast increase in the knowledge of insect molecular genetics. The publication of the draft genome sequences for the fruit fly *Drosophila melanogaster* in 2000 and the mosquito *Anopheles gambiae* in 2002 has greatly increased the knowledge of the enzymes involved in metabolic degradation, particularly cytochromes P450. Consequently, recent research is beginning to make inroads into understanding which of the isozymes of cytochrome P450 are responsible for metabolizing different substructures of the pyrethroid molecule. The situation with respect to the nature of the carboxyesterases responsible for catalysing the hydrolysis of the pyrethroid ester bond is less clear and the carboxyesterases that catalyze the hydrolysis of pyrethroids in different species of insects may be different and nonhomologous.

Insects detoxify pyrethroids at varying rates and this degradative metabolism is important in understanding the detailed toxicology. Indeed, part of the relatively modest insecticidal activity of the natural pyrethrins is attributable to their rapid metabolic breakdown. Consequently, household sprays are usually formulated with synergists that inhibit the enzymes that catalyze this metabolic degradation and thereby enhance the insecticidal activity. Selection of insect strains possessing elevated levels of catabolizing enzymes is also an important mechanism in the development of decreased sensitivity (resistance) toward pyrethroids. There are two principal routes of detoxification of pyrethroids in insects: de-esterification catalysed by both esterases and cytochromes P450, and the hydroxylation of

aromatic rings or methyl groups by cytochromes P450, and these two mechanisms will be considered separately. The points of the chemical structure where a generalized 3-phenoxybenzyl pyrethroid molecule is detoxified are shown in Figure 5. The width of the arrow indicates the approximate extent of metabolic attack. It is in the detailed enzymology and molecular biology of the enzymes responsible for pyrethroid metabolism where there have been the most important advances.





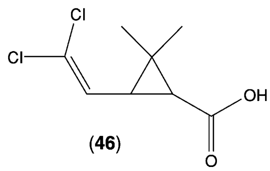


Figure 5 Points of metabolic attack in a generalized pyrethroid structure.

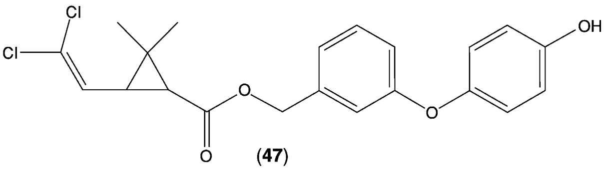

6.1.5.1.1.2. Metabolic pathways The most complete analysis of the metabolic pathways of pyrethroid degradation in insects has been by Shono (Shono *et al.*, 1978; reviewed by Soderlund *et al.*, 1983), who studied the metabolism of permethrin in American cockroaches (*Periplaneta americana*), houseflies (*Musca domestica*), and caterpillars (*Trichoplusia ni*). Forty-two metabolites (including conjugates) were identified, and the most important Phase 1 metabolites are shown in Figure 6. Metabolism occurred by ester cleavage to 3-phenoxybenzyl

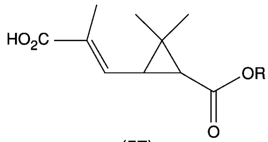
alcohol (3-PBA) (**45**) and 3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropanecarboxylic acid (DCVA) (**46**). Hydroxylation also occurred at the 4′- and 6-positions of the phenoxybenzyl moiety and the *cis* or *trans* methyl groups of the DCVA moiety to give (**47**), (**48**), and (**49**) respectively. Hydroxylation of the *trans*-methyl group rather than the *cis*- was preferred. Ester cleavage of these hydroxylated metabolites gave the structures (**50**), (**51**), and (**52**) respectively. 3-PBA (**50**) was further oxidized to 3-phenoxybenzoic acid (**53**), as were the hydroxylated analogs of 3-PBA to their analogous benzoic acids.

A similar pattern of Phase I metabolites was observed with both *cis*- and *trans*-permethrin, although the relative proportion of certain of the conjugated structures was influenced by the stereochemistry. All metabolites found in the cockroach were also found in houseflies but the series of metabolites arising from the 6-hydroxylation of the 3-PBA moiety was only found in flies. Metabolites consisting of the whole hydroxylated molecule (e.g., (**47**), (**48**), and (**49**)) were exclusively found as their glucosides, whereas the ester cleavage products were found both free and as their glucoside and amino acid conjugates. All three insects conjugated DCVA with one or more of the amino acids glycine, glutamic acid, glutamine, and serine, in addition to forming glucose esters. This study did not identify the 2′-hydroxylated metabolite (**54**), a significant metabolite in mammalian studies. However, this metabolite and compounds derived from it were identified in a study of the metabolism of permethrin by the American bollworm *Helicoverpa zea*, the tobacco budworm *Heliothis virescens* (Lepidoptera, Noctuidae) (Bigley and Plapp, 1978) and the Colorado potato beetle, *Leptinotarsa decemlineata* (Soderlund *et al.*, 1987), in which it was the principal metabolite. Other later studies have confirmed this overall pattern in different insects, although some studies have shown more differences in the pattern of metabolites between *cis*- and *trans*-permethrin isomers.



Holden (1979) showed that *trans*-permethrin was ester-cleaved at a higher rate than the *cis*-isomer in *P. americana*, an observation consistent with the findings that the *trans*-isomers of cyclopropane-containing pyrethroids are much better substrates for esterases than the *cis*-isomers (see below). This pattern of permethrin metabolism by insects can be taken as a template for the breakdown of other pyrethroids comprising esters of 2,2-dimethyl-3-(substituted)vinylcarboxylic acid with 3-PBA. Thus, the principal mechanisms of Phase I metabolism involve ester cleavage, both hydrolytic and oxidative, and aromatic substitution of one or

(**55**)

(**56**)

(**57**)

Figure 7 Metabolites from oxidative attack on the chrysanthemic acid moiety of allethrin (structures **55**–**57**).

other of the 3-PBA rings (the 4′-position is usually the major site) and the 2,2-dimethyl group of the acid moiety. Analogous reactions have been shown to take place with bifenthrin and deltamethrin in the bulb mite *Rhizoglyphus robini* to give the ester-cleaved products and the 4′-hydroxy metabolites (Ruzo *et al.*, 1988). Similarly, *trans*-cypermethrin gave *trans*-DCVA and both 2′- and 4′-hydroxy-cypermethrin in the cotton bollworm *Helicoverpa armigera* and in *H. virescens* (Lepidoptera) (Lee *et al.*, 1989). Fenvalerate, which lacks a cyclopropyl group, was metabolized via ester cleavage and 4′-hydroxylation in houseflies (Funaki *et al.*, 1994). In pyrethroids containing the chrysanthemic acid moiety (rather than a 2,2-dimethyl-3-dihalovinylcarboxylic acid), such as allethrin, phenothrin, and tetramethrin, the methyl groups of the isobutylene group are also subject to oxidative attack. Hydroxylation of these groups in allethrin to the alcohol (**55**) (**Figure 7**), followed by successive oxidation to the aldehyde (**56**) and carboxylic acid (**57**), occurred in houseflies (Yamamoto *et al.*, 1969). Tetramethrin was mainly metabolized via ester cleavage, with the production of the carboxyl derivative (**57**) of the *trans*-methyl group as a minor product (Yamamoto and Casida, 1968).

6.1.5.1.1.3. Ester hydrolysis All pyrethroids with the exception of the nonester compounds, such as MTI 800 which has a hydrocarbon linkage between the “acid” and “alcohol” moieties, are subject to esterase-catalyzed breakdown. Even etofenprox, which has an ether linkage in this position, is cleaved via oxidation of the benzylic carbon and hydrolysis of the resultant ester in the rat (Roberts and Hutson, 1999). The stereochemistry of the cyclopropanecarboxylic acid is important in determining the rate of esteratic detoxification, since the *trans*-isomers are very much better substrates for esterases than are the *cis*-isomers (Soderlund and Casida, 1977). Indeed, *cis*-pyrethroids possessing an α-cyano group (Type II

pyrethroids) and consequently a secondary ester are generally degraded via a microsomal P450 mechanism through oxidation of the α-carbon. Evidence from work with mammalian liver indicates that the esterases responsible for pyrethroid hydrolysis are also microsomal (Soderlund and Casida, 1977). This study also showed that the Type II pyrethroids cypermethrin and deltamethrin were the least susceptible to both esterase-catalysed hydrolysis and oxidation. Generally, the major route of Type II pyrethroid metabolism in mammals is via de-esterification catalysed by microsomal oxidases (e.g., Crawford and Hutson, 1977). Studies on insects have also concluded that ester cleavage is often mainly by an oxidative mechanism (Casida and Ruzo, 1980; Funaki *et al.*, 1994). The latter study concluded that the de-esterification of fenvalerate by pyrethroid-resistant houseflies was principally due to over-expression of cytochromes P450; only a small portion of the ester bond cleavage was caused by hydrolases.

Whether the ester cleavage is hydrolytic or oxidative is apparently largely dependent on the species. For example, *T. ni* (Ishaaya and Casida, 1980), *S. littoralis*, (Ishaaya *et al*., 1983), *S. eridana* (Abdelaal and Soderlund, 1980) (Lepidoptera), and *B. tabaci* (Jao and Casida, 1974; Ishaaya *et al*., 1987) (Hemiptera) all degraded *trans*-pyrethroids via a hydrolytic mechanism. Conversely, houseflies (Diptera) and the rust-red flour beetle *Tribolium castaneum* (Coleoptera) used an oxidative pathway (Ishaaya *et al*., 1987). A rather special case is that of the green lacewing *Chrysoperla carnea* agg. (Neuroptera), which is highly resistant to pyrethroids. This insect has been shown to contain high levels of a pyrethroid-hydrolyzing esterase that is able to catalyze the hydrolysis of *cis*-isomers, including those of Type II ester pyrethroids such as cypermethrin (Ishaaya and Casida, 1981; Ishaaya, 1993). How the over-production of esterases induces resistance to *cis*-pyrethroids such as deltamethrin, which are poor substrates for the enzyme(s) from other species, has been the cause of some conjecture. Devonshire and Moores (1989) presented evidence that *cis*-pyrethroids bind tightly to the active site and are thus sequestered by the large amounts of the resistance-associated esterases (E4 and FE4) produced by resistant peach-potato aphids *M. persicae*. Consequently, deltamethrin acts as a competitive inhibitor of esterase activity but is removed by binding to the protein rather than by hydrolysis. Selection pressure, whether artificially or from frequent commercial use of pyrethroids, frequently leads to multifactorial mechanisms of insecticide resistance, including esterases, cytochromes P450, target-site (*kdr* and *super-kdr*) mechanisms, and sometimes reduced penetration (e.g., Anspaugh *et al*., 1994; Pap and Toth, 1995; Ottea *et al*., 2000; Liu and Pridgeon, 2002). Such insect strains have extremely high resistance and usually show some degree of cross-resistance to all pyrethroids.

Most insect esterases that catalyze the hydrolysis of pyrethroid esters are soluble nonspecific B-type carboxylesterases. These have a wide substrate-specificity and model substrates, such as 1-naphthyl acetate, have been used to visualize electrophoretically distinct protein bands in *B. tabaci* (Byrne *et al*., 2000) and many other insect species. There is little information to date on the occurrence of microsomal esterases in insects analogous to those in mammals (e.g., Prabhakaran and Kamble, 1996). Most evidence for the involvement of esterases in pyrethroid breakdown is indirect and has used model substrates; however, direct evidence for pyrethroid hydrolysis has been obtained for esterases from several species, including the horn fly *Haematobia irritans* (Diptera) (Pruett *et al*., 2001). Concern has been raised of the validity of using model substrates to predict the breakdown of pyrethroids, and consequently some researchers have designed model substrates with pyrethroid-like structures. Thus, Shan and Hammock (2001) developed sensitive fluorogenic substrates based on DCVA coupled to the cyanohydrin of 6-methoxynaphthalene-2-carboxaldehyde. Hydrolysis of this ester and decomposition of the cyanohydrin regenerates this fluorescent aldehyde. An enzyme preparation that used this substrate from a cypermethrin-selected resistant strain of *H. virescens* (Lepidoptera) gave better selectivity (×5) than did 1-naphthyl acetate (×1.4). A similar approach, but using 1-naphthyl esters of the four stereoisomers of DCVA with detection of released 1-naphthol by diazo-coupling to Fast Blue RR, has been reported (Moores *et al*., 2002). In these experiments, only the (1*S*)-*trans*-isomer acted as a substrate for aphid esterases, in agreement with other experiments on the stereospecificity of insect pyrethroid esterases. Activity staining of electrophoretic gels using this novel substrate showed that the pyrethroid-hydrolyzing activity was distinct from the resistance-associated esterases visualized with 1-naphthyl acetate, indicating that the main mechanism for resistance was binding/sequestration rather than hydrolysis.

Work since 1985 has concentrated on understanding the nature of the esterases responsible for pyrethroid hydrolysis. *In vivo* studies have often yielded equivocal results and, using such tools as specific inhibitors of oxidative or hydrolytic metabolism, it has frequently been difficult to prove which mechanism is primarily responsible for pyrethroid catabolism. These problems have arisen in part

because there is no such thing as a specific inhibitor and some compounds thought to be specific inhibitors of cytochromes P450 (e.g., piperonyl butoxide) may also inhibit esterases (Gunning *et al.*, 1998b; Moores *et al.*, 2002).

Studies have included both *in vivo* work on whole insects or their tissues and *in vitro* studies with isolated enzymes. In resistant populations of many insect species, the mechanisms are most frequently due to both enhanced esterase and cytochrome P450 levels, so that dissection of the proportions of the different mechanisms is difficult. However, evidence that resistance ratios are reduced or abolished in the presence of reliably specific inhibitors such as organophosphates (Gunning *et al.*, 1999; Corbel *et al.*, 2003) can be taken as a good indication that enhanced esterase levels are responsible for metabolic resistance.

6.1.5.1.1.4. Cytochrome P450 monooxygenases These are a class of Phase I detoxification enzymes that catalyse various NADPH- and ATP-dependent oxidations, dealkylations, and dehydrogenations. Both microsomal and mitochondrial forms occur in insects. They are probably responsible for the most frequent type of metabolism-based insecticide resistance (Oppenoorth, 1985; Mullin and Scott, 1992; Scott and Wen, 2001). They are also a major mechanism for pyrethroid catabolism (Tomita and Scott, 1995). Their occurrence and importance in insect xenobiotic metabolism has been reviewed by Scott and Wen (2001). The super-family of cytochrome P450 genes has probably evolved by gene duplication and adaptive diversification, and comprises 86 functional genes in *D. melanogaster.* The large number of substrates metabolized by P450s is due both to the multiple isoforms and to the fact that each P450 may have several substrates (Rendic and DiCarlo, 1997). Because these enzymes may have overlapping substrate specificities, it is difficult to ascribe the function to individual P450 enzymes. In insects, although the importance of oxygenases in the metabolism of many substrates is known, the particular P450 isoforms involved have rarely been identified. For a general review on insect P450 enzymes and particularly their regulation, see **Chapter 4.1**.

Several P450 iso-enzymes have been isolated or expressed from insect sources. Regarding pyrethroid metabolism, the best-characterized P450 isoform is CYP6D1. This was originally purified from a strain of highly resistant (ca. ×5000) houseflies designated "Learn pyrethroid resistant" (LPR) selected by the continuous usage of permethrin to control flies in a New York State dairy. A reduced-penetration mechanism and *kdr* were also present in the strain. CYP6D1 has been purified (Wheelock and Scott, 1989) and sequenced via the use of degenerate primers derived from known protein sequences and PCR amplification (Tomita and Scott, 1995). Overproduction of this P450 isozyme was found to be the major mechanism of deltamethrin detoxification in microsomes derived from the LPR flies (Wheelock and Scott, 1992). The enzyme requires cytochrome b5 as a co-factor and is specific in its action, because only the 4′-hydroxy metabolite was produced from cypermethrin (Zhang and Scott, 1996). CYP6D1 was found to be the major and possibly the only P450 isoform responsible for pyrethroid metabolism in this strain of houseflies; consequently, the resistance ratios are very much less for pyrethroids such as fenfluthrin that do not have the 3-phenoxybenzyl group (Scott and Georghiou, 1986). The same mechanism was found to be responsible for PBO suppressible resistance to permethrin from a Georgia poultry farm in the USA (Kasai and Scott, 2000). In both these housefly strains, the mechanism was due to an increased (ca. ×10) transcription of the gene, leading to increased levels of CYP6D1 mRNA and higher levels of the enzyme. CYP6D1 is expressed in the insect nervous system and has been shown to protect the tissue from the effects of cypermethrin (Korytko and Scott, 1998). Clearly, from the metabolic specificity of CYP6D1, other isoforms of cytochromes P450 must also be implicated in pyrethroid metabolism, although which reactions are catalyzed by which isoform has yet to be determined.

It is characteristic of monooxygenases that they are inducible within an individual animal. The use of phenobarbitone to induce monooxygenase activity in rat liver is well known, and many other agents are capable of transiently up-regulating cytochromes P450. Phytophagous insects are exposed to many plant xenobiotics, for example monoterpenes which also induce P450 production. Such induction of P450s may incidentally induce an isoform also capable of metabolizing pyrethroids. For example, feeding larvae of *H. armigera* on mint (*Mentha piperita*) leaves induced a 4× resistance to pyrethroids compared with those fed on a semi-defined diet (Hoque, 1984; Terriere, 1984; Schuler, 1996; Scott *et al.*, 1998). CYP6B2 mRNA, a P450 isoform also implicated in pyrethroid resistance, is inducible by peppermint oil and specifically α-pinene in larvae of *H. armigera* (Ranasinghe *et al.*, 1997). This induction was rapid (ca. 4 h) and disappeared within a similar period of removing the stimulus. Clearly, the mechanism for the transient induction of P450s (Ramana, 1998) is different

from the situation with the LPR houseflies, in which CYPD1 is permanently up-regulated (Liu and Scott, 1998), although the precise mechanistic details still remain to be elucidated. In nonphytophagous arthropods for example the cattle tick *Boophilus microplus* which is not subjected to a barrage of allelochemicals in its diet, P450s were found to be of little importance in the induction of resistance to pyrethroids (Crampton *et al*., 1999), although the converse has been found for adults of the mosquito *Culex quinquefasciatus* (Kasai *et al*., 1998).

6.1.5.1.1.5. Model substrates When managing insecticide resistance, it is important that resistant alleles can be detected at low frequency in populations. Data from bioassays will only detect a quite high proportion of individuals with reduced sensitivity in the population. Consequently, it is useful to design biochemical or DNA (molecular) tests that can identify resistance in individual insects. Thus, model substrates commonly used to measure P450 levels *in vitro* need to be substrates of the relevant P450 isoforms that degrade the insecticide. Amongst such model substrates are the sensitive fluorogenic reagents 7-ethoxycoumarin, ethoxyresorufin, and methoxyresorufin, and the chromogenic substrate 4-nitroanisole. These compounds are dealkylated by monooxygenases to yield a fluorescent or colored product. Unfortunately, it has generally been found that these substrates are also isozyme specific, so that they may not be good indicators of P450-induced pyrethroid resistance. In the case of CYP6D1, methoxyresorufin was found to be a substrate, but ethoxyresorufin and 7-ethoxycoumarin were not (Wheelock and Scott, 1992). A similar variation in the activity of elevated oxygenases to 4-nitroanisole, benzo(a)pyrene, benzphetamine, and methoxyresorufin in the mid-gut of a multi-resistant (cypermethrin and thiodicarb) strain of *H. virescens* larvae was noted (Rose *et al*., 1995). In this strain, demethylation rates of both 4-nitroanisole and methoxyresorufin were useful as indicators of insecticide resistance; however, on such multi-resistant strains, several P450 isoforms are probably elevated in tandem making comparisons difficult. Consequently, the use of model substrates to estimate the levels of P450 monooxygenases in individual insects may only give equivocal information on levels of P450-derived metabolic resistance to pyrethroids.

6.1.5.1.1.6. Glutathione-*S*-transferases (GSTs) GSTs are important in the detoxification of organophosphorus insecticides and other electrophilic compounds, which are dealkylated and conjugated with glutathione (see **Chapter 5.11**). Pyrethroids are not electrophilic and would not be expected to be detoxified by this mechanism. However, there are several reports that have correlated enhanced levels of GSTs with pyrethroid resistance in a number of species, *S. littoralis* (Lagadic *et al*., 1993), *T. castaneum* (Reidy *et al*., 1990), and *Aedes aegypti* (Grant and Matsumura, 1989). Additionally, pyrethroids have been shown to induce production of GSTs in the honeybee *Apis mellifera* (Yu *et al*., 1984), fall armyworm *Spodoptera frugiperda* (Punzo, 1993), and German cockroach *Blatella germanica* (Hemingway *et al*., 1993). The role of the glutathione-*S*-transferase system as a mechanism of defence against pyrethroids is not fully understood, but it is thought that GST proteins sequester the pyrethroids (Kostaropoulos *et al*., 2001) or possibly protect the tissues from pyrethroid-induced lipid peroxidation (Vontas *et al*., 2001).

6.1.5.1.2. Cuticle penetration As a resistance mechanism, reduced penetration of the insect cuticle has been studied less and has generally been considered of subordinate importance to enhanced detoxification and target-site mutations. Where detected, it is usually found with other mechanisms, e.g., the "LPR strain" of houseflies referred to above. Reduced cuticular penetration of pyrethroids has been detected in resistant strains of a number of other species, including *H. armigera* (Gunning *et al*., 1991), *H. zea* (AbdElghafar and Knowles, 1996), *H. virescens* (Little *et al*., 1989), *S. exigua* (Delorme *et al*., 1988), the diamond-back moth *Plutella xylostella* (Noppun *et al*., 1989), *B. germanica* (Wu *et al*., 1998), and *B. microplus* (Schnitzerling *et al*., 1983). In all these cases, reduced cuticular penetration was found in addition to other resistance mechanisms, enhanced metabolism, and/or target-site resistance (*kdr*). Mechanisms involving reduced uptake appear not to give significant resistance to the lethal effects of insecticides but provide a more than additive effect when combined with other mechanisms. Thus, decreased penetration, although a minor factor on its own, can, when coupled with other mechanisms, increase resistance many-fold (Ahmad and McCaffery, 1999).

6.1.5.1.3. Target-site resistance Target-site resistance is the most important mechanism of pyrethroid resistance and its selection and spread have compromised the use of pyrethroid insecticides on many insect pests. It is a particularly important mechanism of pyrethroid resistance, as it confers a degree of loss of sensitivity to all members of the class. It is characterized by a reduction in the sensitivity of the insect nervous system and has been

termed "knockdown resistance" or *kdr* (Sawicki, 1985). The *kdr* trait was first identified in the early 1950s in houseflies (Busvine, 1951). It causes a loss of sensitivity to DDT and its analogs, and to pyrethrins and pyrethroids, which all owe their activity to interaction with the *para*-type voltage-gated sodium channel in nerve membranes. This loss of activity is characterized by a reduction in the binding of these insecticides to the sodium channel (Pauron *et al.*, 1989). An enhanced form of this resistance termed *super-kdr* has also been characterized in houseflies (Sawicki, 1978). Both the *kdr* and *super-kdr* traits were mapped to chromosome 3 and found to occupy the same allele, the *para*-type sodium channel. This has been confirmed by molecular cloning studies of these channels in *kdr* and *super-kdr* houseflies (Williamson *et al.*, 1996) and *kdr B. germanica* (Miyazaki *et al.*, 1996; Dong, 1997). The *super-kdr* resistance in houseflies is due to a methionine to threonine (M918T) point mutation in the gene encoding the *para* sodium channel. Both mutations were located with domain II of the ion channel. The L1014F mutation in IIS6 was found in both housefly and cockroach strains, and confers *kdr* resistance. To date, the M918T mutation has not been detected as a single substitution in any housefly strain, but only occurs in conjunction with L1014F. Mammals are intrinsically much less susceptible to pyrethroids and DDT. Significantly, mammalian neuronal sodium channels have an isoleucine rather than methionine in the position (874) that corresponds to the housefly *super-kdr* site (918). Site-directed mutation of this residue to methionine gives rise to a channel with >100x increased sensitivity to deltamethrin, suggesting that differential pyrethroid sensitivity between mammals and insects may be due in part to structural differences between the mammalian and insect sodium channels (Vais *et al.*, 2000). In some insect species, the existence of *kdr*-type target-site resistance has often been masked by efficient metabolic resistance mechanisms; an example is *M. persicae*, in which resistance-associated esterase is responsible for much of the reduced sensitivity towards organophosphates, carbamates, and pyrethroids. Any inference that target-site resistance might also be a factor has usually been based on the sensitivity of the insects in the presence of synergists such as PBO or DEF *S,S,S*,-tributyl phosphorotrithiolate, and the assumption that any residual decreased sensitivity is due to *kdr*-type target-site resistance.

Use of degenerate DNA primers for the *para*-type sodium channel and sequencing of the gene have resulted in the unequivocal identification of resistance-inducing mutations in the trans-membrane domain II (Martinez-Torres *et al.*, 1999b) of the channel in *M. persicae*, in which a leucine to phenylalanine (L1014F) mutation associated with *kdr* was identified. Insects containing this mutation could also be identified by the use of a discriminating dose of DDT, as DDT is unaffected by the enhanced-esterase mechanisms also present in most of the aphid clones. Indeed, of 58 aphid clones analysed for both *kdr*- and esterase-based mechanisms, only four contained an esterase (E4) mutation and not *kdr*. Estimates for resistance factors in aphids containing both mechanisms are 150–540-fold, in comparison to 3–4-fold (FE4 esterase alone) or 35-fold for *kdr* alone. Consequently, these dual-resistance mechanisms afford a level of decreased sensitivity whereby insects become totally immune to field dosages of pyrethroids. Similar *kdr* mutations have also been detected in cockroaches (Miyazaki *et al.*, 1996; Dong, 1997), *H. irritans* (Guerrero *et al.*, 1997), *P. xylostella* (Schuler *et al.*, 1998), and *An. gambiae* (Martinez-Torres *et al.*, 1998). In a pyrethroid-resistant strain of the tobacco budworm *H. virescens*, the same locus was mutated to histidine rather than phenylalanine (Park and Taylor, 1997)

As with metabolic resistance mechanisms, it is important to establish methods that can identify sodium-channel *kdr*-type mechanisms in single insects so that it is possible to adjust insect-control methods. The *kdr*-mutation of nerve insensitivity was originally identified by electrophysiology, and this method still remains a fundamental way of confirming nerve insensitivity. However, it is a specialized and rather cumbersome technique that is out of the question when attempting to test large numbers of an agricultural pest species. The DDT bioassay using a discriminating dose remains a useful method but may not completely discriminate between homozygous and heterozygous individuals. The most useful technique has been direct diagnosis of the mutation(s) based on PCR amplification and sequencing. The identification of the L1014F mutation in knockdown-resistant housefly strains has led to the development of several diagnostic assays for its occurrence in other species, including *H. irritans* (Guerrero *et al.*, 1997), the mosquitoes *An. gambiae* (Martinez-Torres *et al.*, 1998), and *Culex pipiens* (Martinez-Torres *et al.*, 1999a), as well as *M. persicae*. However, this technique will only identify known mutations and the test designed to detect L1014F in *An. gambiae* (Ranson *et al.*, 2000) did not detect the additional L1014S.

The molecular biology of knockdown resistance to pyrethroids has been reviewed (Soderlund and Knipple, 2003). Sequencing of the *para*-sodium

channel gene from several arthropod species has led to the discovery of a number of amino-acid polymorphisms in the protein. Of the 20 amino-acid polymorphisms each uniquely associated with pyrethroid resistance, those occurring at four sites have so far been found as single mutations in resistant populations. These are valine 410 (V410M in *H. virescens*; Park *et al*., 1997), methionine 918 (M918V in *B. tabaci*; Morin *et al*., 2002), leucine 1014 (L1014F in several species; L1014H in *H. virescens*; Park and Taylor, 1997; L1014S in *C. pipiens*; Martinez-Torres *et al*., 1999a), *An. gambiae* (Ranson *et al*., 2000), and phenylalanine 1538 (F538I, in *B. microplus*; He *et al*., 1999). All these sites have been located on trans-membrane regions of the channel and it is inferred that they are close to the binding site(s) of pyrethroids and DDT. Additionally, other polymorphisms have been found that only occur in the presence of L1014F and appear to act in a similar way to M918T in houseflies, causing enhanced resistance.

6.1.5.2. Resistance to Pyrethroids in the Field

The main cause of development of resistance in insects in the field is a persistent and high selection pressure as a consequence of repeated applications of a single class of insecticide (or another with the same mode of action). Therefore, despite effective control in the initial stages, a small number of survivors with innate resistance then rapidly multiply until control fails. In this regard, pyrethroids are no different from other insecticide classes. It is noteworthy that it was the development of resistance to pyrethroids that first prompted companies to take resistance seriously and to take joint action. Pyrethroids suffered an inherent disadvantage at the outset in that *kdr* also confers resistance to DDT, and prior use of DDT had already selected *kdr* alleles to significant levels in the same pests. Presently over 80 species have developed resistance to pyrethroids (Whalon *et al*., 2003).

Until the late 1970s, the major agrochemical companies had seen the development of resistance to established classes as commercially beneficial and motivation for the introduction of new classes. However, the increasing cost of discovery, together with the realization that pyrethroids could be rendered ineffective in the field within a much shorter period of time than other classes of insecticides, forced them to take collective action. In 1979 they set up the Pyrethroid Efficacy Group (PEG), which in 1984 become a sub-group of a larger international organization called the Insecticide Resistance Action Committee (IRAC). This group communicates its actions through a website (http://www.irac-online.org) and also sponsors the biannual Resistant Pest Management newsletter. Before the establishment of PEG, the investigation of resistance mechanisms and their consequences had remained the domain of academic research, and the development of resistance to pyrethroids was largely overlooked and even denied by some companies. The primary aim of PEG was to prolong the effectiveness of pyrethroids in the field. It encouraged and assisted in the investigation of all aspects of resistance to pyrethroids and particularly the development and implementation of insecticide-resistance management (IRM) strategies.

Persistent selection with a single class of insecticide will invariably lead to resistance, even if synergists are used. Therefore the overall aim is to minimize use of any single insecticide class so as to limit selection pressure and thereby conserve susceptibility in pest insects. This requires an in-depth knowledge of factors ranging from resistance mechanisms to genetic and ecological attributes of both pest and beneficial insects. Any strategy has also to integrate the judicious use of different insecticide types (namely those with different modes of action and synergy where possible) with other pest-management options (e.g., agronomic practices), together with regular monitoring of both the levels of resistance and the nature of the resistance mechanisms. Finally, the key requirement for the success of any strategy is the cooperation of the growers. By way of example, two IRM strategies are considered below which encompass these factors.

The first successful and the most publicized IRM strategy came from Australia. Synthetic pyrethroids were introduced in Australia in 1977 when there was already widespread resistance to virtually all established classes. However, within six years of introduction, resistance to these pyrethroids had also developed in commercially important insect species (Forrester *et al*., 1993). A resistance-management strategy for *H. armigera* was implemented in the 1983/4 season. A different approach was used for each class of insecticide, depending on the severity of the resistance risk and predicted selection pressure. It integrated the use of chemical and nonchemical control methods, especially biological and cultural. For chemical control, unrelated chemistries were used with a strong emphasis on pyrethroid/ovicide mixtures. In essence, a three-stage strategy was implemented. In Stage I (September to February), only endosulfan (an organochlorine) was permitted. Stage II (January to February) allowed a maximum of three pyrethroid sprays within a 42-day window (later reduced to 38 days), enough to control only one of the five *H. armigera*

generations present within a single growing season. In Stages I and II, ovicidal compounds (e.g., methomyl) could also be used. Organophosphates and carbamates were used in Stage III and also if required for additional sprays during Stages I and II.

The use of a "softer" insecticide (endosulfan) in the early season was deliberate to minimize disruption of beneficial parasitoids and predators and to avoid a potential upsurge of secondary pests such as mites, aphids, and whiteflies, which were not controlled by the pyrethroids available at the time. Examples of nonchemical countermeasures incorporated in the strategy to reduce selection pressure included the use of early-maturing crops, avoiding early-growing crops (e.g., maize) in adjacent fields, which may act as early-season nurseries for resistant *H. armigera*, and utilization of host plants in refugia to maintain a large pool of susceptible individuals, which would continually dilute the resistant population in the crop. Resistance was monitored on a weekly basis using a discriminating dose of fenvalerate with and without the synergist PBO. Later monitoring showed a rise in metabolic resistance attributed to MFOs and this resulted in the inclusion of PBO in the last of the maximum of three pyrethroid sprays. This strategy was successful for many years but the underlying trend of upward increase in the proportion of resistant insects continued and finally led to a complete reorganization of the strategy in the mid 1990s with a shift away from reliance on pyrethroids.

Initial resistance to pyrethroids was thought to be due to the presence of the knockdown site-insensivity resistance (*kdr*) mechanism probably as a direct result of cross-resistance to DDT. Over the years of the IRM strategy, metabolic resistance mechanisms appear to have taken over. However, there is still controversy over whether it is primarily due to elevated levels of esterases or mixed-function oxidases (MFOs). The main reason for the uncertainty concerns the role of synergists used in the studies. For example, PBO is now thought to inhibit both these types of enzymes. Furthermore, it has been suggested that such inhibitors may themselves have become resisted in the field over time (McCaffery, 1998), thus obscuring the mechanism of resistance.

The second IRM strategy involved the whitefly, *B. tabaci*, a representative sucking pest on a wide range of crops (Denholm *et al*., 1998). In 1995, overreliance on a limited range of pyrethroids in Arizona had led to a classic treadmill scenario, with farmers responding to rising levels of resistance by increasing the number of sprays (as many as 8–12 applications per season). In this pest, the haplodiploid breeding system encourages rapid selection and fixation of resistance genes. Males are produced uniparentally from unfertilized, haploid eggs, and females are produced biparentally from fertilized diploid eggs. In addition, for this (and other) highly polyphagous species, the interaction between pest ecology and resistance is complex and generally not well understood, making formulation of IRM strategies even more difficult. The strategy of Dennehy and Williams (1997) implemented in 1996 had several features in common with that for *H. armigera*. It too relies on the continuous availability of a pool of susceptible whiteflies in refugia (e.g., Brassica crops) throughout the year and alteration of agronomic practices (e.g., timing of planting) in crops to minimize whitefly numbers whilst still maintaining the level of natural enemies. The first of the three-stage IRM strategy involved use of a single spray each of pyriproxyfen and buprofezin (then newly available insect-growth regulators) with a 14- or a 21-day gap. The second stage allowed nonpyrethroid conventional insecticides and the third used pyrethroids synergized with acephate as late as possible in the season. A threshold of infestation was defined to initiate insecticide applications. Mixtures were limited to no more than two compounds and any one active ingredient was restricted to no more than two applications in one season. This strategy has been extremely successful in reducing the number of sprays required and regaining susceptibility both to synergized pyrethroids and key nonpyrethroid insecticides.

As for *H. armigera*, the need for monitoring, establishing threshold levels to trigger spray applications, and cooperation of the growers was key to the strategy. Long-term success of any IRM strategy depends on many factors because, even when an IRM strategy has been successful (McCaffery, 1998), effectiveness of synergized pyrethroids can be lost after just two applications in areas with a history of resistance to pyrethroids.

In conclusion, the key requirement for the development and sustainability of an IRM strategy is diagnosis of the resistance mechanism(s) in field populations. This is especially important when assessing the relative importance of individual mechanisms when several are present, which influences changes to the strategy with time. As alluded to earlier, there is still much uncertainty in the diagnosis of mechanisms. The use of established inhibitors or just *in vitro* bioassay data has been shown to be unreliable in this regard. For example in *M. persicae*, elevated esterase was considered for many years to be the main resistance mechanism.

It was only recently shown (Devonshire *et al.*, 1998) that this mechanism made only a minor contribution to the observed resistance to pyrethroids, with a *kdr* mechanism being the main contributor. This case further emphasized the need for not only accurately identifying the resistance mechanisms present but also their relative contribution. One way forward would be to design selective inhibitors on the basis of *in vivo* and *in vitro* structure–activity relationship studies from susceptible and resistant insects.

6.1.5.2.1. Chemistry-led options for circumventing resistance The established IRM strategies (considered above) successfully exploit a range of options including use of insecticides with different modes of action, agronomic practices, and biological control. However, there are two additional options involving insecticides that have hitherto not been fully exploited.

1. Negative cross-resistance is a phenomenon in which a resistant pest is rendered more susceptible to another class of pesticide. This phenomenon is rare in insects but for pyrethroids, two different classes, the *N*-alkylamides (Elliott *et al.*, 1986) and dihydropyrazoles (and related classes) (Khambay *et al.*, 2001), have been found to cause this effect. They both exhibit similar, albeit small (resistance factors of 0.4), levels of negative cross-resistance to houseflies with nerve insensivity (*super-kdr*) as the main resistance mechanism. The mechanisms involved are not properly understood. However this phenomenon is apparent only in the presence of the *super-kdr* mechanism, with *kdr* alone having little impact. BTG 502 (**Figure 8**; (58)) is representative of the *N*-alkylamides, a class with which this phenomenon was first identified. No compounds of this class have been commercialized to date, but see **Chapter 6.2**.

   In insects that have developed resistance to pyrethroids as a consequence of increased levels of metabolic enzymes (MFOs and esterases), negative cross-resistance has been demonstrated towards insecticides that require *in vivo* activation (i.e., pro-insecticides). For example, negative cross-resistance has been observed with indoxacarb in *H. armigera* with increased levels of esterases (Gunning, 2003). However, this compound has little effect in *M. persicae* with elevated levels of esterase (Khambay, unpublished data). This difference may be accounted for by the kinetics of the hydrolysis reaction. In susceptible *H. armigera*, hydrolysis is incomplete by the end of the bioassay time. The increased levels of esterases in resistant *H. armigera* generate more active compound over the same period, resulting in a higher level of activity. In *M. persicae*, the hydrolysis is complete during the test period even in susceptible insects and therefore no additional effects are observed if increased levels of esterases are present. Negative cross-resistance has also been observed for pyrethroid-resistant insects with increased levels of MFOs. Examples of such insecticides include the pyrazole chlofenapyr, the organophorothioates diazinon and chlorpyrifos, and the methylcarbamate propoxur.
2. Pyrethroids constitute a diverse class of chemical structures and levels of resistance to them also vary considerably. For example, in houseflies with the *super-kdr* resistance mechanism, the resistance factor for different pyrethroids can vary from less than 10 to over 500. Structure–activity relationships have been discerned and the levels of resistance factors (RFs, derived by dividing the LD50 of resistant insects by that of the corresponding susceptible insects) have been shown to be directly influenced by the nature of the alcohol group and the α substituent, but independent of the nature of the acid group (Farnham and Khambay, 1995a, 1995b; Beddie *et al.*, 1996). This is reflected in the description of

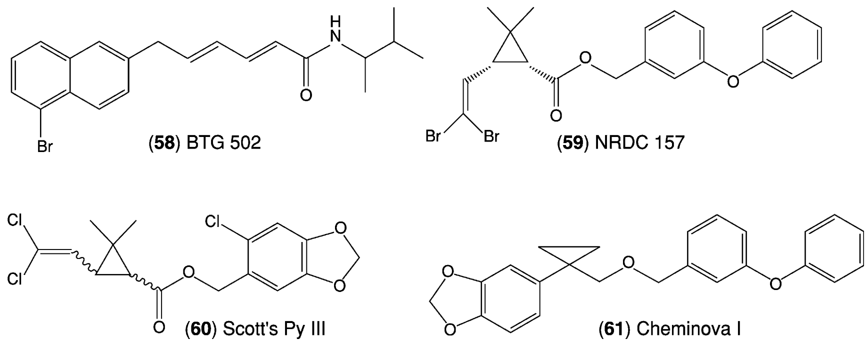


Figure 8 Compounds referred to in the resistance section (structures **58**–**61**).

Types I and II. Thus, highest RFs are shown by compounds with a 3-phenoxybenzyl (or equivalent) alcohol ester with an α-cyano substituent (e.g., deltamethrin) with an RF of 560. The RF of 91 for NRDC 157 (**59**) (deltamethrin analog lacking the α-cyano group) is significantly smaller, and indeed surprisingly the LD_{50} values against *super-kdr* flies are similar for the two compounds. This indicates that the additional target-site binding, and hence increased insecticidal activity, in susceptible flies gained by introducing an α-cyano group into NRDC 157 has been lost in *super-kdr* flies. The lowest RFs are observed for pyrethroids with alcohols containing a single ring and no α substituent, an example being tefluthrin with RF < 4.

In *H. armigera*, there has been some controversy regarding the resistance mechanism. Though it is accepted that the major mechanism is due to increased metabolism, it is unclear whether MFOs or esterases prevail. The highest RFs were shown by ester pyrethroids containing a phenoxybenzyl alcohol moiety in combination with an aromatic acid. The lowest RFs were with pyrethroids containing simple alcohol moieties as in bioallethrin. Resistance-breaking pyrethroids (RF < 1) were also identified e.g., those containing a methylenedioxyphenyl moiety as in Scott's Py III (**60**) and Cheminova 1 (**61**).

This approach clearly has potential to prolong the usefulness of pyrethroids as a class of insecticides. However, the agrochemical industries are unlikely to develop new pyrethroids purely for a role in "breaking" resistance to established compounds due to commercial considerations.

Despite the detection of resistance to pyrethroids soon after their introduction over 30 years ago, it has proved possible to manage it in many field situations. Therefore it is likely that pyrethroids will continue to be a useful tool for the foreseeable future.

6.2.1. Introduction

There is an increasing need to discover novel chemical insecticides which act on unique biochemical target sites. This is necessary for insecticide resistance management, to maintain agricultural food and fiber production at reasonable economic levels, and also to retain the effectiveness of older and new classes of chemistry as useful tools.

The modes of action of the major insecticide classes are reviewed in Ishaaya (2001) and in this Encyclopedia. These insecticidal compounds are required not only for economic pest control, but also as critical probes to elucidate their respective biochemical target sites, allowing insights into their fundamental biological function.

While there is an increasing need for new agrochemicals, regulatory requirements for the registration of new insecticides continue to escalate, and society's requirements for safety to nontarget organisms and the environment and compatibility with ongoing agricultural practice, pose increasing challenges.

The voltage-gated sodium (Na^+) channel is a primary insecticide target for the synthetic and natural pyrethroids, DDT, *N*-alkylamides, and a host of natural product and peptide toxins (Zlotkin, 2001). At least ten independent target sites exist for these compounds, based on functional studies, and the compounds can exert allosteric effects on one another via these independent sites. In addition, it has been definitively shown that specific genetic mutations in the Na^+ channel in both laboratory and field insects can confer resistance to pyrethroids and DDT (see **Chapters 5.1** and **6.1**). The discovery of additional new Na^+ channel toxins acting at novel

sites thus creates the possibility of useful invertebrate control agents as well as the development of additional tools for understanding ion channel function.

The identification of the Na^+ channel blocker insecticides (SCBIs) represents such a discovery. These compounds all act at a unique site in insect voltage-gated Na^+ channels, which may correspond to the local anesthetic/anticonvulsant site. Our knowledge of the mode of action of indoxacarb derives largely from studies on the pyrazoline (also known as dihydropyrazole) forerunners of this family, carried out in the 1980s at the Rohm and Haas Company (Salgado, 1990, 1992). Pyrazolines were found to paralyze insects by blocking action potential initiation in nerve cells. The mechanism of this block was due to a voltage-dependent blocking action on voltage-gated Na^+ channels. This mechanism is also observed with many therapeutically useful local anesthetic, antiarrhythmic, and anticonvulsant drugs. The bioactivated form of indoxacarb, *N*-decarbomethoxylated DPX-MP062 (DCMP), also works in this manner. Indoxacarb's selective toxicity towards pest insects is due to its rapid bioactivation to the active metabolite DCMP, while higher animals primarily degrade indoxacarb to inactive metabolites via alternate routes.

This article will trace the chemical evolution of these compounds and their physiological activity in invertebrates, which eventually led to the commercial introduction of a member of this class, indoxacarb (Harder *et al*., 1996; Wing *et al*., 2000). The unique metabolic, insecticidal, and pest management control properties of indoxacarb will also be discussed.

6.2.2. Chemistry of the Na^+ Channel Blockers

6.2.2.1. Chemical Evolution and Structure–Activity of the Na^+ Channel Blocker Insecticides

The first insecticidal pyrazoline Na^+ channel blockers were reported in patents from Philips-Duphar in 1973 and are represented by PH 60–41 (Mulder and Wellinga, 1973) (**Figure 1**). These compounds were reported to have high levels of efficacy against coleopteran and lepidopteran pests. In 1985, Rohm and Haas reported pyrazolines such as RH-3421 with ester substituents on the pyrazoline 4-position (Jacobson, 1985). These compounds were later reported to have high insecticidal efficacy, low mammalian toxicity, and a rapid rate of dissipation in the environment (Jacobson, 1989). Subsequent work by DuPont on the SCBIs resulted in the discovery of several classes of related structures, all with similarly high levels of insecticidal activity (**Figure 2**). It was found that transposition of the N1 and C3 atoms in the pyrazoline core gave active compounds (compound B). Conformationally constrained pyrazolines, resulting from bridging the pyrazoline C4 postion with the C3 aryl substituent (forming indazoles and oxaindazoles) (compound C in **Figure 2**), were also highly active. Semicarbazones D are also insecticidal; these compounds are structurally similar to pyrazolines, but with the C5 carbon removed. Expanding the pyrazoline ring by one carbon gave highly active pyridazine compounds (compound E). Substituting oxygen or nitrogen for the C5 pyridazine atom gives oxadiazines and triazines, also with high insecticidal activity (compound F). Indoxacarb is, in fact, a representative of the oxadiazine subclass of SCBIs.

The insecticidal structure–activity relationships for the oxadiazines are summarized in **Figure 3**. For substituent R1, 4- or 5-Cl, Br, OCH_2CF_3, and CF_3 groups gave compounds with the highest activity. In the R2 position, 4-halo-phenyl and CO_2Me were the most active substituents. For groups at R3, 4-OCF_3, 4-CF_3, and 4-Br were best for activity. For the substituents on nitrogen (R4), CO_2CH_3 and $COCH_3$ were the most active, followed by H, Me, and Et.

6.2.2.2. Chemistry and Properties of Indoxacarb

Indoxacarb is synthesized as described in McCann *et al*. (2001, 2002) and Shapiro *et al*. (2002). Its

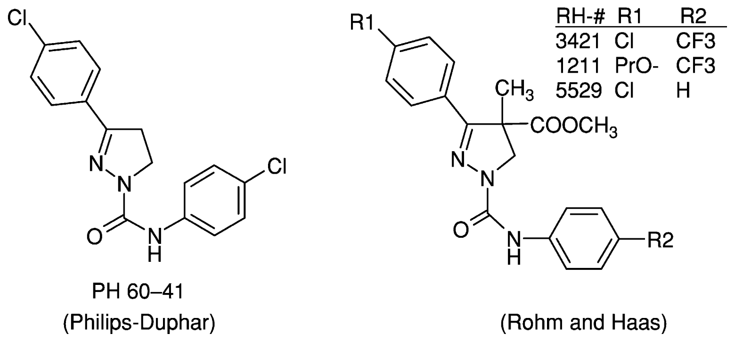

Figure 1 Structures of original pyrazoline Na^+ channel blockers.

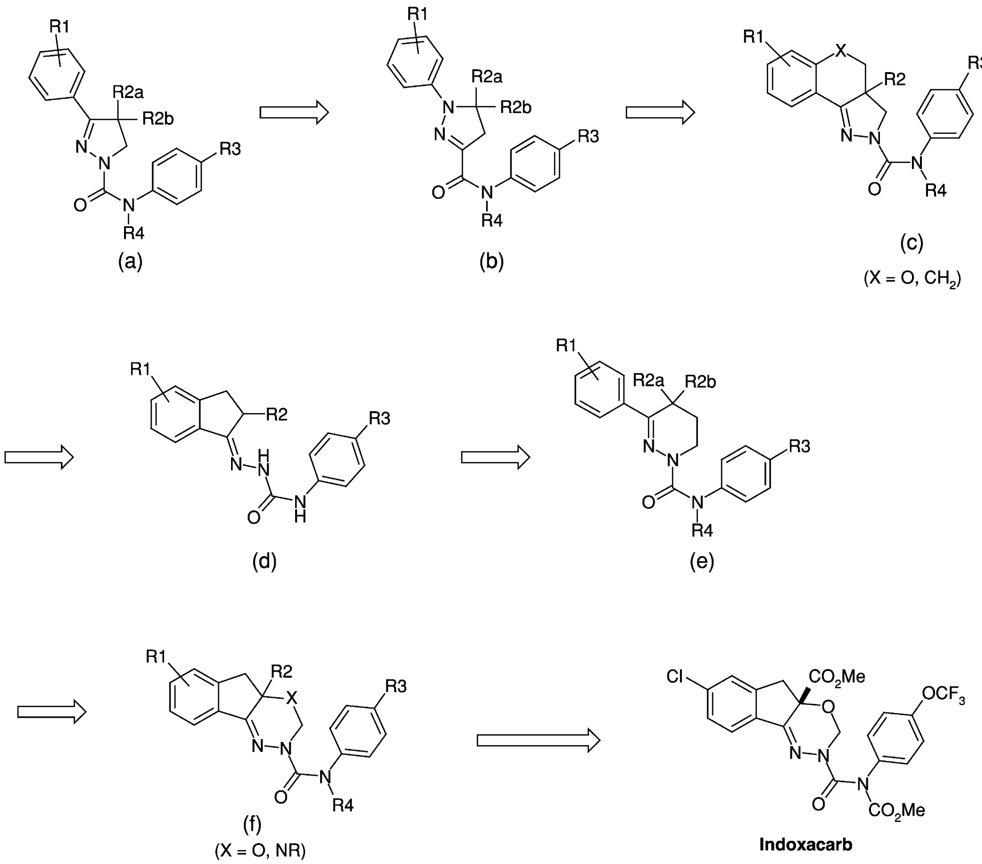

Figure 2 Structures of pyrazoline-like Na^+ channel blockers.

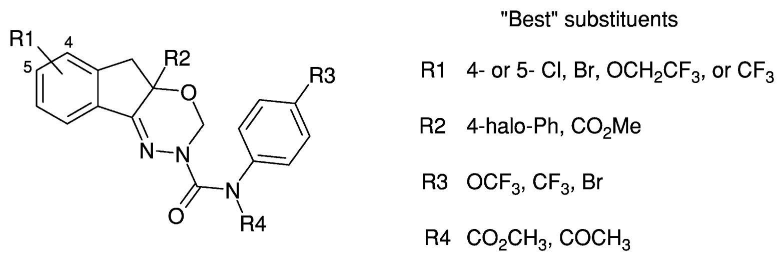

Figure 3 Structure–activity relationships for oxadiazine insecticides vs. *Spodoptera frugiperda*.

physical, toxicological, and environmental properties are shown in Table 1; the profile indicates a safe, environmentally benign compound with relatively low water solubility.

6.2.3. Metabolism and Bioavailability of Indoxacarb

6.2.3.1. Bioactivation of Indoxacarb

Indoxacarb requires metabolic activation by insects before it acts as a strong Na^+ channel blocker (Figure 4). An esterase or amidase-type of enzyme(s) cleaves the carbomethoxy group from the urea linkage, liberating the free urea DCMP, which then acts as the voltage-dependent Na^+ channel blocker. This was first demonstrated for the racemic compound DPX-JW062 (50 : 50 mixture of active *S* and inactive *R* enantiomers) being converted to the corresponding *N*-decarbomethoxylated DPX-JW062 (DCJW) (Wing *et al.*, 1998). The enzyme involved has been only partially characterized. It is clear that the enzyme is a hydrolase of some type, may be serine dependent. In Lepidoptera the enzyme is found in high concentrations in midgut cells (but not the gut contents) and in fat body, and also found in high concentrations in several subcellular fractions (nuclear, mitochondrial, microsomal, and cytosolic). The enzyme can be inhibited by several

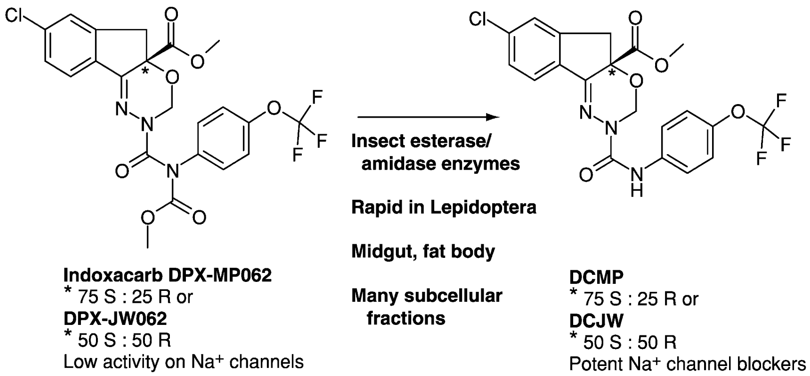

Figure 4 Bioactivation of oxadiazines to *N*-decarbomethoxylated Na^+ channel blocker metabolites in insects.

Table 1 Properties of indoxacarb (DPX-MP062)

Physical state (99% active enantiomer DPX-KN128)	Solid, powder
Melting point	88.1 °C
Solubility (for DPX-MP062, 75% DPX-KN128 + 25% R-enantiomer)	Water – 0.20 ppm *n*-Heptane – 1.72 mg ml^{-1} 1-Octanol – 14.5 mg ml^{-1} Methanol – 103 mg ml^{-1} Xylene – 117 mg ml^{-1} Acetonitrile – 139 mg ml^{-1} Ethyl acetate – 160 mg ml^{-1} Dichloromethane – >250 g kg^{-1} Acetone – >250 g kg^{-1} Dimethylformamide – >250 g kg^{-1}
Partition coefficient in octanol/water (KPX-KN128)	log K_{ow} = 4.65
Vapor pressure (DPX-KN128)	9.8×10^{-9} Pa at 20 °C 2.5×10^{-8} Pa at 25 °C
Acute toxicity of indoxacarb (DPX-MP062)	Oral LC_{50}: 1730 mg kg^{-1} (male rats); 268 mg kg^{-1} (female rats) Dermal LD_{50}: greater than 5000 mg kg^{-1} in rats Inhalation LC_{50}, 4 h: greater than 5.5 mg l^{-1} Dermal irritation: nonirritant Eye irritation: moderate eye irritant Ames test: negative
Environmental fate characteristics	''No major issues in the areas of soil persistence, mobility, and fish bioaccumulation for indoxacarb.''

Data from EPA, **2000**. Fact Sheet on Indoxacarb. Issued Oct. 30, 2000, Environmental Protection Agency, Washington, DC.

organophosphate esterase inhibitors but not the cytochrome p450 monooxygenase inhibitors piperonyl butoxide or 1-phenyl imidazole, nor the glutathione transferase inhibitor *N*-ethyl maleimide. Formal structural proof of the indoxacarb active metabolite was obtained by ^{14}C cochromatography and reversed phase high-performance liquid chromatography (HPLC)/electrospray mass spectrometry with authentic standards.

The bioactivation reaction is widespread throughout several orders of insects. Wing *et al.* (1998) first demonstrated that Lepidoptera representing *Trichoplusia, Spodoptera, Helicoverpa/Heliothis*, and *Manduca* species perform this reaction after oral administration of [^{14}C]DPX-JW062 within 3 h, by which time all larvae were observed to halt feeding, and to suffer a lack of righting, mild convulsions, and a distinct and irreversible pseudoparalysis. A more comprehensive study including Lepidoptera, Homoptera (*Nephotettix, Nilaparvata, Peregrinus, Myzus* species), and Hemiptera (*Lygus* species) indicate that onset of toxic symptoms in all of these insects is well correlated with formation of [^{14}C]DCJW from [^{14}C]DPX-JW062 or unlabeled indoxacarb to DCMP after oral administration (Wing *et al.*, 2000). However, it was noted that the bioactivation rate as well as speed of onset of symptoms was noticeably more rapid with Lepidoptera, and that the Lepidoptera quantitatively converted far more of the parent oxadiazine into the active metabolite than the other orders examined. In addition, there is no apparent stereoselectivity of activation for either the *S* (active Na^+ channel blocker) or *R* enantiomers of parent oxadiazine – both enantiomers appeared to be cleaved rapidly to the corresponding free ureas. However, it appears that all of the insecticidal activity resides in the *S*-enantiomer of DCJW or indoxacarb (Wing *et al.*, 1998) as has been observed for dihydropyrazoles (Hasan *et al.*, 1996). Bioactivation and subsequent cessation of feeding and pseudoparalysis in lepidopteran larvae was slower and required higher doses after topical, compared to oral administration.

While only these free ureas demonstrated strong Na^+ channel blocking activity, it was frequently

observed that both indoxacarb and its activated metabolite were similarly potent in intoxicating Lepidoptera (Wing *et al*., 1998; Tsurubuchi *et al*., 2001). This again argues for efficient bioactivation in this order of insects.

Indoxacarb bioactivation was also studied in the hemipteran cotton pest, the tarnished plantbug (*Lygus lineolaris*), compared to its hemipteran predator, big-eyed bug (*Geochoris punctipes*) (Tillman *et al*., 2001). These studies again demonstrate that the onset of neurotoxic symptoms in both bugs was well correlated with the appearance of the activated metabolite DCMP (albeit at slower rates than observed in Lepidoptera). The importance of oral uptake as a major route of bioactivation/intoxication, compared to tarsal absorption of residues or through dermal uptake, was clearly evident. Interestingly, laboratory studies showed both pest and predator to be similarly sensitive to indoxacarb, although *Geochoris* could tolerate higher levels of indoxacarb before showing signs of intoxication. However, in treated cotton fields, *Lygus* has been found to be more sensitive to indoxacarb treatment while *Geochoris* has been relatively refractory; further studies showed that this was largely due to infield behavior and the preference of *Geochoris* to feed on pest insects and their eggs as opposed to foliage, which significantly slowed oral indoxacarb uptake (Tillman *et al*., 2001).

In addition, all current evidence points to a SCBI structural requirement for an underivatized urea linkage to be present to exert strong, quasi-irreversible insect Na^+ channel blocking effects, as opposed to derivatized ureas.

6.2.3.2. Catabolism of Indoxacarb and Other Na+ Channel Blocker Insecticides

Relatively little is known about the metabolic breakdown of indoxacarb or other SCBIs in insects. On balance, it is clear that bioactivation is occurring much more rapidly than degradation after field application, when satisfactory insect control is observed. However, like any other novel insecticide, resistance management will be a key to maintaining the agricultural utility of this insecticide class.

Indeed, several field populations of North American oblique-banded leafroller (*Choristoneura rosaceana*) have shown a degree of insensitivity to indoxacarb, which is unique for Lepidoptera (Ahmad *et al*., 2002). Though this insect has never been exposed to indoxacarb for commercial control in the field, it has been treated with several other insecticide classes, including a number of organophosphates. Current studies indicate that resistant strains of this leafroller may be able to catabolize indoxacarb more rapidly than susceptible strains; the specific mechanisms and metabolites are currently being characterized (Hollingworth *et al*., unpublished data).

Interestingly, indoxacarb is apparently degraded primarily by higher animals via routes including cytochrome p450 mediated attack of the indanone and oxadiazine rings, while *N*-decarbomethoxylation is a relatively minor pathway (EPA, 2000; Scott, 2000). The rapid metabolic degradation is a critical factor responsible for the high nontarget animal safety of indoxacarb.

6.2.4. Physiology and Biochemistry of the Na+ Channel Blockers

6.2.4.1. Symptoms of SCBI Poisoning in Insects: Pseudoparalysis

Pyrazolines and indoxacarb produce identical acute neurotoxic symptoms in the American cockroach *Periplaneta americana*, progressing through initial incoordination (5–20 min after 1–10 μg injection), then tremors and prostration, and finally a distinctive pseudoparalysis, so named because the apparently paralyzed insects produce violent convulsions when disturbed. This pseudoparalysis was maintained for 3–4 days, after which the ability to move when disturbed waned. By 4–6 days, the insects could be considered dead. Lower doses caused a similar progression of symptoms, but the time before appearance of symptoms was delayed. This unusual pseudoparalysis was key to unraveling the complex mode of action of this family in insects.

Irreversible pseudoparalysis was also observed in lepidopterous larvae, with disturbance during the pseudoparalyzed state leading to squirming, and tremors of legs and mandibles evident upon microscopic examination. Higher doses of pyrazolines, especially in lepidopterous larvae, led within a few hours to flaccid paralysis (Salgado, 1990). Injection of 10 μg g^{-1} indoxacarb into fifth instar *Manduca sexta* larvae produced excitatory neurotoxic symptoms leading to convulsions and then relatively rapidly to flaccid paralysis (Wing *et al*., 1998). As discussed above, indoxacarb itself is converted *in vivo* to DCMP by esterase-like enzymes. The pseudoparalytic symptoms caused by indoxacarb have also been clearly observed in *Spodoptera frugiperda* larvae treated by injection of 20 μg g^{-1} indoxacarb or DCJW, and also in male *P. americana* injected with 1, 3, or 10 μg g^{-1} DCJW (Salgado, unpublished data).

Under field conditions, after ingesting or being directly sprayed with indoxacarb, insects will irreversibly stop feeding within a few minutes to 4 h; higher doses cause more rapid onset of symptoms.

Higher temperatures increase desiccation and speed of kill. Unlike the pyrethroids, indoxacarb exhibits a positive temperature coefficient. Uncoordinated insects may fall off the plant and desiccate, drown, or become subject to predation. Affected insects can stay alive for 4–96 h, depending on the dose of indoxacarb and susceptibility of the insect. Insects exposed to subparalytic doses eat much less than untreated larvae, develop more slowly, gain less weight, and pupate and emerge later than untreated insects.

6.2.4.2. Block of Spontaneous Activity in the Nervous System

RH-3421 and RH-1211, two highly active pyrazolines, were used as model compounds in an electrophysiological analysis of poisoned *P. americana*, together with RH-5529, which was useful for some experiments because of its ready reversibility (**Figure 1**). The upper panel in **Figure 5** compares extracellular recordings from three parts of the nervous system before and shortly after paralysis with 5 μg g^{-1} RH-3421. The connectives between the second and third thoracic ganglia are major pathways for interneurons within the central nervous system (CNS); the crural nerve is the major leg nerve, with both sensory and motor traffic; and the cercal nerve is exclusively sensory. In all cases, the complete absence of neural activity upon dihydropyrazole poisoning is striking. It has likewise been shown that activity in the CNS connectives of *M. sexta* larvae is completely blocked after paralysis with indoxacarb or DCJW via injection (Wing *et al*., 1998). The lower panel in **Figure 5** shows recordings from *S. frugiperda* larvae before and shortly after paralysis with both DCJW and indoxacarb. In the CNS connectives and also in the ventral nerve roots of the abdominal ganglia, which carry motor and sensory axons, there is no nerve activity in the paralyzed insects. The assessment of the state of the nervous system during poisoning is completed with **Figure 6**, which shows that even in a cockroach paralyzed for 24 h, tactile stimulation of the trochanter could elicit sensory spikes in the crural nerve that in turn initiate reflex motor activity in the same nerve. This is a clear demonstration that axonal conduction and synaptic transmission function more or less normally in paralyzed insects; the evident defect is that the nerves no longer generate action potentials spontaneously.

Normally, even in a quiescent insect, there is background or spontaneous action potential activity in the nervous system arising from pacemaker cells in the CNS and from tonic sensory receptors. Mechanoreceptors exist in many places on the cuticle to detect cuticular deformations or hair

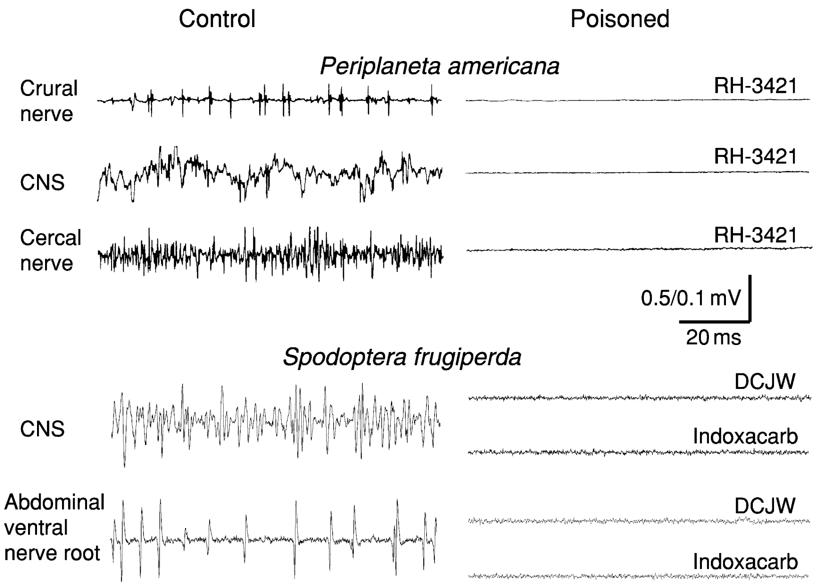

Figure 5 SCBI poisoning inhibits all spike activity in the nervous system. Representative extracellular recordings from the central nervous system (CNS) and peripheral nerves of paralyzed insects and untreated DMSO-injected controls. Adult male cockroaches were treated by injection of 5 μg g^{-1} RH-3421 and fifth instar *Spodoptera* larvae weighing 500 mg were treated with 5 μg g^{-1} DCJW or indoxacarb, 3–4 h before dissection of and recording from the paralyzed insects. (Cockroach data: reproduced with permission from Salgado, V.L., **1990**. Mode of action of insecticidal dihydropyrazoles: selective block of impulse generation in sensory nerves. *Pestic. Sci. 28*, 389–411; © Society of Chemical Industry, permission is granted by John Wiley & Sons Ltd. on behalf of the SCI. *Spodoptera* data previously unpublished.)

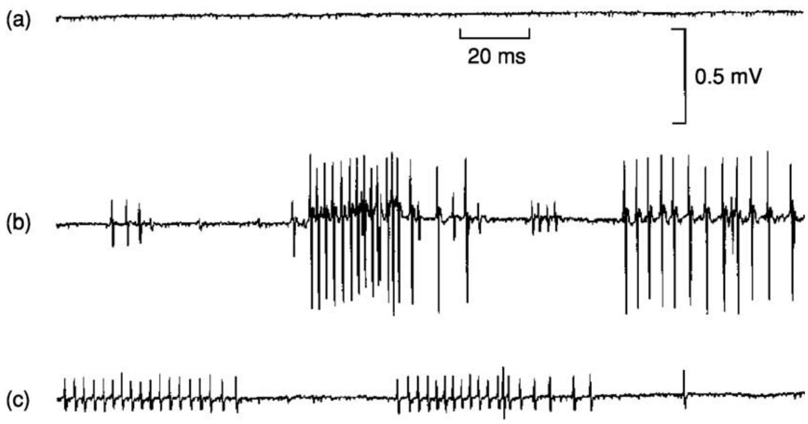

Figure 6 Sensory and motor nerve activity could still be elicited long after the onset of paralysis. These recordings, from nerve 5 (crural nerve) of a cockroach injected 24 h earlier with 5 $\mu g\,g^{-1}$ RH-3421, show that although there was no background activity (trace a), tactile stimulation of the ipsilateral trochanter elicited activity in several axons (trace b). Furthermore, cutting nerve 5 proximal to the recording site abolished the larger spikes (trace c), showing that the remaining smaller spikes were in primary sensory neurons while the larger ones in trace (b) were reflexly evoked motor spikes. (Reproduced with permission from Salgado, V.L., **1990**. Mode of action of insecticidal dihydropyrazoles: selective block of impulse generation in sensory nerves. *Pestic. Sci. 28*, 389–411; © Society of Chemical Industry, permission is granted by John Wiley & Sons Ltd. on behalf of the SCI.)

deflections resulting from stresses due to the body's own movements or to external stimuli, and internally in the form of chordotonal organs or muscle stretch receptor organs to report on joint angles. Mechanoreceptors in general have both phasically and tonically responding sensory cells or units. The phasic units respond with a burst of activity at the start or end of a stimulus, but rapidly adapt in the presence of constant stimuli, because their function is to sensitively detect changes in stimulus level. The tonic units maintain a steady firing rate during stimulus presentation and give rise to slowly adapting sensations. In insect muscle stretch receptor organs, both phasic and tonic functions are subserved by a single neuron. A sudden elongation of this receptor induces firing initially at a high rate, which then declines to a constant rate that is proportional to static elongation, so that both velocity and position are encoded (Finlayson and Lowenstein, 1958).

The complete absence of neural activity in poisoned insects indicates that SCBIs block not only tonic sensory activity, but also pacemaker activity in the CNS. Both of these effects involve action potential generation in regions of neurons that are able to generate action potentials repetitively in response to constant stimuli. The ability of phasic receptors to respond long after paralysis at a high dose (Figure 6), suggests that phasic receptors are not as sensitive as the tonic ones, although they may also be affected at higher doses in Lepidoptera, when insects are completely paralyzed, as mentioned earlier. At this point in the electrophysiological analysis, the pseudoparalysis resulting from SCBI poisoning is apparently due to inhibition of spontaneous activity in tonic sensory receptors and pacemaker neurons. However, excitatory symptoms are also seen during the course of poisoning; a plausible hypothesis is that early in poisoning, before the compound reaches the CNS, sensory receptors in the periphery become blocked. In the absence of adequate sensory feedback to the CNS in response to attempted movements, there would be a tendency to overaccentuate these movements, resulting in the altered posture and gait that is observed. The quiet periods that predominate later in pseudoparalysis may be due to block of pacemaker activity in the CNS. An explanation of the tremors will be proposed below, after the cellular effects of the compounds that cause the observed block are considered. What is noteworthy, however, about the excitatory symptoms arising from a blocking action is the long time period over which apparent excitatory effects can be seen. Compounds with primary excitatory effects on neurons lead to continuous excitation, and within a few hours to complete paralysis due to, among other things, neuromuscular block, as seen for example with pyrethroids (Schouest *et al.*, 1986) or spinosad (Salgado, 1998). Insects poisoned with SCBIs, alternatively, do not suffer this pysiological exhaustion, and can therefore show strong tremors intermittently for several days after poisoning.

6.2.4.3. Block of Na^+ Channels in Sensory Neurons

A deeper understanding of the mode of action of the SCBIs required the investigation of their cellular effects on sensory neurons. Abdominal stretch receptors from cockroach adults and *M. sexta* larvae were shown to be blocked by various pyrazolines

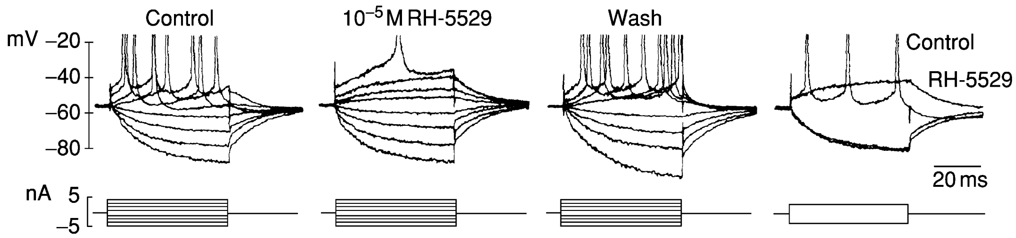

Figure 7 RH-5529 raised the threshold in current-clamped crayfish stretch receptors, without affecting passive membrane resistance. Records show voltage (upper) and current (lower) traces for current steps before, during, and after application of 10 µM RH-5529. Corresponding traces superimposed on the right show that the spike threshold was raised by RH-5529, with no change in resting potential or in the response to hyperpolarizing pulses. (Reproduced with permission from Salgado, V.L., **1990**. Mode of action of insecticidal dihydropyrazoles: selective block of impulse generation in sensory nerves. *Pestic. Sci. 28*, 389–411; © Society of the Chemical Industry, permission is granted by John Wiley & Sons Ltd., on behalf of the SCI.)

(Salgado, 1990), but the slowly adapting stretch receptor (SASR) of the crayfish *Procambarus clarkii* (Wiersma *et al.*, 1953) was selected for studies of the cellular mechanism of action, because the greater size of its neuron enables intracellular recordings at the site of spike initiation.

Pyrazolines blocked the stretch receptor in crayfish with a potency similar to that in insects. In mechanoreceptors, membrane deformation resulting from elongation activates stretch-sensitive ion channels that induce a so-called generator current that depolarizes the membrane of the spike initiation zone to the threshold for action potential generation. In other words, the generator current resulting from mechanosensory transduction is encoded as a spike train in the spike initiation zone. Insertion of a microelectrode into the spike-initiation zone of an SASR neuron allowed the function of this transduction and spike-encoding process to be studied. Figure 7 shows a SASR neuron studied under current clamp, in which current pulses of varying amplitude were injected to either hyperpolarize or depolarize the membrane. Such currents bypass the sensory transduction process and allow direct assessment of the spike-encoding process. The voltage traces in response to the injected currents are shown in the upper row. For negative or hyperpolarizing pulses, represented as downward deflections of both current and voltage, RH-5529 did not affect the membrane response, indicating that it did not affect passive membrane properties (Figure 7). The singular effect of RH-5529 was to raise the threshold for spike generation in response to depolarizing pulses, making it more difficult for injected currents and, by inference, for generator currents, to elicit spikes. From this result, it was immediately clear that voltage-dependent Na^+ channels, whose activation determines the threshold and initiates the action potential, were blocked by the pyrazoline. This was also likely the mechanism of block in the spike initiation zones of CNS pacemaker neurons, where spikes are also generated by the activation of Na^+ channels in response to depolarization by summation of synaptic inputs and pacemaker currents.

6.2.4.4. Mechanism of Na^+ Channel Block

In order to better understand the action of SCBIs on Na^+ channels, further studies were carried out on crayfish giant axons treated with pyrazolines, with techniques that allowed the study of Na^+ channels under highly controlled conditions. A first hypothesis to explain the insensitivity of axonal Na^+ channels to pyrazolines was that the compounds block Na^+ channels in a voltage-dependent manner, and are therefore selective for channels in the spike initiation zone. Voltage-gated Na^+ channels are complex proteins, whose function is regulated by membrane potential through voltage-dependent conformational changes occurring on a timescale from less than a millisecond to several seconds (Pichon and Ashcroft, 1985). At the spike initiation zone, neurons operate near the threshold for action potential generation, in the range of −70 to −50 mV, where important conformational changes in Na^+ channels occur prior to opening. In contrast, axons have a resting potential near −90 mV, where Na^+ channels are predominantly in the resting state. However, when axons are depolarized to the range where Na^+ channels begin to undergo conformational changes, they become sensitive to pyrazolines (Salgado, 1990). Likewise, the extracellularly recorded compound action potential from motor nerves of *M. sexta* abdominal ganglia, which was likewise highly insensitive to DCJW, was rendered sensitive by depolarization of the nerves with a high K^+ saline (Wing *et al.*, 1998).

Figure 8 shows membrane currents evoked by test pulses to 0 mV before and after equilibration with 10 µM RH-3421 at various holding potentials. For each trace, after initial rapid downward and upward transients, the current became inward and peaked

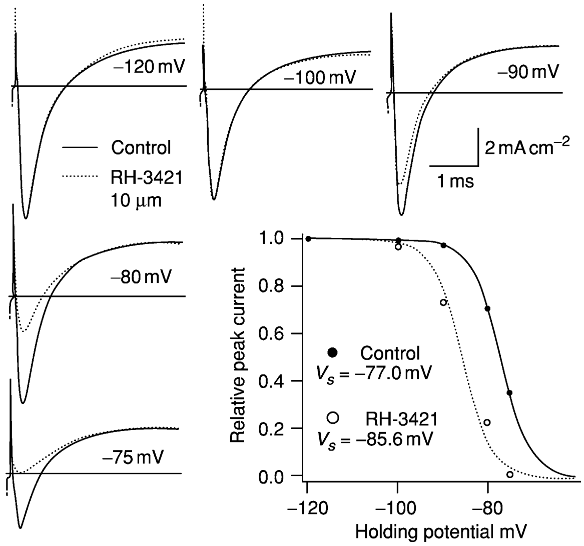

Figure 8 Dihydropyrazole block appears as a parallel shift of the steady state slow inactivation curve in the direction of hyperpolarization. Ionic current traces were scaled by a common factor so that the peak at −120 mV matched the peak before treatment with the dihydropyrazole. Peak I_{Na} was depressed most at depolarized potentials, whereas outward current, I_K, was not affected by the treatment. The graph shows plots of peak current normalized to the value at −120 mV. RH-3421 (10 μM) appears to shift the steady state inactivation relation to the left by 8.6 mV. (Reproduced with permission from Salgado, V.L., **1992**. Slow voltage-dependent block of Na^+ channels in crayfish nerve by dihydropyrazole insecticides. *Mol. Pharmacol. 41*, 120–126; © American Society for Pharmacology and Experimental Therapeutics.)

within 0.5 ms, then reversed and became outward. The inward (downward) peak is the Na^+ current and the outward (upward) steady state current is the K^+ current (Pichon and Ashcroft, 1985). Depolarization of the axon to potentials more positive than −90 mV in the control suppressed the Na^+ current by a process known as inactivation, which in this case had a midpoint potential of −77 mV. Na^+ channels have two partially independent inactivation processes, known as fast and slow inactivation. Fast inactivation occurs on a millisecond timescale and serves to terminate the action potential, while slow inactivation occurs on a much slower timescale, over hundreds of milliseconds, and performs a slow, modulatory function. Slow inactivation occurs at more negative potentials than fast inactivation, and is responsible for the inactivation seen in Figure 8. After equilibration of the axon with RH-3421, there was no effect on either Na^+ or K^+ current at −120 or at −100 mV (Figure 8). At more depolarized potentials, however, the Na^+ current was specifically depressed by RH-3421, whereas the K^+ current was unaffected. When peak Na^+ current is plotted against membrane potential, it appears that

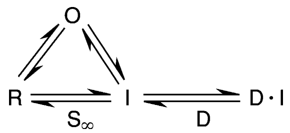

Figure 9 A model showing the resting (R), Open (O), and inactivated (I) states of the Na^+ channel, and specific interaction of the SCBIs (D) with the inactivated state.

RH-3421 has shifted the slow inactivation curve by 9 mV to the left.

The next step in the analysis is to consider the mechanism of this apparent shift of slow inactivation. Whereas fast inactivation occurs with a time course of hundreds of microseconds to a few milliseconds, and slow inactivation on the order of tens to hundreds of milliseconds, the changes in peak Na^+ current in the presence of SCBIs occur on a much slower timescale, on the order of 15 min. This slow readjustment of peak current in response to voltage change can therefore be attributed to a new process: the binding and unbinding of SCBIs to Na^+ channels.

The Na^+ channel undergoes transitions between many different conformations or states, which can be grouped into resting (R), open (O), and inactivated (I) states, each of which may have several substates. The transitions between these naturally occurring states are shown on the left in Figure 9. In this simplified model, $S_\infty = [R]/[R] + [I]$, is the steady-state slow inactivation parameter, which depends on membrane potential according to

$$S_\infty = \frac{1}{1 + \exp[(V - V_S)/k]} \qquad [1]$$

where V is membrane potential, V_S is the potential at which $S_\infty = 0.5$ (half of the channels are in the inactivated state), and k is a constant that includes the Boltzmann constant and describes the voltage sensitivity of the inactivation process (Hodgkin and Huxley, 1952).

This model ignores the fast-inactivated state, but interaction of the SCBIs with the channels is so slow, that it and the open state, O, can be ignored in the analysis. The observed enhancement of slow inactivation can be explained if we assume that the SCBI drug (D) binds selectively to an inactivated state, as also shown on the right-hand side in the model (Figure 9). Drug binding would then effectively remove channels from the I pool, which would be compensated for by mass action rearrangements among the other states, leading to net flux of more receptors from the R pool into the I and D • I pools. $K_I = [D] \times [I]/[D \bullet I]$ is defined as the equilibrium dissociation constant of the D • I complex.

In the presence of SCBI drug, two processes lead to the decrease in current upon depolarization: slow

inactivation and drug binding. Fortunately, slow inactivation can be removed from the measurements by hyperpolarizing to −120 mV before applying the depolarizing pulse to measure the peak current. Figure 10a shows the time course of block after stepping from −120 mV to various depolarized potentials, in an axon equilibrated with 1 μM RH-1211. The pulse protocol, shown in the inset in panel A (Figure 10), includes a 500 ms hyperpolarizing

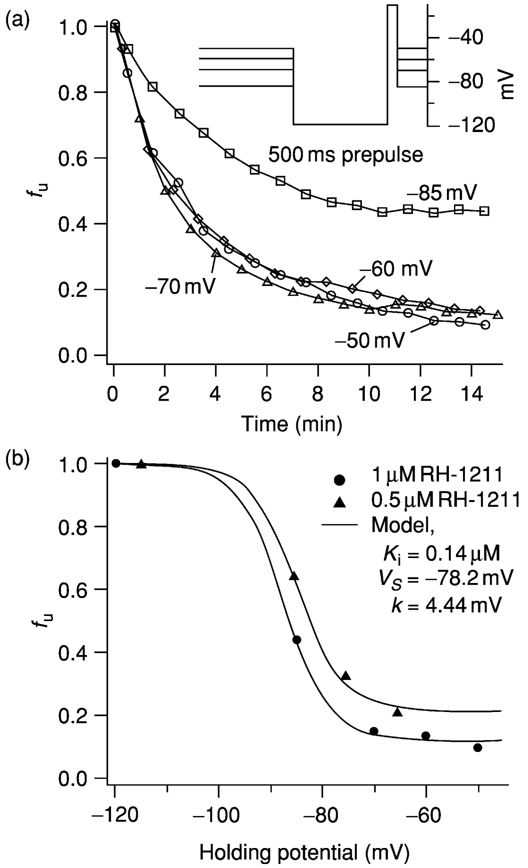

Figure 10 Block is asymptotic at strong depolarizations. The model predicts that block of Na^+ channels by SCBIs is voltage dependent only over the voltage range over which inactivation occurs. In order to observe block directly at strong depolarizations, where inactivation is complete, the axon was held at various potentials as in **Figure 8**, but a 500 ms hyperpolarizing prepulse to −120 mV was applied just before the 10 ms test pulse, during which I_{Na} was measured (see inset protocol). The prepulse was of sufficient amplitude and duration to remove inactivation completely, without interfering with block. (a) Time course of f_u, the fraction of channels unblocked, following steps from −120 mV to various other potentials, in an axon equilibrated with 1 μM RH-1211. Steady state block from this and another axon treated with 0.5 μM RH-1211 are plotted in (b). The solid curves in (b) were plotted according to eqn [2], with $K_i = 0.14$ μM, $V_h = 78.2$ mV, and $k = 4.44$ mV. (Reproduced with permission from Salgado, V.L., **1992**. Slow voltage-dependent block of Na^+ channels in crayfish nerve by dihydropyrazole insecticides. *Mol. Pharmacol. 41*, 120–126; © American Society for Pharmacology and Experimental Therapeutics.)

prepulse to −120 mV before each test pulse, which was long enough to completely remove slow inactivation, but not long enough to permit significant dissociation of D • I complexes, thus allowing direct assessment of block. The fraction of channels unblocked, f_u, is plotted against time, and shows that block, which is equivalent to the formation of D • I complexes, occurs with a time constant of 5–6 min at 1 μM. The voltage dependence occurs only over the range where slow inactivation occurs, saturating near −70 mV. This is seen clearly in Figure 10b, where f_u is plotted against holding potential. In terms of the model shown above, $f_u = ([R] + [I])/([R] + [D \bullet I] + [I])$. Substituting the above relations for K_I and S_∞ and eqn [1] into this expression, an equation for f_u as a function of [D] and V can be derived:

$$f_u = \frac{1}{1 + \frac{[D]}{K_I}\left(\frac{1}{1 + \exp[(V_S - V)/k]}\right)} \qquad [2]$$

The solid curves in Figure 10 were calculated from this equation, using a K_I of 140 nM, $V_S = -78.2$ mV and $k = 4.44$ mV, and fit the data quite well.

The quantitative correspondence of the blocking voltage dependence with model predictions supports the hypothesis that SCBIs bind selectively to the slow-inactivated state of the channel, in comparison with the resting state. However, because of the very slow binding reaction, in the equilibrium studies described to this point, only the resting and slow-inactivated states are populated significantly enough to participate in drug binding. In order to test whether SCBIs bind to the fast-inactivated state, the slow inactivation gate was removed by pretreatment of the internal face of the axon membrane with trypsin. After this pretreatment, block by the pyrazoline RH-1211 at −90 mV was comparable to that in intact axons, indicating that RH-1211 can block fast-inactivated channels as well. Treatment of the axon internally with the protein-modifying reagent *N*-bromoacetamide (NBA) is known to remove the fast inactivation gate. Pretreatment of axons with both trypsin and NBA therefore yields Na^+ channels that do not inactivate. At depolarized potentials, RH-1211 was just as potent at blocking these noninactivating channels as intact channels, showing that it can also block open channels (Salgado, 1992).

The metabolic bioactivation of DPX-JW062 and indoxacarb to *N*-decarbomethoxylated metabolites and the similarity of the mode of action of DCJW to pyrazolines was established by Wing *et al.* (1998), who showed that spontaneous activity and action

potential conduction in the CNS of *M. sexta* were blocked, consistent with block of Na^+ channels. These workers also established that the DCJW Na^+ channel block was voltage-dependent. Subsequently, studies in dorsal unpaired median (DUM) neurons isolated from the CNS of *P. americana* with the patch clamp technique have also shown the action of DCJW on Na^+ channels (Lapied *et al.*, 2001). Action potentials in these pacemaking neurons were blocked by 100 nM DCJW, and this action was shown to be due to block of voltage-dependent Na^+ channels. The block was very potent, with a 50% inhibitory concentration (IC_{50}) of 28 nM at −90 mV, in good agreement with the IC_{50} of racemic DCJW of 40 nM in blocking the compound action potential in *M. sexta* CNS determined by Wing *et al.* (1998). In addition, Wing *et al.* (1998) showed that *M. sexta* compound action potential block by DCJW was stereospecific for the *S*-enantiomer, which is also the only enantiomer toxic to insects.

Although the SCBIs enhance slow inactivation, it is important to realize that the slow inactivation of any particular channel is not affected. Instead, slow inactivation of the entire population of channels is enhanced because of the addition to the system of the highly stable SCBI-bound slow-inactivated state. In the presence of the SCBI, time for this very slow equilibration of the drug with the receptors must be allowed in order to measure slow inactivation properly. It is not enough to simply measure slow inactivation with pulses long enough to attain a steady state in the absence of SCBI. While pulses on the order of 1 s are long enough to attain steady-state slow inactivation in control axons, 15 min are required in the presence of insecticide (Salgado, 1992). Direct measurements of the effect of DCJW and indoxacarb on Na^+ channels have until now only been carried out with the whole cell voltage clamp method. With this technique, it is difficult to make measurements from a single cell for more than 30 min, so it is difficult to measure the effects of these slow-acting insectides under steady state conditions. The block on washing of DCJW requires at least 15 min to reach a steady state level and appears to be irreversible (Lapied *et al.*, 2001; Tsurubuchi and Kono, 2003; Zhao *et al.*, 2003). However, after equilibration of the cell with DCJW at a negative holding potential, the level of block increases in response to membrane depolarization on a faster time course, with steady state levels being attained within 2–3 min (Zhao *et al.*, 2003). Using 3 min conditioning pulses, Zhao *et al.* (2003) demonstrated that DCJW indeed enhanced slow inactivation of two different Na channel subtypes studied in isolated neurons; shifts of 12–13 mV in the direction of hyperpolarization were observed.

An additional effect on the *P. americana* DUM neurons observed by Lapied *et al.* (2001) was a strong hyperpolarization of the resting potential, associated with an increase in membrane resistance, indicating the block of a depolarizing conductance, thought to be the background Na^+ channels involved in the maintenance of the resting potential in these pacemaking neurons and characterized by Lapied *et al.* (1989, 1999). This finding is extremely interesting and should be investigated in more detail, because it demonstrates the existence of a second potential target site for SCBIs.

6.2.4.5. SCBIs Act at Site 10 on the Na^+ Channel

The voltage-dependent Na^+ channel blocking action of pyrazolines was immediately recognized as being similar to that of local anesthetics, class I anticonvulsants, and class I antiarrhythmics (Salgado, 1992), a structurally broad range of drugs (Clare *et al.*, 2000; Anger, 2001) all known to act at a common blocker site within the Na^+ channel pore. Consistent with the nomenclature of Soderlund (see **Chapter 5.1**), this will be called site 10. Like the SCBIs, drugs acting at site 10 all exhibit voltage dependence of block, deriving from selective binding to open and inactivated channel states.

Drugs acting at site 10 displace the binding of the radioligand [^{3}H]batrachotoxin (BTX)-B from the BTX binding site in the Na^+ channel (Postma and Catterall, 1984; Catterall, 1987). The interaction is clearly allosteric, because local anesthetics can block BTX-modified open channels without displacing the toxin (Wasserstrom *et al.*, 1993; Zamponi *et al.*, 1993), although they speed the dissociation rate of BTX from its binding site. Pyrazolines were also shown to potently displace specific binding of [^{3}H]BTX-B (Deecher *et al.*, 1991; Salgado, 1992). Payne *et al.* (1998) further examined the interaction between the pyrazoline RH-3421 and the local anesthetic dibucaine in BTX binding studies. Each of these compounds decreased the potency of the other as an inhibitor of BTX binding approximately as much as expected from the assumption that they share a common binding site. Furthermore, RH-3421 increased the dissociation rate of [^{3}H]BTX-B from its binding site, also expected from an action at site 10 (Deecher *et al.*, 1991).

Lapied *et al.* (2001) examined the interactions of DCJW with the local anesthetic lidocaine and the guanidinium blocker tetrodotoxin, which is known to block the pore from the external face, at a binding

site distinct from the local anesthetics (see **Chapter 5.1**). The IC_{50} for DCJW was not affected by the presence of an IC_{50} concentration of tetrodotoxin (TTX) in the external solution, consistent with independent action of the two compounds at distinct binding sites. In the presence of an IC_{50} concentration of lidocaine, however, the IC_{50} for DCJW was increased about 30-fold. A twofold shift in equilibrium binding would be expected from the hypothesis that both compounds act at the same site (Cheng and Prusoff, 1973), so the mechanism of the observed 30-fold shift is not fully understood. Nevertheless, available evidence is consistent with the action of the SCBIs at site 10.

Studies on permanently charged quaternary derivatives of local anesthetics were crucial in localizing site 10 within the Na^+ channel pore. Being permanently charged, these molecules cannot cross membranes and are therefore not clinically useful. However, when applied within the cell, they are able to enter the channel from the internal mouth, only when the channel is open, giving rise to a phenomenon known as use dependence – increase in the number of blocked channels with stimulation. Because the permanently charged quaternary molecule cannot fit through the ion-selective constriction in the channel known as the selectivity filter, it remains trapped within the channel after activation gate closure. Alternatively, more lipophilic compounds acting at site 10, when caught within the closed channel, can diffuse out laterally through lipophilic pathways in the channel wall. SCBIs behave like local anesthetics with very slow kinetics, and do not display use dependence (Zhao *et al.*, 2003), suggesting that the insecticides can only access the binding site from the lipophilic pathway and not through the internal mouth of the pore.

In addition to modulation of blocker access to the binding site by the activation gate, channel gating also modulates the equilibrium binding affinity of the channel for the molecules. Like the pyrazolines and DCMP/DCJW, there is little affinity of the blocker molecule for the resting state, but strong binding to the open and inactivated states. The bound molecule is thought to lie in a hydrophobic pocket that can be reached via either the aqueous or hydrophobic pathways. When bound, the molecule is thought to lie within the pore and block ion flow through it. Several excellent reviews on the interaction of blocking drugs with Na^+ channels have recently been published (Clare *et al.*, 2000; Anger *et al.*, 2001; Wang and Wang, 2003).

The fact that blockers acting at site 10 bind strongly to a number of states after channel opening but not to the resting state, indicates that the movements of the S6 segments (see Section 6.2.4.6) associated with channel activation lead to formation of the receptor for these compounds. The subsequent fast and slow inactivation steps are thought to involve processes at the internal membrane face that involve blocking of the pore by a so-called inactivation particle, presumably without further significant changes in the conformation of site 10 (see **Chapter 5.1**).

6.2.4.6. The Molecular Nature of Site 10 in Insects

The primary structure of the Na^+ channel α subunit consists of four homologous repeat domains (D1 to D4), each with six transmembrane segments S1 to S6. The six transmembrane segments of each domain are thought to be arranged into a quasicylindrical pseudosubunit, and all four of these pseudosubunit domains are arranged in pseudotetrametric fashion, forming the Na^+ channel pore in the space between them (see **Chapter 5.1**).

The existence of several mutations in the S6 segments from domains 1, 3, and 4 that affect potency of both tertiary and quaternary local anesthetics, the latter of which have access to the receptor only through aqueous pathways, indicates that the S6 segments line the pore of the Na channel (**Figures 11 and 12**). The voltage sensor for activation gating has been localized, also using site-directed mutagenesis, to the positively charged S4 segments, which are thought to exhibit voltage-dependent outward and/or rotary movements to open the activation gate, which is thought to be located at the cytoplasmic ends of the S6 segments. Although the voltage sensors are located on the S4 segments, their movement appears to be coupled to critical movements of the S6 segments, leading to opening of the activation gate at the cytoplasmic S6 ends, and modulation of three receptor sites known to be associated with the midsections of the S6 segments: the blocker site (site 10), the pyrethroid site (site 7), and the BTX site (site 2) (**Figure 13**). Several amino acid residues clustered around the middles of the S6 segments which, when mutated, affect binding of compounds to these sites, have been identified, and those associated with the binding of Na^+ channel blocking drugs have been the subject of much recent research because they potentially identify the faces of the S6 segments that face the pore (Yarov-Yarovoy *et al.*, 2002). These mutations are colored red in the sequence alignments in **Figure 11**. **Figure 12** shows a helical wheel representation of the four S6 segments arranged according to Kondratiev and Tomaselli (2003), who have only considered the residues

Figure 11 Sequence alignment of the pore-forming S6 transmembrane segments from various arthropod pest species, to show the location of residues known to be important for binding of local anesthetics (red), batrachotoxin (underscored), and pyrethroids (blue). Residues conforming with the consensus sequence are shown with a gray background.

known to affect blocker affinity, without alterations in the voltage dependence or kinetics of gating that would otherwise account for an increase in the IC_{50} for block. The S6 segments can be arranged so that all such residues, shown in red, face into the pore. A total of 10 residues affecting BTX action have also been identified scattered among the middle of all four S6 segments (Wang and Wang, 2003), but it is not yet clear if these are all associated with the binding site.

Residues in the S6 segments of domains 1, 2, and 3 that are known to affect pyrethroid sensitivity (see **Chapter 5.1**) are shown in blue in **Figures 11 and 12**. These are on the sides thought to face away from the pore. Mutations conferring pyrethroid resistance have also been identified in the S5 segments, indicating that the pyrethroid receptors may be located at the interfaces between S5 and S6 segments. The number of pyrethroid receptors per channel is not certain, but the locations of the resistance mutations in the S6 segments suggests that there could be as many as four receptors. Interestingly, quantitative studies with tetramethrin isomers on squid axon Na^+ channels indicated that there may be at least three pyrethroid receptors in each channel (Lund and Narahashi, 1982).

The extremely high conservation of the S6 segments among the arthropods compared in **Figure 11** is striking. The residues associated with the binding sites are all absolutely conserved. However, the P loops in the extracellular S5–S6 connecting segments dip deep into the external mouth of the barrel formed by the S6 segments to form the selectivity filter and the outer boundary of the inner chamber containing site 10 (Cronin *et al.*, 2003). The contributions of the P loops to the binding of blockers in site 10 have not yet been explored. **Figure 13** shows a diagram summarizing current knowledge of the locations of the S4, S5, and S6 segments and the three receptors associated with the S6 segments. TTX is also shown, binding to site 1 at the external mouth of the channel.

6.2.4.7. Biochemical Measurements of the Effects of SCBIs

While electrophysiology and in particular voltage-clamp measurements are essential for studying the detailed interactions of drugs with ion channels, certain receptor binding techniques are also useful, especially when quantitative potency data on many compounds is needed. Displacement of [^{3}H]BTX-B

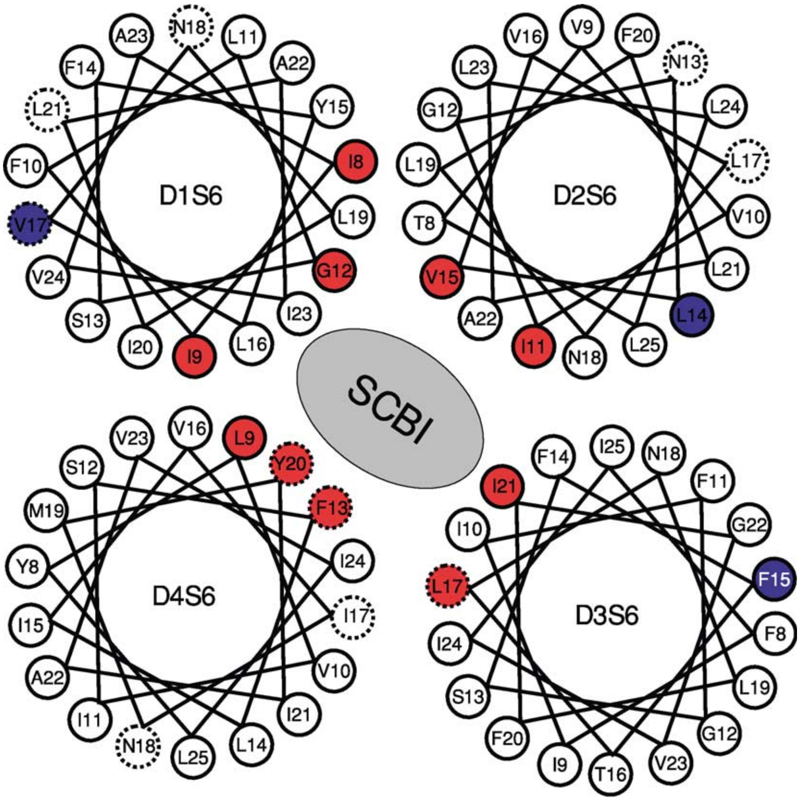

Figure 12 Helical wheel representation of residues 8–25 of the four S6 transmembrane segments arranged so that the residues known to be important for blocker binding (red) face the pore. Pyrethroid-binding residues are blue and BTX-binding residues are shown as broken circles. (Adapted from Kondratiev, A., Tomaselli, G.F., **2003**. Altered gating and local anesthetic block mediated by residues in the I-S6 and II-S6 transmembrane segments of voltage-dependent Na^+ channels. *Mol. Pharmacol. 64*, 741–752; and Wang, S.Y., Wang, G.K., **2003**. Voltage-gated Na^+ channels as primary targets of diverse lipid-soluble neurotoxins. *Cell Signal. 15*, 151–159.)

has been used effectively to quantify the potency of pyrazolines on Na^+ channels. The quantitative correspondence with electrophysiology and biological activity is good (Deecher *et al*., 1991; Salgado, 1992), and this is the method of choice for structure–activity relationship studies.

Block of the Na^+ flux through channels activated by the activator veratridine has also been used to measure effects of dihydropyrazoles. In this case, Na^+ flux can be assessed directly as flux of $^{22}Na^+$ into membrane vesicles (Deecher and Soderlund, 1991), or indirectly from the resulting depolarization as measured by voltage-sensitive dyes (Nicholson, 1992) or depolarization-triggered release of preloaded radiolabeled neurotransmitter (Nicholson and Merletti, 1990). With flux assays, however, veratridine is often used at a high concentration in order to achieve a strong signal, but since this activator acts at the BTX site, it inhibits the action of the pyrazolines (Deecher and Soderlund, 1991) and thereby interferes with accurate potency measurements.

6.2.4.8. Intrinsic Activity of Indoxacarb on Na^+ Channels

The initial mode of action studies with indoxacarb indicated that it was a proinsecticide, being metabolized to DCJW, which potently blocked the compound action potential in *M. sexta* nerve in a voltage-dependent manner (Wing *et al*., 1998). Indoxacarb itself also had this effect, but was much slower acting; while 1 μM DCJW blocked the compound action potential by 50% after 10 min, 40 min were required for indoxacarb to exert this same effect, and in that preparation one cannot be certain that the compound is not metabolized to DCJW within the ganglion. However, studies on patch-clamped neurons, which cannot metabolize the compound, confirmed that indoxacarb indeed has intrinsic activity on Na^+ channels. The effects of the two compounds were comparable, but while indoxacarb block was reversible with about 5 min washing or with hyperpolarization, block by DCJW was not reversible with either washing or hyperpolarization (Tsurubuchi and Kono, 2003; Zhao *et al*., 2003).

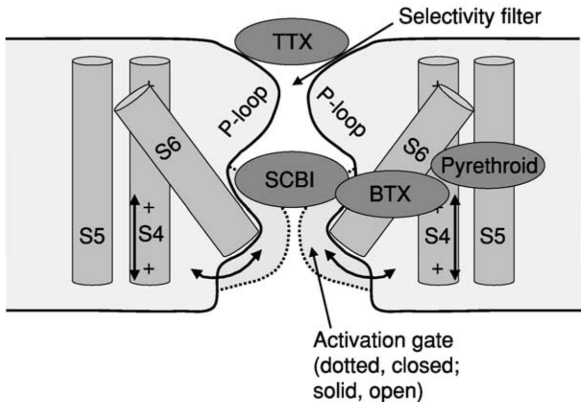

Figure 13 Diagrammatic representation of the location of the binding sites associated with the S6 segments of the Na^+ channel. The extracellular mouth of the channel is at the top of the figure. Two sets of the S4, S5, and S6 transmembrane helices are shown. Bidirectional arrows show the movements of the S4 and S6 segments associated with activation gating. The thick solid curves show the outline of the channel protein in the activated or open conformation, and the thick dotted line shows the activation gate at the cytoplasmic end of the S6 segments in the closed position. There is one tetrodotoxin (TTX) and one Na^+ channel blocker insecticide (SCBI) binding site per channel, but the number of batrachotoxin (BTX) and pyrethroid sites is not certain, although only one of each is shown. All three drug sites are in the middle of the S6 segments, and the pyrethroid site also includes residues in segment 5.

Table 2 Action of DCJW and indoxacarb on the abdominal stretch receptor organ of *Spodoptera frugiperda*

	Average percent block (five preparations, in exposure)	
Concentration[a] (M)	*DCJW*	*Indoxacarb*
3e-9	0	0
1e-8	40	0
3e-8	100	25
1e-7	100	60
3e-7	100	100

[a] In a saline containing, in mM, 28 NaCl, 16 KCl, 9 $CaCl_2$, 1.5 NaH_2PO_4, 1.5 mgCl_2, and 175 sucrose, pH 6.5, the stretch receptor fired continuously for several hours between 25 and 75 Hz.

The actions of indoxacarb and DCJW were also compared quantitatively on the abdominal stretch receptor organs of *S. frugiperda* (Table 2). In this preparation, the insecticides in solution are perfused rapidly over the body wall containing the stretch receptor, a small, thin organ directly exposed to the saline. Significant metabolism in this preparation is unlikely, but cannot be excluded. The organ fires continually at a rate of between 25 and 75 Hz for many hours, and is very sensitive to block by SCBIs. DCJW blocked activity consistently within 20–40 min at 3×10^{-8} M, but in five tests at 10^{-8} M the average percent block within 1 h was 40%. Indoxacarb was also intrinsically active, but 3- to 10-fold weaker than DCJW, blocking consistently at 3×10^{-7} M, but only 60% within 1 h at 1×10^{-7} M and 25% at 3×10^{-8} M.

In conclusion, it appears that indoxacarb is weaker (about three to ten times) than DCJW on Na^+ channels, and that the block is readily reversible. Furthermore, the much slower effect of indoxacarb on the compound action potentials in *M. sexta* ganglia in comparison with DCJW indicates that indoxacarb enters the ganglion much more slowly than does DCJW. Based on the appearance of insect symptoms concurrent with the appearance of high levels of metabolically formed DCJW in larval Lepidoptera (Wing *et al.*, 1998, 2000) and the greater potency and irreversibility of DCJW Na^+ channel block, it appears that the toxicologically significant compound after indoxacarb or DPX-JW062 administration is DCMP or DCJW, respectively.

6.2.4.9. Effects of SCBIs on Alternative Target Sites

Other possible target sites for SCBIs have been considered. The voltage-gated Ca^{2+} channel α subunits belong to the same protein superfamily as the voltage-gated Na^+ channels, and have a similar structure, composed of 24 transmembrane segments arranged into four domains of six segments each. Not unexpectedly, Ca^{2+} channels were also found to be blocked by pyrazolines, although at higher concentrations than Na^+ channels (Zhang and Nicholson, 1993; Zhang *et al.*, 1996). So far, there is no evidence that Ca^{2+} channel effects are significant in insect poisoning. In the initial work on the pyrazolines, it was observed in paralyzed cockroaches and *M. sexta* larvae that the heart continued to beat normally, and conduction across the cholinergic cercal–giant fiber synapses as well as γ-aminobutyric acid (GABA) and glutamate synapses on muscle, all Ca^{2+} channel-dependent processes, functioned normally (Salgado, 1990). Furthermore, DCJW had no effect on low-voltage activated and high-voltage activated calcium currents in isolated cockroach neurons (Lapied *et al.*, 2001).

A strong hyperpolarization of *M. sexta* muscle, on the order of 20 mV, was observed after poisoning by pyrazolines (Salgado, 1990). The effect was not reversible with prolonged washing and could not be reproduced by treatment with pyrazoline in solution, and therefore appears to be secondary and not related to the hyperpolarization of DUM neurons observed by Lapied *et al.* (2001). Muscles of *Periplaneta* or *Musca* were not hyperpolarized during pyrazoline poisoning (Salgado, 1990).

Table 3 Potency of indoxacarb to pest insects in the laboratory: larval ingestion and contact vs. adult contact

	Insecticidal potency of indoxacarb (LC_{50} values, ppm)		
		Direct spray contact	
Insects	*Ingestion*	*Larvae*	*Adults*[a]
Heliothis virescens	1.47	12.96	56
Helicoverpa zea	0.68	2.55	
Spodoptera frugiperda	0.61	5.25	
Spodoptera exigua	1.96	7.66	
Trichoplusia ni	0.28		45
Plutella xylostella	3.69		30
Empoasca fabae	1.11		
Cydia pomonella	7.68		
Lygus lineolaris	1.46		

[a] Toxicity measured with methylated seed oil (1%) or vegetable oil plus organosilicone surfactant (0.5%) at 7 days posttreatment.

6.2.5. Biological Potency of Indoxacarb

6.2.5.1. Spectrum and Potency of Indoxacarb in the Laboratory

Laboratory assays show that lepidopteran, hemipteran, and homopteran pests are inherently very sensitive to indoxacarb, and are significantly more affected when indoxacarb is ingested (Wing *et al.*, 2000). When treated plant leaves were fed to a variety of lepidopterous larvae, this resulted in 50% lethal concentration (LC_{50}) values ranging from 0.3 to 7.7 ppm when evaluated 3 days posttreatment (**Table 3**). These values are similar to LC_{50} values published by other researchers (Seal and McCord, 1996; Pluschkell *et al.*, 1998; Liu and Sparks, 1999; Liu *et al.*, 2002; Giraddi *et al.*, 2002; Smirle *et al.*, 2002; Ahmad *et al.*, 2003; Liu *et al.*, 2003), and indicates the high toxicity of this compound to Lepidoptera. Indoxacarb halts insect feeding within 4 h after ingestion. Insect mortality generally takes place within 2–4 days, and it is critical to evaluate both mortality after 72 h and feeding damage to assess the compound's true effectiveness. *Trichoplusia*, heliothines, and *Spodoptera* are the most sensitive among the lepidopterans while *Plutella* and *Cydia* are somewhat less sensitive. Variation in activity among species may be due to the rate of bioconversion of indoxacarb to the active metabolite DCJW or to the amount of product consumed. Insecticidal activity of indoxacarb against the sucking insects *Empoasca fabae* and *L. lineolaris* in the laboratory are similar to that of the lepidoptera (**Table 3**). Lepidopteran adults were also effected when they ingested a sugar water solution with indoxacarb.

The ingestion activity of indoxacarb to lepidopteran larvae is about three to nine times greater than its dermal contact activity (**Table 3**). For some insects however, such as *Lobesia botrana*, the potency of the two modes of entry is almost equivalent (Anonymous, 2000). Indoxacarb shows negligible activity when insects walk on a dried residue, and has no activity as a fumigant.

Indoxacarb was also significantly less active as a direct contact spray to moths compared to larvae; however, it is still effective. Directly spraying lepidopteran moths with indoxacarb plus methylated seed oil at 1% or a vegetable oil plus organosilicone surfactant at 0.5% resulted in LC_{50} values ranging from 30 to 56 ppm for lepidopteran adults at 7 days post treatment (**Table 3**). The ability of indoxacarb to provide moth control or suppression in the field will contribute to overall pest suppression.

Indoxacarb has inherent toxicity to select coleopteran (Parimi *et al.*, 2003), hemipteran (*Lygus*), homopteran (*Myzus*, *Empoasca, Nephotettix, Nilaparvata*), and dipteran (Chen *et al.*, 2003) pests after feeding on treated leaves or artificial diets (Wing *et al.*, 2000) (**Table 3**). Indoxacarb has low water solubility; however, leaf penetration and translaminar activity are responsible for controlling certain sucking pests and is enhanced by inclusion of oil-based formulations or tank-mixed adjuvants. Indeed, the compound is toxic in the field to plantbugs, fleahoppers, and leafhoppers; however, it is ineffective against species such as aphids because of poor systemicity and low phloem oral bioavailability. Overall, indoxacarb's utility as a field insecticide active against sucking insects is constrained by its very limited systemicity, compared to many neonicotinoids.

Indoxacarb exhibits ovilarvicidal activity on Lepidoptera such as *L. botrana*, *Eupoecilia ambiguella, Heliothis armigera*, and *Cydia pomonella* (Anonymous, 2000). Laboratory data indicates

that the probable mechanism of ovilarvicidal activity is due to adsorption of indoxacarb into the chorion and subsequent oral uptake as the neonate chews through the chorion to hatch. Indoxacarb directly sprayed onto the egg is more effective than placed in a dried residual deposit on which the eggs are laid.

6.2.5.2. Safety of Indoxacarb to Beneficial Insects

Beneficial insects walking over a dried residue of indoxacarb on a leaf are generally unaffected, as shown by Mead-Briggs *et al.* (1996) with the hoverfly *Episyrphus balteatus* and predatory mite *Typhlodromus pyri*. Indoxacarb is safe to the parasitoids *Eurytoma pini, Haltichella rhyacioniae, Bracon* sp., and *Macrocentrus ancylivorus* (Nowak *et al.*, 2001), *Cotesia marginiventris* and *Trichogramma pretiosum* (Ruberson and Tillman, 1999) and for the predator *G. punctipes* (Tillman *et al.*, 1998). Williams *et al.* (2003), Musser and Shelton (2003), Michaud and Grant (2003), Tillman *et al.* (2001), and Baur *et al.* (2003) also reported the safety of indoxacarb to beneficial insects. The insecticidal selectivity of indoxacarb against herbivorous pests is explained by Andaloro *et al.* (2000). There is little movement of product through the tarsi of insects thus rendering carnivorous predators and parasitic wasps largely insensitive to indoxacarb. However, any insect behavior that culminates in ingestion of the product, such as preening (ants), probing (nabids), or lapping exudates from the leaf (apple maggot flies) will impact insect survival. Indoxacarb controls fire ants, *Solenopsis* spp., on crops (Turnipseed and Sullivan, 2000) as a result of ants preening their antennae and legs, and subsequent ingestion of preened materials. Indoxacarb is formulated on a 5–7 μm silica particle and may readily adhere to the body of the insect through antennal drumming behavior and general locomotory activity.

6.2.5.3. Sublethal Effects of Indoxacarb

Liu *et al.* (2002) observed numerous effects of indoxacarb on the development of cabbage looper (*Trichoplusia ni*) larvae feeding on field-aged leaf residues 18–20 days old as well as on subsequent pupae and emerging adults. These effects were also documented on heliothine and *Spodoptera* species fed on diet with indoxacarb at 0.1 and 0.01 ppm (Andaloro, unpublished data). Larval development was greatly extended compared to the untreated check; survivors pupated 1–2 weeks later. Treated larvae were much smaller than untreated larvae. Some larvae could not molt or pupate properly, with exuvia remaining attached and sometimes severely restricting the body. Treated lepidopteran larvae and Colorado potato beetle (*Leptinotarsa decemlineata*) larvae sometimes are unable to dig into the soil and thus pupate on top of the soil. In the laboratory, lepidopteran adults emerging from treated larvae often have abnormal wings or are unable to fly. *Liriomyza* adults whose larvae were exposed to leaves treated with sublethal doses of indoxacarb emerged disoriented, stumbling, and unable to fly (Leibee, unpublished data). There are sufficient data indicating indoxacarb has significant growth regulating effects on the larvae, pupae, and adults of pest insect species observed which contribute to overall suppression of the field population.

6.2.5.4. Spectrum and Insecticidal Potency of Indoxacarb in the Field

Indoxacarb is active against a wide spectrum of insect pests from at least ten orders and well over 30 families (**Table 4**). Lepidopteran insects represent the majority of pests on the indoxacarb label but it is also used to control many species of plant bugs, leafhoppers, fleahoppers, weevils, beetles, flies, cockroaches, and ants. Ahmad *et al.* (2003), Brickle *et al.* (2001), and Andaloro *et al.* (2001) documented the activity of indoxacarb against lepidopteran pests on cotton, while Hammes *et al.* (1999), Tillman *et al.* (2001), and Teague *et al.* (2000) showed indoxacarb activity against hemipteran pests of cotton. The rates of indoxacarb range from approximately 40 to 125 g ha^{-1} active ingredient to control agricultural pests. These rate ranges are very consistent regardless of environmental conditions that can often cause degradation of performance of other registered products. Indoxacarb formulations are extremely stable to ultraviolet radiation, pH, and temperature extremes, and have a positive temperature correlation. Indoxacarb provides excellent rainfastness relative to most labeled products (Flexner *et al.*, 2000) providing growers with additional flexibility and control at labeled rates despite rainfall within hours after application.

Leaf penetration by indoxacarb not only results in activity against leafhoppers and plant bugs, but also pinworm, such as the tomato pinworm (*Keiferia lycopersicella*) and the tomato leafminer (*Tuta absoluta*), and provides suppression of lepidopteran leafminers such as the spotted tentiform leafminer (*Phyllonorycter blancardella*) and the citrus leafminer (*Phyllocnistis citrella*). Indoxacarb is also active against some dipteran leafminers such as *Liriomyza trifolii* on tomato and other vegetable crops.

The rate range for nonagricultural pests, such as structural, nuisance, or household pests ranges from 0.01% to 1.0% v/v concentration. Indoxacarb has shown excellent activity when prepared in a bait

Table 4 Spectrum of insects pests controlled by indoxacarb and range of indoxacarb rates for control[a]

Global field use rate range[b]	*Insect orders*	*Selected insect families*	*Selected representative genera*
40–125 g ha^{-1}	Lepidoptera	Arctiidae	*Estigmene*

0.1–1%	Thysanura	Lepismatidae	*Lepisma*

[a] The majority of these insects are on indoxacarb labels or development work is ongoing to include them on labels, or sufficient data exists indicating the activity of indoxacarb. The list of insect families and genera is not inclusive of the total insect control activity of indoxacarb.
[b] Indoxacarb rates are expressed in grams of active ingredient per hectare or percent of active ingredient published on global labels or used in laboratory and field experiments to achieve a high level of insect mortality.

against German cockroaches (*Blattella germanica*) (Appel, 2003) and fire ant species (Barr, 2003; Patterson, 2003). However, the suspension concentrate formulation is also effective against certain roach, ant, fly, silverfish, and termite species when the pest is sprayed directly or as a surface or soil residual spray.

6.2.5.5. Indoxacarb and Insecticide Resistance

Indoxacarb is highly active against insect pest species that are already resistant to other insecticide classes. This has been demonstrated in the housefly (*Musca domestica*) resistant to spinosad (Shono and Scott, 2003) and organophosphates (Sugiyama *et al.*, 2001); tobacco budworm (*Heliothis virescens*) resistant to spinosad (Young *et al.*, 2001); German cockroach resistant to pyrethroids (Appel, 2003; Dong, unpublished data); tortricid leafrollers resistant to organophosphates (Olszak and Pluciennik, 1998); cotton bollworm (*H. armigera*) resistant to cyclodienes, organophosphates, carbamates and pyrethroids (Ahmad *et al.*, 2003); diamondback moth (*Plutella xylostella*) resistant to several conventional chemistries and spinosad (Boyd, 2001);

beet armyworm (*Spodoptera exigua*) resistant to pyrethroids, organophosphates, and benzoylurea insect growth regulators (Eng, 1999); and *H. virescens* resistant to multiple conventional chemistries (Holloway *et al*., 1999).

It is likely that the insects mentioned above are resistant to conventional insecticides due to a variety of mechanisms, including increased metabolism, decreased penetration and target site insensitivity. Because indoxacarb is bioactivated via esterase/amidase enzymes, overproduction of esterases in insects resistant to organophosphates or pyrethroids could lead to faster liberation of the active toxin DCMP than in nonresistant insects. This suggests that resistant insects may in fact develop a negative cross-resistance to indoxacarb, as has been observed in laboratory strains of *H. armigera* (Gunning and Devonshire, 2003). However, it is important to note that we have no clear evidence thus far for negative cross-resistance to indoxacarb in the field, indicating the speed and ease with which susceptible Lepidoptera can bioactivate indoxacarb. The aggregate resistance data also indicate that insects with increased resistance to conventional chemistries also have highly sensitive Na^+ channel DCMP binding sites, as would be expected since there has been no previous exposure to commercial SCBIs in the field. Thus, indoxacarb is an excellent rotation partner for alternating modes of action in insect resistance management programs.

As has been mentioned, certain field strains of *C. rosaceana*, which have developed resistance to many conventional insecticides, are also poorly sensitive to indoxacarb (Ahmad *et al*., 2002). This may be due to an enhanced ability to detoxify indoxacarb; however, this insect is not on the indoxacarb US label and is an extremely unusual example of such poor susceptibility in Lepidoptera.

Insect pests representing eight species (*H. virescens, H. armigera, S. exigua, S. eridania, S. littoralis, P. xylostella,* and *T. absoluta*) in over 20 countries have been targeted for a sustained susceptibility monitoring program by DuPont Agricultural Products (Andaloro, unpublished data). These populations are evaluated by a feeding assay throughout each season in locations that have a history of insecticide resistance, and where a significant number of indoxacarb applications are made, so that early signs of resistance can be detected before widespread field failures occur. This proactive approach to indoxacarb resistance management is beneficial not only for preservation of this product in key markets, but also to maintain its usefulness as a rotation partner, thus promoting the longevity of other products with different modes of action, and thus ultimately benefiting the agricultural field in general.

6.2.6. Conclusions

In summary, indoxacarb is the first insecticide product that acts by blocking the voltage-dependent Na^+ channel at site 10. The mode of action of this novel SCBI class was determined by sequential observation of poisoned insect symptoms, electrophysiology (starting with intact neuronal preparations and progressing towards more targeted ion channel techniques), and confirmation with Na^+ flux and biochemical radioligand binding techniques. It is believed that this approach is the most direct and elegant to determine the mode of action of insect neurotoxins, as opposed to testing the toxin in broad panels of specific target site biochemical assays and trusting that positive responses are indicative of toxicologically significant modes of action. Thus far no qualitative difference has been observed in the mode of action of the subclasses of the SCBIs. Indoxacarb itself is able to bind to Na^+ channels, but the main toxicologically active principle is the insect bioactivation metabolite DCMP. SCBIs appear to bind to a novel site, which appears to correspond to site 10 within the channel pore, and have almost no effect on resting Na^+ channels, so that in axons that normally have a very negative resting potential, they exert no effect unless the cell is artificially depolarized. Alternatively, sensory neurons and certain pacemaking neurons in the CNS generate action potentials in a region of the cell with a relatively low resting potential, where currents flowing through the cell membrane depolarize it, giving rise to trains of action potentials at a frequency that is dependent on membrane potential. Because the Na^+ channels in these regions are continually shuttling through the inactivated state, and are even, because of the low resting potential, spending a significant amount of time in the inactivated state, they are highly susceptible to compounds such as the SCBIs, which bind to the inactivated state. Inactivation is voltage-dependent, and at any given potential there is a dynamic equilibrium between inactivated and resting channels. As inactivated channels become bound to the active compound, they are removed from this equilibrium, with the result that more channels become inactivated to take their place in the equilibrium. In a sense, SCBIs pull channels into the inactivated state. While local anesthetics can access their binding site via an aqueous pathway from the internal solution as well as via a lipid pathway, SCBIs may have access only via the lipid pathway.

At a physiological level, the very slow off-rate of the receptor-bound SCBI (as evidenced by extremely slow washout in electrophysiology) may be largely responsible for the irreversible feeding inhibition seen in poisoned insects. Since this occurs at very low doses of indoxacarb in lepidopteran larvae, it is likely that in pseudoparalyzed insects only a relatively small proportion of total Na^+ channels is poisoned. Thus once DCJW is pseudoirreversibly bound to the slow inactivated state, return of the Na^+ channel to the unpoisoned inactivated state is very slow, which helps explain the high potency of indoxacarb/DCMP in halting insect feeding.

Indoxacarb was designed as a proinsecticide to confer favorable environmental degradation and mammalian safety, while maintaining high levels of insecticidal activity. Proinsecticide design is a common strategy to enhance insecticide selectivity (Prestwich, 1990). The enzymatic cleavage in pest insects via *N*-decarbomethoxylation is a novel insecticide bioactivation. The divergent indoxacarb metabolic pathways (insects primarily to *N*-decarbomethoxylated sodium channel blockers, while mammals degrade the compound primarily via other routes leading to multiple inactive metabolites) ensures a high degree of nontarget organism safety, a critical feature for modern insecticides.

Also, since hydrolytic esterases are largely responsible for the bioactivation, it is likely that insects that have become resistant to pyrethroids and organophosphates via induction of detoxifying esterases may in fact liberate DCMP more rapidly than susceptible insects. Because of this feature, and DCMP's novel Na^+ channel target site, accumulated field evidence shows that indoxacarb is generally highly active against insects resistant to these other commercial insecticide classes, and is thus an excellent insect pest management tool. This includes the pyrethroids and DDT, which bind to a different site on the voltage-gated Na^+ channel.

These properties have contributed to indoxacarb's strong potency in the field against Lepidoptera and some other pest orders. The bioavailability characteristics of indoxacarb make it ideal for foliar applications, where a surface residue of a strong chewing insect compound is desired. Its limited leaf penetration allows control of some Homoptera, some Hemiptera and both lepidopteran and dipteran leafminers, and its broad spectrum also confers activity against many nonagricultural pests such as termites, cockroaches, and certain ants. However, as with any new insecticide class, proactive resistance management is key to ensuring the maintenance of this compound and its target site of action as effective pest management tools.

6.3 Insect Growth- and Development-Disrupting Insecticides

T S Dhadialla, Dow AgroSciences LLC,
Indianapolis, IN, USA
A Retnakaran, Canadian Forest Service,
Sault Ste. Marie, ON, Canada
G Smagghe, Ghent University, Ghent, Belgium

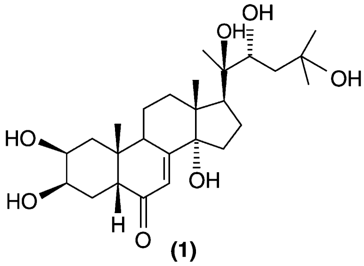
6.3.1. Introduction

In 1967 Carrol Williams proposed that the term "third generation pesticide" be applied to the potential use of the insect juvenile hormone (JH) as an insecticide, and suggested that it would not only be environmentally benign but that the pest insects would also be unable to develop resistance. However, it took several years before the first commercial juvenile hormone analog (JHA) made its debut (reviews: Retnakaran *et al*., 1985; Staal, 1975). Since then, several compounds that adversely interfere with the growth and development of insects have been synthesized, and have been collectively referred to as "insect growth regulators (IGRs)" (review: Staal, 1982). Concerns over eco-toxicology and mammalian safety have resulted in a paradigm shift from the development of neurotoxic, broad-spectrum insecticides towards softer, more environmentally friendly pest control agents such as IGRs. This search has led to the discovery of chemicals that: (1) interfere with physiological and biochemical systems that are unique to either insects in particular or arthropods in general; (2) have insect-specific toxicity based on either molecular target site or vulnerability to a developmental stage; and (3) are safe to the environment and nontarget species. At

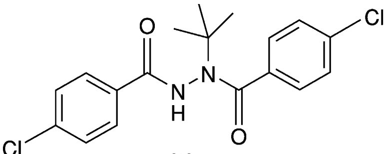
the physiological level, opportunities to develop insecticides with such characteristics existed, *inter alia*, in the endocrine regulation of growth, development, reproduction, and metamorphosis. The rationale was that if the pest insect is treated with a chemical analog, which mimics the action of hormones like JHs and ecdysteroids, at an inappropriate stage the hormonal imbalance would force the insect to go through abnormal development leading to mortality. It was also thought that because such chemicals would in many instances work via the receptor(s) of these hormones, it was less likely for the affected population to develop target site resistance. Yet other target sites are the biosynthetic steps of cuticle formation, which insects share with other arthropods. Adversely interfering with this process would result in the inability of the intoxicated insect to molt and undergo further development. Unlike neurotoxic insecticides that are fast acting, IGRs are in general slow acting, which might result in more damage to the crop. However, some IGRs, such as ecdysone agonists, induce feeding inhibiton, significantly reducing the damage to below acceptable levels. The slow mode of action of some IGRs, such as chitin synthesis inhibitors, can be an advantage in controlling social insects, such as termites, where the material has to be carried to the brood and spread to other members.

It was in the early seventies that the first chitin synthesis inhibitor, a benzoylphenylurea, was discovered by scientists at Philips-Duphar BV, (now Crompton Corp., Weesp, The Netherlands), and marketed as Dimilin® by the Uniroyal Chemical Company (Crompton Corp. Middlebury, CT) in the USA. Since then several new analogs that interfere with one or more steps of cuticle synthesis have been synthesized and are being marketed for controlling various pests. These products are reviewed in Section 6.3.4, with emphasis on recent developments.

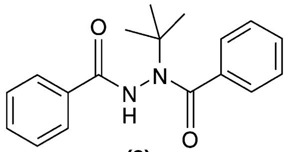
After the initial success with the synthesis of methoprene by Zoecon (Palo Alto, CA, USA) very few new JHAs with good control potential other than pyriproxyfen and fenoxycarb have been developed. These compounds have been particularly useful in targeting the eggs and embryonic development as well as larvae. The synthesis of pyriproxifen and fenoxycarb was a departure from the terpenoid structure of JHs and earlier JHAs, and is reviewed in Section 6.3.3. For extensive reviews on earlier JHAs the reader is referred to Retnakaran *et al.* (1985) and Staal *et al.* (1975).



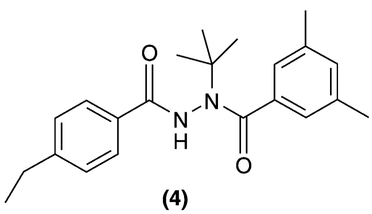
Early attempts in the 1970s to synthesize insecticides with molting hormone (20-hydroxyecdysone) activity failed because they were based on a cholesterol backbone, which resulted in chemical and metabolic instability of the steroid nucleus (Watkinson and Clarke, 1973). It took nearly two more decades before the first nonsteroidal ecdysone agonist, based on the bisacylhydrazine class of compounds, was synthesized (Hsu, 1991). Structure activity optimization of the first such compound over the subsequent few years led to the synthesis of four highly effective compounds that have since been commercialized (see Section 6.3.2.1). The reader is also referred to earlier reviews on the ecdysone agonist insecticides (Oberlander *et al.*, 1995; Dhadialla *et al.*, 1998).



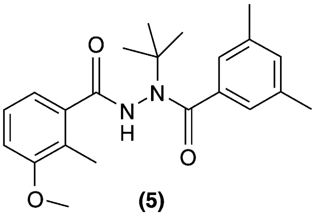
For more basic information, the reader is referred to the chapters in this series on insect hormones (ecdysteroids, JHs see **Chapter 3.4**) and cuticle synthesis (see **Chapter 4.2**) for further details on hormone physiology and chitin synthesis to augment the brief overviews presented in this chapter.



6.3.1.1. Physiological Role and Mode of Action of the Insect Molting Hormone



Amongst the animal kingdom, arthropods display a remarkable adaptability and diversity in inhabiting very different ecological niches. Between larval and adult stages of a given insect, an insect undergoes distinct developmental and morphological changes that help it to survive in different environments. For example, mosquito larvae are perfectly suited to surviving in an aqueous environment, whereas the adult mosquitos inhabit terrestrial and aerial environments. Larval or nymphal stages of most of the agricultural pests develop on host plant species, and the adult assumes an aerial space to look for food and a mate, returning to the host plant only to oviposit and start another life cycle.



The growth and development from one stage to another is regulated by two main hormones, the steroidal insect molting hormone, 20-hydroxyecdysone (20E; **Figure 1, 1**) and the sesquiterpenoid JH, of which there are five types (**Figure 15**). Even as an insect embryo grows, it undergoes embryonic molts, where each molt is regulated by 20E. The molting process continues through the larval and pupal stages culminating in the adult stage. While molting to accommodate growth is regulated by 20E, the development from an egg to a larva to a pupa to an adult is regulated by the timing and titers of JH (**Figure 17**; also reviewed extensively by Riddiford, 1996). In the adult stage, both these hormones, being pleiotropic, change their roles to regulating reproductive processes (Wyatt and Davey, 1996).

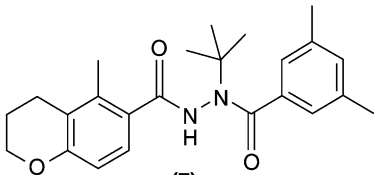
(2)

(3)

(4)

(5)

(6)



(7)

Figure 1 Chemical structures of 20-hydroxyecdysone (**1**), the first discovered symmetrically substituted dichloro-dibenzoylhydrazine (**2**), RH-5849 (**3**), tebufenozide (**4**), methoxyfenozide (**5**), halofenozide (**6**), and chromofenozide (**7**).

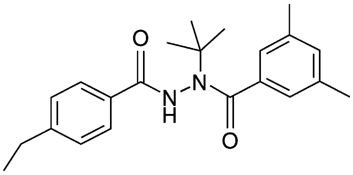
The molting process is initiated by an increase in the titer of 20E, and is completed following its decline and the release of eclosion hormone. In preparation for a molt and as the 20E titers increase, the larva stops feeding and apolysis of the epidermis from the old cuticle takes place leaving an ecdysial space that is filled with molting fluid containing inactive chitinolytic enzymes. During this time, the epidermal cells also reorganize in order that large quantities of protein can be synthesized for deposition of a new cuticle. This happens with up- and downregulation of a number of genes encoding a number of epidermal proteins and enzymes (Riddiford, 1994). The fall in the 20E titer triggers the activation of enzymes in the molting fluid for digestion of the procuticle underlying the old cuticle. This event is followed by the resorption of the molting fluid and preparation for ecdysis (Retnakaran *et al.*, 1997; Locke, 1998). Finally, when the 20E titer is cleared from the system, the eclosion hormone is released, which in turn results in the release of the ecdysis-triggering hormone, and all these events lead to the ecdysis of the larva leaving behind the remnants of the old cuticle (Truman *et al.*, 1983; Zitnanova *et al.*, 2001). With the completion of ecdysis, feeding resumes and endocuticular deposition continues during the intermolt period.

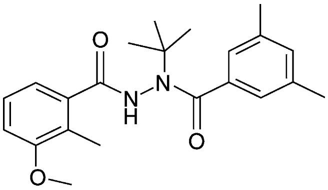
6.3.1.1.1. Molecular basis of 20E action Of the two hormones 20E and JH, the molecular basis of 20E action is much better understood. The pioneering work of Clever and Karlson (1960) and Ashburner (1973) on the action of 20E to induce/repress "puffs" in the polytene chromosomes of *Chironomus* and *Drosophila* led Ashburner and co-workers to propose a model for ecdysteroid action (Ashburner *et al.*, 1974). According to this model, 20E binds to an ecdysone receptor to differentially regulate several classes of "early" and "late" genes. While the "early" genes are activated by the 20E–receptor complex, the "late" genes are repressed. The protein products of the "early" genes such as E75 and CHR3 derepress the expression of the "late" genes such as DOPA decarboxylase

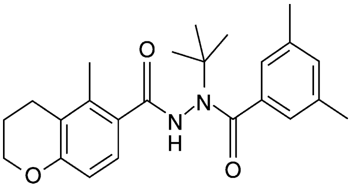
(DDC) and at the same time repress their own expression.

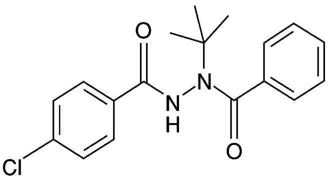
6.3.1.1.2. Ecdysone receptors The ecdysone receptor complex is a heterodimer of two proteins, ecdysone receptor (EcR) and ultraspiracle (USP), which is a homolog of the mammalian retinoic acid receptor (RXR) (Yao *et al*., 1992, 1995; Thomas *et al*., 1993). In several insects, both EcR and USP exist in several transcriptional and splice variants, presumably for use in a stage- and tissue-specific way (review: Riddiford *et al*., 2001). Both EcR and USP are members of the steroid receptor superfamily that have characteristic DNA and ligand binding domains. Ecdysteroids have been shown to bind to EcR only when EcR and USP exist as heterodimers (Yao *et al*., 1993), although additional transcriptional factors are required for ecdysteroid dependent gene regulation (Arbeitman and Hogness, 2000; Tran *et al*., 2000). Moreover, EcR can heterodimerize with RXR to form a functional ecdysteroid receptor complex in transfected cells (Yao *et al*., 1992; Tran *et al*., 2000). cDNAs encoding both EcR and USPs from a number of dipteran (Koelle *et al*., 1991; Imhof *et al*., 1993; Cho *et al*., 1995; Kapitskaya *et al*., 1996; Hannan and Hill, 1997, 2001; Veras *et al*., 1999), lepidopteran (Kothapalli *et al*., 1995; Swevers *et al*., 1995), coleopteran (Mouillet *et al*., 1997; Dhadialla and Tzertzinis, 1997), homopteran (Zhang *et al*., 2003; Dhadialla *et al*., unpublished data; Ronald Hill, personal communication), and orthopteran (Saleh *et al*., 1998; Hayward *et al*., 1999, 2003) insects, tick (Guo *et al*., 1997) and crab (Chung *et al*., 1998) have been cloned. Some of the EcRs and USPs have been characterized in ligand binding (Kothapalli *et al*., 1995; Kapitskaya *et al*., 1996; Dhadialla *et al*., 1998) and cell transfection assays (Kumar *et al*., 2002; Toya *et al*., 2002). In all cases, the DNA binding domains (DBDs) of EcRs show a very high degree of homology and identity. However, homology between the ligand binding domains (LBDs) of EcRs varies from 70% to 90%, although all EcRs studied so far bind 20E and other active ecdysteroids. The DBDs of USPs are also highly conserved. The USP LBDs, however, show very interesting evolutionary dichotomy: the LBDs from the locust, *Locusta migratoria*, the mealworm beetle, *Tenebrio molitor*, the hard tick, *Amblyoma americanum*, and the fiddler crab, *Uca puglitor*, show about 70% identity with their vertebrate homolog, but the same sequences from dipteran and lepidopteran USPs show only about 45% identity with those from other arthropods and vertebrates (Guo *et al*., 1997; Hayward *et al*., 1999; Riddiford *et al*., 2001). The functional significance of RXR-like LBDs in USPs of primitive arthropods is not well understood, because EcRs from the same insects still bind ecdysteroids (Guo *et al*., 1997; Chung *et al*., 1998; Hayward *et al*., 2003; Dhadialla, unpublished data for *Tenebrio molitor* EcR and USP (TmEcR/TmUSP)).

The crystal structures of USPs from both *Heliothis virescens* and *Drosophila melanogaster* have been elucidated by two groups (Billas *et al*., 2001; Clayton *et al*., 2001). The crystal structure of USP is similar to its mammalian homolog RXR, except that USP structures show a long helix-1 to helix-3 loop and an insert between helices 5 and 6. These variations seem to lock USP in an inactive conformation by displacing helix 12 from the agonist conformation. Both groups found that crystal structures of the two USPs had large hydrophobic cavities, which contained phospholipid ligands.









Finally, the crystal structures of *Heliothis viresens* EcR/USP (HvEcR/HuUSP) heterodimers liganded with an ecdysteroid or a nonsteroidal ecdysone agonist have been determined (Billas *et al*., 2003; see Section 6.3.2.2.2 for more details). The crystal structure of liganded EcR/USP from the silverleaf whitefly, *Bemesia tabaci*, has also been determined and awaits publication (Ronald Hill, personal communication).

6.3.2. Ecdysteroid Agonist Insecticides

6.3.2.1. Discovery of Ecdysone Agonist Insecticides and Commercial Products

Although attempts to discover insecticides with an insect molting hormone activity were made in the early 1970s (Watkinson and Clarke, 1973), it was not until a decade later that the first bisacylhydrazine ecdysone agonist ((**2**) in **Figure 1**) was serendipitously discovered by Hsu (1991) at Rohm and Haas Company, Springs House, PA, USA. Several years later, after several chemical iterations of this early lead, a simpler, unsubstituted, but slightly more potent analog, RH-5849 ((**3**) in **Figure 1**), was discovered (Aller and Ramsay, 1988). Further work on the structure and activity of RH-5849, which had commercial-level broad spectrum activity against several lepidopteran, coleopteran, and dipteran species (Wing, 1988; Wing and Aller, 1990), resulted in more potent and cost-effective bisacylhydrazines with a high degree of selective pest toxicity (review: Dhadialla *et al*., 1998). Of these, three bisacylhydrazine compounds, all substituted analogs of RH-5849, coded as RH-5992 (tebufenozide (**4**); **Figure 1**), RH-2485 (methoxyfenozide (**5**); **Figure 1**), and RH-0345 (halofenozide (**6**); **Figure 1**) have been commercialized (**Table 1**). Both tebufenozide and

Table 1 Bisacylhydrazine insecticides with ecdysone mode of action

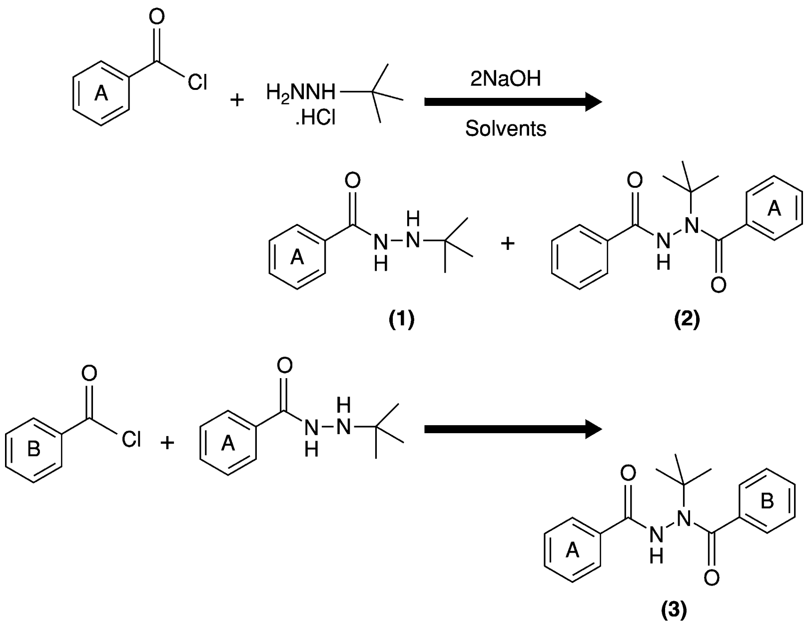
methoxyfenozide are selectively toxic to lepidopteran larvae (Hsu, 1991). However, methoxyfenozide is more potent than tebufenozide, and is toxic to a wider range of lepidopteran pests of cotton, corn, and other agronomic pests (Ishaaya *et al.*, 1995; Le *et al.*, 1996; Trisyono and Chippendale, 1997). Halofenozide has a broader and an overall insect control spectrum somewhat similar to that of RH-5849, but with significantly higher soil-systemic efficacy against scarabid beetle larvae, cutworms, and webworms (RohMid LLC, 1996). Another bisacylhydrazine, chromafenozide (7) coded as ANS-118; **Figure 1**) was discovered and developed jointly by Nippon Kayaku Co., Ltd., Saitama, Japan and Sankyo Co., Ltd. Ibaraki, Japan (Yanagi *et al.*, 2000; Toya *et al.*, 2002; **Table 1**). Chromafenozide, registered under the trade names, MATRIC® and KILLAT®, is commercialized for the control of lepidopteran larval pests of vegetables, fruits, vines, tea, rice, and ornamentals in Japan (Yanagi *et al.*, 2000; Reiji *et al.*, 2000).

6.3.2.1.1. Synthesis and structure–activity relationships (SAR) The synthesis of symmetrical and asymmetrical 1,2-dibenzoyl-1-*t*-butyl hydrazines can be achieved by the following two step reaction shown in **Figure 2**. In 1984, during the process of synthesizing compound number (**1** in **Figure 2**), which was to be used for the synthesis of another class of compounds, Hsu (Rohm and Haas Company) obtained an additional undesired product (**2** in **Figure 2**), 1,2-di (4-chlorobenzoyl)-1-*t*-butylhydrazine (A = 4-Cl). Testing of this undesired by-product revealed that it had ecdysteroid activity, and eventually led to the development of a bisacylhydrazine class of compounds. This serendipitous discovery can be attributed to the inquiring mind of Hsu, who decided to test this compound for biological activity even though it was a contaminant! By treating equivalent amounts of different benzoyl chlorides with **1** (benzoyl hydrazide), unsubstituted analogs (**3**) can be prepared as shown in **Figure 2**.



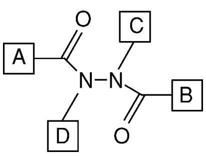


Figure 2 Synthetic routes for unsubstituted and substituted bisacylhydrazines. See text for details. (Reprinted with permission from Hsu, A.C.-T., Fujimoto, T.T., Dhadialla, T.S., **1997**. Structure-activity study and conformational analysis of RH-5992, the first commercialized nonsteroidal ecdysone agonist. In: Hedin, P.A., Hollingworth, R.M., Masler, E.P., Miyamoto, J., Thompson, D.G. (Eds.), Phytochemicals for Pest Control, ACS Symposium Series, vol. 658. American Chemical Society, pp. 206–219; © American Chemical Society.)

The discovery of the first ecdysone agonist (**1**) offered 18 possible sites for possible structural variation. Between 1985 and 1999, approximately 4000 structural bisacylhydrazine analogs were synthesized at the Rohm and Haas Company. This resulted in the selection of 22 candidate compounds for field testing; three of these were selected for commercial development.

Extensive SAR research was carried out around the bisacylhydrazine chemistry to discover additional more potent nonsteroidal agonists with different pest spectrum activity (Oikawa *et al*., 1994a, 1994b; Nakagawa *et al*., 1995a, 1995b, 1998, 2000, 2001a, 2001b; Hsu *et al*., 1997; Shimuzu *et al*., 1997; Smagghe *et al*., 1999b). Some general conclusions for the most active compounds can be drawn, in addition to those drawn by Hsu *et al*. (1997), as illustrated below:

A and B rings: phenyl, heterocyclic, or alkyl. The most active analogs are those that have different substituents on two phenyl rings (e.g., chromofenozide, halofenozide, tebufenozide, and methoxyfenozide). However, the phenyl ring furthest away from the *t*-butyl group (A region) can be replaced with alkyl chains without greatly affecting the biological activities (Shimuzu *et al*., 1997). Phenyl ring (A region) can have various 2, 3, 4, 5 methylene or ethylene dioxan substituents and maintain lepidopteran specific activity. Analogs derived from symmetrically substituted phenyl rings are generally less active than asymmetrically substituted compounds.

D region: In most cases, hydrogen is necessary for activity. When substituted with an unhydrolyzable group, the analogs tend not to be active.

C region: A bulky alkyl group like *t*-butyl is important for activity. The *t*-butyl group can be modified to a benzodioxan group without significantly decreasing the affinity of the compound.

Based on the X-ray crystal structures of RH-5849, a number of models have been developed that demonstrate superimposition of RH-5849 on the 20E structure (Chan *et al*., 1990; Mohammed-Ali *et al*., 1995; Cao *et al*., 2001; Kasuya *et al*., 2003). More recent X-ray crystallography studies of liganded (20E or diacylhydrazine) HvEcR/HvUSP show that the two compounds share common sites occupied by the side chain of 20E and the B ring of bisacylhydrazine (Billas *et al*., 2003).

6.3.2.2. Bisacylhydrazines as Tools of Discovery

The discovery of bisacylhydrazine has been a catalyst in stimulating research on the biological activity of ecdysteroids and nonsteroidal ecdysone agonists in whole insects, tissues, and in cells (reviews: Dhadialla *et al.*, 1998; Oberlander *et al.*, 1995). Because bisacylhydrazines have a greater metabolic stability than 20E *in vivo*, it was possible to confirm and further understand the effects of rising and declining titers of 20E during growth and development (Retnakaran *et al.*, 1995).

With the cloning and sequencing of cDNAs encoding EcRs from different insects it became clear that there were homology differences in the LBDs of the cloned EcRs but the functional significance of these differences was not apparent. In almost all insects, the effect of 20E is manifested by an interaction with EcR in the ecdysone receptor complex. Therefore, it is paradoxical that tebufenozide and methoxyfenozide, which also manifest insect toxicity via interaction with EcR, are predominantly toxic to lepidopteran insects and to a lesser degree to other insects. Through the use of these ecdysone agonists it became clear that while 20E can bind to different LBDs of EcRs from different orders of insects, the same LBDs bound bisacylhydrazines with unequal affinities, which reflected their insect specificity (reviewed by Dhadialla *et al.*, 1998). It also became clear that while a relatively low but similar affinity (K_d = 10–100 nM) of 20E to different EcRs was functional, only high-affinity (nM range) interactions of tebufenozide and methoxyfenozide with EcR were functionally productive (**Table 2**). On the other hand, the low affinity of halofenozide was most likely compensated for by its high metabolic stability in susceptible insects.

6.3.2.2.1. Molecular modeling Molecular modeling studies on both EcR LBDs (Wurtz *et al.*, 2000; Kasuya *et al.*, 2003) and bisacylhydrazines (Chan *et al.*, 1990; Mohammed-Ali *et al.*, 1995; Hsu *et al.*, 1997; Cao *et al.*, 2001) were conducted, perhaps partly prompted by the molecular modeling and X-ray crystal structure data of LBDs of steroid receptors from vertebrates and the search for new classes of nonsteroidal ecdysone agonists/antagonists. The results suggested that the tertiary protein structure of EcR LBDs is similar to that of vertebrate steroid receptor LBDs, and that helix 12 forms a "mouse trap" for a ligand in the binding cavity (**Figure 3**; see also description of crystal structures of EcR and USP below and **Chapter 3.5**). Results of molecular modeling and *in silico* docking experiments with 20E and RH-5849 have provided conflicting information about the orientation of 20E in the binding pocket. However, the recent description of the X-ray crystal structure of ligand bound HvEcR/HvUSP LBDs has provided definite answers to this (see below).

6.3.2.2.2. Mutational analysis In a very elegant study, Kumar *et al.* (2002) extended the *in silico* molecular modeling approach to construct a homology model of *Choristoneura fumiferana* EcR (CfEcR) LBD with 20E docked in to predict amino acid residues involved in interaction with 20E. The authors identified 17 amino acid residues as possibly being critical for 20E binding. In order to confirm this prediction, all 17 of these amino acids were mutated to alanine, except for A110 (where the 110 residue is numbered starting from helix one, which otherwise is A393 in the full-length CfEcR), which was mutated to proline. When the single point mutated LBDs were tested in ligand binding assays and transactivation assays (in insect and mammalian cells and in mice *in vivo*) the A110P mutant was ineffective in the two assays for a response to ecdysteroids (ponasterone A and 20E). While there was a 30% decrease in transactivation assays for the nonsteroidal bisacylhydrazines, their

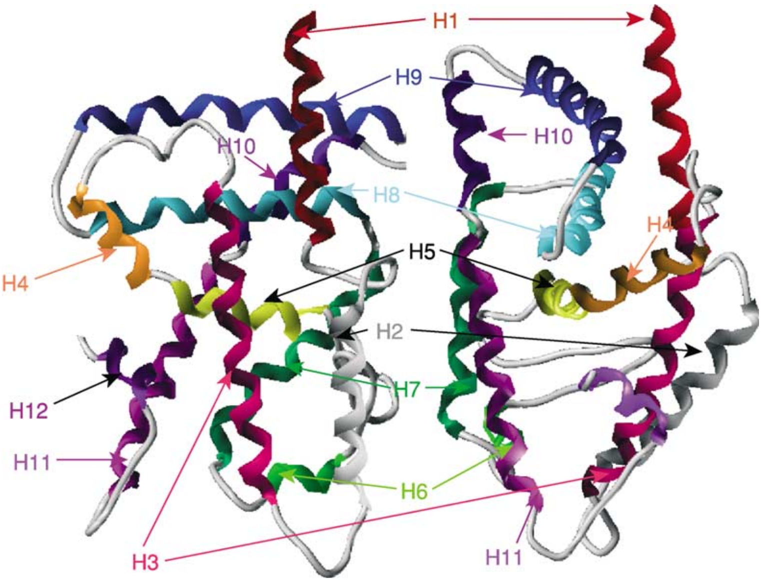

Figure 3 Different elevations of computer model(s) of the three-dimensional structure of the LBD of insect ecdysone receptors. The different helices are represented in different colors, and indicated by arrows and numbers. After a ligand has docked into the ligand binding pocket of EcR heterodimerizd with USP, helix 12 closes on the binding cavity like a ''mouse trap.''

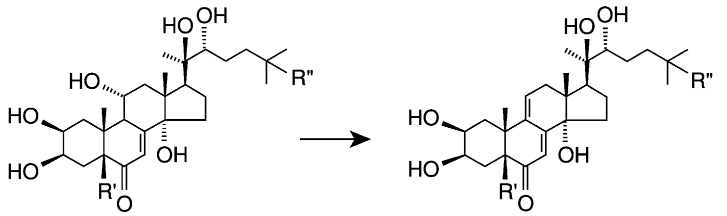
ability to bind was unaffected. Changing A110 to leucine was as effective as the change to proline. Further work along these lines should make it possible not only to design new effective chemistries as ecdysone agonists/antagonists for pest control, but also to design EcR LBDs that result in productive binding with different chemistries, thus allowing their use in several gene switch applications.



The necessity of EcR and USP forming a heterodimer for ligand interaction coupled with the difficulty in producing large enough quantities of EcR and USP LBDs required for X-ray diffraction studies have been overcome by Billas *et al.* (2003). These authors reported the crystal structures of the LBDs of the moth *H. virescens* EcR-USP heterodimer in complex with the ecdysteroid ponasterone A and with a nonsteroidal, lepidopteran specific agonist, BY106830 (a bisacylhydrazine). Comparison of the crystal structures liganded with ponasterone A and BY106830 revealed that the two ligands occupy very different but slightly overlapping spaces in the ligand binding pockets. The overlap of the two ligands was observed on the side chain of ponasterone A with the *t*-butyl group and the benzoyl ring closest to it in BY106830. The presence of the *t*-butyl group and its occupation in a hydrophobic groove of the HvEcR LB pocket confers lepidopteran specificity on it. Further examination of the residues in this hydrophobic cavity revealed that V384 in helix 5, which was conserved in lepidopteran insect EcR LBDs and is replaced by methionine in other insects, is essential for the lepidopteran specificity. The crystal structure observations supported the results of Kumar *et al.* (2002).

6.3.2.2.3. Ligand-dependent conformational changes Yao *et al.* (1995) used limited proteolysis protection to demonstrate that binding of muristerone A, a potent ecdysteroid, to *Drosophila melanogaster* EcR and USP (DmEcR/DmUSP) induces a conformation change in EcR that can be detected by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS–PAGE) and autoradiography. In these experiments, incubation of muristerone A with DmEcR-^{35}S-methionine labeled/DmUSP proteins produced by transcription and translation of corresponding cDNAs in rabbit reticulocyte cell-free mixtures, afforded partial protection to EcR from trypsin as the protease. In an extension of this approach, Dhadialla *et al.* (unpublished data) used EcR-^{35}S-methionine labeled/USP proteins produced *in vitro* to demonstrate that muristerone A bound to DmEcR/DmUSP, *Aedes aegypti* EcR and USP (AeEcR/AeUSP), and CfEcR/CfUSP protected an EcR fragment of 36 kDa from limited proteolysis with trypsin, chymotrypsin, and proteinase K. On the other hand, the ability of tebufenozide (RH-5992) to induce a similar conformational change upon binding to EcR, which affords limited proteolytic protection as with muristerone A, correlated with its affinity to the various EcRs (**Table 3**). Interestingly, peptide fragments of a similar size (36 kDa)

Table 3 Size distribution of protease protected fragments of ^{35}S-labeled EcRs incubated in the presence of homologous USPs and an ecdysteroid, muristerone A, or a bisacylhydrazine, tebufenozide

Cloned EcR and USP cDNAs from the three insects, *Drosophila melanogaster* (Dm), *Aedes aegypti* (Aa), and *Choristoneura fumiferana* (Cf) were expressed using *in vitro* transcription and translations of the rabbit reticulocyte system. However, EcRs were *in vitro* labeled with ^{35}S-methionine. Both EcR and USPs from the same species were incubated in the presence of 1 µm muristerone A or 1 µm tebufenozide and binding allowed to reach equilibrium. At that point the binding reactions were aliquated and subjected to increasing protease concentrations for 20 min at RT (limited proteolysis). The digests were analyzed by SDS-PAGE, and the labeled EcR bands visualized by fluorography. The K_d values are the same as those given in **Table 2**.

Ajugasterone C (R′ = H, R″ = H) ⟶ Dacryhainansterone (R′ = H, R″ = H)
Muristerone A (R′ = OH, R′ = H) ⟶ Kaladasterone (R′ = OH, R″ = H)
Turkesterone (R′ = H, R″ = OH) ⟶ 25-Hydroxydacryhainansterone (R′ = H, R″ = OH)

Figure 4 Schematic derivatization of ajugasterone C, muristerone A, and turkesterone to photo affinity ecdysteroid 7,9(11)-dien-6-ones, dacryhainansterone, kaladasterone, and 25-hydroxydacryhainansterone, respectively. (Adapted from Bourne, P.C., Whiting, P., Dhadialla, T.S., Hormann, R.E., Girault, J.-P., *et al.*, 2002. Ecdysteroid 7,9(11)-dien-6-ones as potential photoaffinity labels for ecdysteroid binding proteins. *J. Insect Sci.* 2, 1–11.

to the three EcRs with either muristerone A or tebufenozide (in the cases of AaEcR and CfEcR) bound were protected from proteolysis with proteinase K, suggesting similar ligand-induced conformational changes. Such a conformational change *in vivo* may be necessary for ligand-dependent transactivation of a gene.

With respect to the hypothesis of Billas *et al.* (2003) that in the EcR/USP heterodimer the EcR ligand binding pocket may conform to accommodate an active ligand, it is not clear if the changes seen in limited proteolysis experiments (above) are a result of just ligand-induced changes in the binding pocket or a result of ligand-induced changes in the whole of the EcR LBD.

6.3.2.2.4. Photoaffinity reagents for studying receptor–ligand interactions Before the X-ray crystal structures of the EcR/USP heterodimer were available, alternative approaches to understanding the interaction of ecdysteroid and nonsteroidal bisacylhydrazine ligands with residues in the EcR ligand binding pocket were explored. One such approach was to synthetically produce photoaffinity analogs of ecdysteroids (Bourne *et al.*, 2002) and bisacylhydrazines (Dhadialla *et al.*, unpublished data) as has been achieved for vertebrate steroids and their receptors (Katzenellenbogen and Katzenellenbogen, 1984). An ideal affinity labeling reagent should have: (1) a high affinity for the binding protein with low nonspecific binding to other proteins; (2) a photo-reactive functional group; and (3) a radiolabeled moiety for detection purposes.

Bourne *et al.* (2002) synthesized three ecdysteroid 7,9(11)-dien-7-ones (**Figure 4**; dacryhainansterone, 25-hydroxydacryhainansterone, and kaladasterone)

as photoaffinity ecdysteroids by dehydration of the corresponding 11α-hydroxy ecdysteroids (ajugasterone, turkesterone, and muristerone A, respectively). Of the three photoaffinity ecdysteroids, dacryhainansterone and kaladasterone showed the greatest potential for use in determining contact amino acid residues in EcR LBDs. All three dienone ecdysteroids retained their biological activity in the *D. melanogaster* B_{II} cell assay developed by Clement *et al.* (1993). However, upon irradiation with UV at 350 nM in the presence of bacterially expressed DmEcR/DmUSP and CfEcR/CfUSP, both dacryhainansterone and kaladasterone blocked subsequent specific binding of tritiated ponasterone A by >70%. These results clearly showed the potential of using radiolabeled dienones for further characterization of their interaction within EcR LBDs.

Photoaffinity analogs of bisacylhydrazines have also been produced and used to characterize their binding to EcRs from dipterans and lepidopterans (Dhadialla *et al.*, unpublished data). A tritiated benzophenone analog of methoxyfenozide (**Figure 5**), coded as RH-131039, displays the above-mentioned characteristic requirements of a photoaffinity reagent as well as the specificity to bind to lepidopteran EcR (CfEcR) with high affinity. Binding to dipteran EcR (DmEcR) could not be detected. Binding of either tritiated ponasterone A or tritiated RH-131039 to CfEcR/CfUSP could be competitively displaced using excess unlabeled RH-131039, tebufenozide, ponasterone A, or 20E. These results indicate that the ecdysteroids and the two nonsteroidal ecdysone agonists share a common binding site in the ligand binding pocket of CfEcR/CfUSP (**Figure 6**), an observation that has been confirmed by Billas *et al.* (2003) in their work on the crystal structure of liganded HvEcR/HvUSP. However, further experiments, which can now be done with the ecdysteroid and bisacylhydrazine photoaffinity compounds, need to be done to determine the ligand–receptor contact residues. Similar results were obtained for AaEcR/AaUSP, but not for DmEcR/DmUSP, indicating that even within an insect order, differences in the homology and folding of EcR LBDs is sufficient to discriminate between affinities of nonsteroidal ecdysone agonists. The bisacylhydrazine and ecdysteroid photoaffinity reagents described are additional useful tools that can be combined with data from chemical structure–activity relationships (SAR), analytical (liquid chromatography/mass spectrometery (LC/MS) and mass laser desorption ionization (MALDI)), and mutational analysis approaches to hypothesize and/or define the three-dimensional space of non-lepidopteran EcR LBDs. However, the availability of the liganded HvEcR/HvUSP LBD crystal structure provides the needed information for defining the three-dimensional ligand receptor interaction for homology modeling of such interactions with non-lepidopteran EcR LBDs, and for the design and discovery of new biologically potent ligands as insecticides for different insects orders.

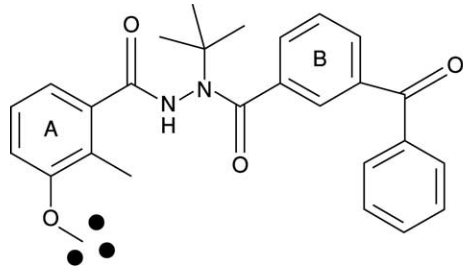

Figure 5 Structure of the tritiated photoaffinity benzophenone analog, RH-131039, of methoxyfenozide. The three dots on the methoxy substitution on the A-phenyl ring indicate tritiation of the methyl group. The benzophenone group on the B-phenyl ring can be activated with UV light for it to cross-link to the nearest amino acid residue.

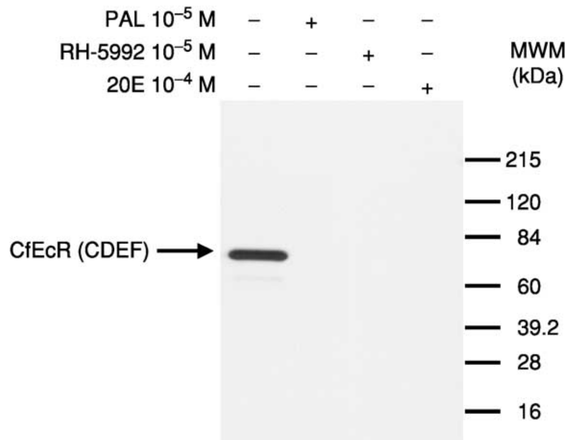

Figure 6 Fluorograph to show specific binding of tritiated RH-131039 (PAL; photo affinity ligand) to CDEF domain of *Choristoneura fumiferana* EcR (CfEcR) expressed by *in vitro* transcription and translation using rabbit reticulocyte system. CfEcR (CDEF domain) plus CfUSP was incubated with tritiated PAL in the presence of excess cold PAL, RH-5992, or 20E at the indicated concentrations under equilibrium binding conditions after which the reaction mixture was irradiated with $UV_{350\,nm}$ for 20 min at 4 °C. The reaction mixture was then mixed with SDS-PAGE sample buffer containing 1 mM DTT, heated for 5 min at 95 °C and then subjected to SDS-PAGE. The gel was dried and fluorographed to get the above image. The numbers on the right indicate relative migration of molecular weight markers (MWM).

6.3.2.3. Mode of Action of Bisacylhydrazines

In the earlier reviews on insecticides with ecdysteroid and JH activity (Oberlander *et al.*, 1995; Dhadialla *et al.*, 1998), much of the focus on mode of

action of ecdysone agonists was from data using RH-5849 and RH-5992. RH-5849, the unsubstituted bisacylhydrazine that was not commercialized, had a broader spectrum of insect toxicity than the four that have been commercialized. In this chapter, the focus will be on work published since 1996 on the commercialized bisacylhydrazine insecticides tebufenozide, methoxyfenozide, chromofenozide, and halofenozide. References will be made to earlier publications where relevant.

6.3.2.3.1. Bioassay A number of *in vitro* and *in vivo* assays have been used to study the effects and mode of action of the bisacylhydrazine insecticides (reviews: Oberlander *et al*., 1995; Dhadialla *et al*., 1998). Larvae of susceptible and nonsusceptible insects (described below), and a number of insect cell lines and dissected tissues have been used *in vitro* to understand the mode of action of bisacylhydrazines. Wing *et al*. (1988) were the first to use *D. melanogaster* embryonic Kc cells to demonstrate that like 20E, RH-5849 also induced aggregation and clumping of otherwise confluent cultures of Kc cells. Similar morphological effects of tebufenozide, methoxyfenozide, and halofenozide have also been demonstrated for cell lines derived from embryos or tissues of *Drosophila* (Clement *et al*., 1993), the mosquito, *Aedes albopictus* (Smagghe *et al*., 2003a), the midge, *Chironomus tentans* (Spindler-Barth *et al*., 1991), the forest tent caterpillar, *Malacosoma disstria*, the spruce budworm, *Choristoneura fumiferana* (Sohi *et al*., 1995), the Indian meal moth, *Plodia interpunctella* (Oberlander *et al*., 1995), the cotton boll weevil, *Anthonomus grandis* (Dhadialla and Tzertzinis, 1997), the European corn borer, *Ostrinia nubilalis*, the Southwestern corn borer, *Diatraea grandiosella*, and the cotton bollworm, *Helicoverpa zea* (Trisyono *et al*., 2000).

Some of these cell lines, imaginal wing discs, and larval claspers from susceptible insects have also been used to study the relative binding affinities, and biochemical and molecular effects of tebufenozide (Mikitani, 1996b), methoxyfenozide, or halofenozide (**Table 4**) and other ecdysone agonists (Nakagawa *et al*., 2002). Cytosolic and or nuclear extracts from 20E responsive cells and tissues containing functional ecdysone receptors, as well as bacterially expressed EcRs and USPs from different insects, have also been used to determine the relative binding affinities of bisacylhydrazines or to screen for new chemistries with similar mode of action in radiometric competitive receptor binding assays (**Table 5**).

Finally, in order to increase the throughput for screening a higher number of compounds, Tran *et al*. (2000) reconstituted ligand-dependent transactivation of *C. fumiferana* EcR in yeast. Reconstitution of the system required transforming yeast with four plasmids carrying cDNAs encoding CfEcR, CfUSP, or RXRγ, an activation factor, a glucocorticoid receptor interacting protein (GRIP), and a plasmid with four copies of an ecdysone response element (hsp27) in tandem fused to a reporter gene (**Figure 7**). The potency of a number of ecdysone agonists in transactivating the reporter gene in the reconstituted EcR ligand dependent assay correlated well with the known activities of the tested bisacylhydrazines in whole insect assays (**Figure 8**), indicating the utility of such assays for high throughput screening of new and novel chemistries with ecdysone mode of action. A similar yeast-based strain was also reconstituted using AaEcR/AaUSP (Tran *et al*., 2001).

6.3.2.3.2. Whole organism effects The commercialized bisacylhydrazine insecticides are toxic to susceptible insects mainly as a result of ingestion. Toxicity via topical application is expressed only when very high doses are applied. The effects of bisacylhydrazines in susceptible insects have been studied in a number of insects (Slama, 1995; Smagghe *et al*., 1996b, 1996c, 2002; Retnakaran *et al*., 1997; Dhadialla *et al*., 1998; Carton *et al*., 2000). In general, because bisacylhydrazines are more metabolically stable *in vivo* than ecdysteroids and because they are true ecdysone agonists at the receptor level, ingestion of bisacylhydrazines creates "hyperecdysonism" in susceptible insects,

Table 4 Relative affinities of 20E and bisacylhydrazines in imaginal wing evagination assays

Species	*20E*	*RH-5849*	*RH-5992*	*RH-2485*	*RH-0345*	*Reference*

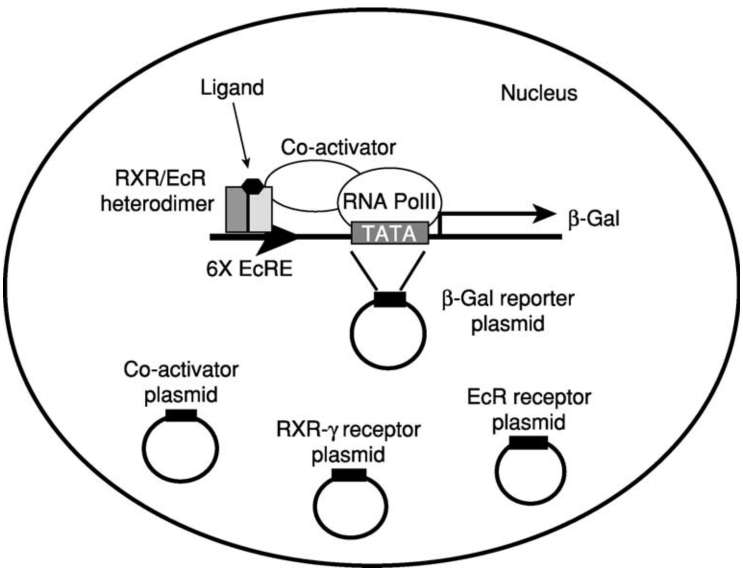

Figure 7 Schematic diagram showing a yeast cell transformed with plasmids carrying cDNAs encoding ecdysone receptor, RXR-γ, co-activator glucocorticoid receptor interaction protein (GRIP), and β-galactosidase (β-Gal) reporter gene fused to 6 heat shock protein 27 (hsp27) ecdysone response elements in a reconstituted and ecdysteroid (muristerone A) inducible high throughput screening system for discovery of new nonsteroidal ecdysone agonists.

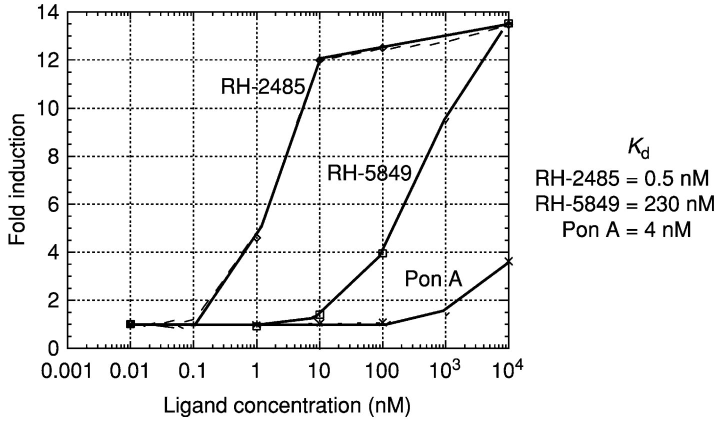

Figure 8 Dose-dependent induction of reporter (β-gal) gene in an ecdysone inducible, transformed yeast cell assay system, with RH-2485 (methoxyfenozide), RH-5849, and the phytoecdysteroid, ponasterone A. While the fold induction achieved with RH-2485 and RH-5849 correlate with their relative affinities (indicated on the right of the graph) for the ecdysone receptor (CfEcR) used in this study, the activation achieved by ponasterone does not correlate with its determined binding affinity to ecdysone receptor.

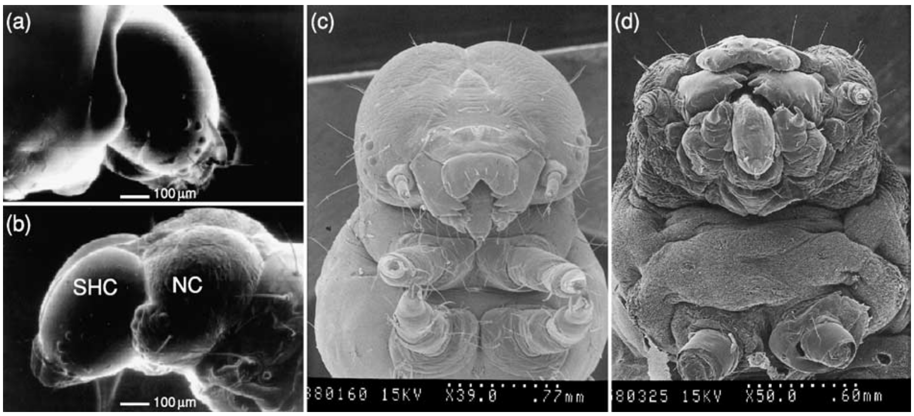

Figure 9 Scanning electron micrographs of control treated (a and c) and tebufenozide intoxicated (b and d) by ingestion (fava bean leaves dipped in a 10 ppm aqueous solution and 100 ng, respectively) second instar southern armyworm (a and b) and third instar spruce budworm (c and d) larvae 48 h after intoxication. In both control armyworm and budworm larvae (a and c), well formed sclerotized cuticle and mouthparts can be seen. In the intoxicated armyworm (b), the larvae is tricked into undergoing a precocious molt and the slipped head capsule (SHC) can be seen over the mouthparts. The new cuticle (NC) covering the head is soft, malformed, and unsclerotized. The soft unsclerotized mouthparts of the intoxicated spruce budworm (d) are shown after manually removing the slipped head capsule. In both cases, tebufenozide intoxicated larvae initiate a molt, slip head capsule, but are unable to complete a molt, and hence die of starvation, desiccation, and hemorrhage from the malformed unsclerotized new cuticle. (Adapted and composed from Dhadialla, T.S., Carlson, G.R., Le, D.P., **1998**. New insecticides with ecdysteroidal and juvenile hormone activity. *Annu. Rev. Entomol. 43*, 545–569; as well as other unpublished electron micrographs.)

thus inducing effects and symptomology of a molt event. One of the first effects of bisacylhydrazine ingestion by susceptible larvae is feeding inhibition within 3–14 h (Slama, 1995; Smagghe *et al*., 1996a; Retnakaran *et al*., 1997), which prevents further plant damage. During this time, synthesis of a new cuticle begins and apolysis of the new cuticle from the old one takes place. Subsequently, the intoxicated larvae become moribund, slip their head capsule (Figures 9 and 10), and, in extreme cases, the hind gut may be extruded (Figure 11). The new cuticle is not tanned or sclerotized. One resulting consequence is that the mouth parts under the slipped head capsule remain soft and mushy, preventing any crop damage even if the head capsule came off from mechanical or physical force. The larvae ultimately die as a result of their inability to complete a molt, starvation, and desiccation due to hemorrhage.

The reasons for the lethal precocious molt effects of bisacylhydrazines have been investigated at the ultrastructural level in *C. fumiferana* (Retnakaran *et al*., 1997), in beet armyworm, *Spodoptera exigua* (Smagghe *et al*., 1996c), in tomato looper, *Chrysodeixis chalcites* (Smagghe *et al*., 1997), in the Colorado potato beetle, *Leptinotarsa*

Figure 10 Control (left) and tebufenozide intoxicated by ingestion (right) larvae of the white tussock moth. While the control larva continues normal growth and development, the tebufenozide intoxicated larva undergoes a precocious lethal molt. In this case the intoxicated larva is in the slipped head capsule stage.

Figure 11 Photomicrograph showing the severe growth inhibitory effects of ingested tebufenozide in spruce budworm larvae. While both larvae show slipped head capsules, one larva (bottom) shows an additional effect, extrusion of the gut.

decemlineata (Smagghe *et al*.,1999c; Dhadialla and Antrium, unpublished observations), and in cultured abdominal sternites of the mealworm, *Tenebrio molitor* (Soltani *et al*., 2002). Some general conclusions can be drawn from these studies. Examination of the cuticle following intoxication with any of the three bisacylhydrazines revealed that the larvae synthesize a new cuticle that is malformed (Figure 12; Dhadialla and Antrim, unpublished data). Unlike during normal cuticle synthesis, the lamellate endocuticule deposition in bisacylhydrazine intoxicated larvae is disrupted and incomplete. The epidermal cells in intoxicated larvae have fewer microvilli, show hypertrophied Golgi complex and an increased number of vesicles compared to normal epidermal cells active in cuticle synthesis. The visual observations of precocious production of new cuticle have also been demonstrated by *in vivo* and *in vitro* experiments to demonstrate the inductive effects of tebufenozide and 20E on the amount of chitin in *S. exigua* larval cuticle and chitin synthesis in cultured claspers of *O. nubilalis*, respectively (Smagghe *et al*., 1997).

At the physiological level the state of "hyperecdysonism," coined by Williams (1967), manifested by bisacylhydrazines in intoxicated susceptible larvae is achieved by various mechanisms. Blackford and Dinan (1997) demonstrated that while larvae of the tomato moth, *Lacnobia oleracea*, detoxified ingested 20E as expected, it remained susceptible to ecdysteroid agonists RH-5849 and RH-5992. This suggested that the metabolic stability of the ecdysone agonists induced the "hyperecdysonism" state in the tomato moth larvae. In another study, RH-5849 was shown to repress steroidogenesis in the larvae of the blowfly, *Caliphora vicina*, as a result of its action on the ring gland (Jiang and Koolman, 1999). However, the production of ecdysteroids in abdominal sterintes of *T. molitor*, cultured *in vitro* in the presence of RH-0345, increased compared to that in control cultured abdominal sternites (Soltani *et al*., 2002). Ecdysteroid production, measured by an ecdysteroid enzyme immunoassay, by sternites cultured *in vitro* in the presence of 1–10 μM RH-0345 increased with increasing incubation times and concentrations of the bisacylhydrazine. Topical application of 10 μg RH-0345 to newly ecdysed pupae also caused a significant increase in hemolymph ecdysteroid amount as compared to control treated pupal hemolymph ecdysteroid levels. However, there was no effect in the timing of the normal ecdysteroid release in the hemolymph. Contrary to the *in vitro* and *in vivo* effects observed in the above *Tenebrio* study, Williams *et al*. (1997) observed that injection of RH-5849 into larvae of the tobacco hornworm, *Manduca sexta*, induced production of midgut cytosolic ecdysone oxidase and ecdysteroid phosphotransferase activities, which are involved in the inactivation of 20E. In addition, both 20E and RH-5849 caused induction of ecdysteroid 26-hydroxylase activity in the midgut mitochondria

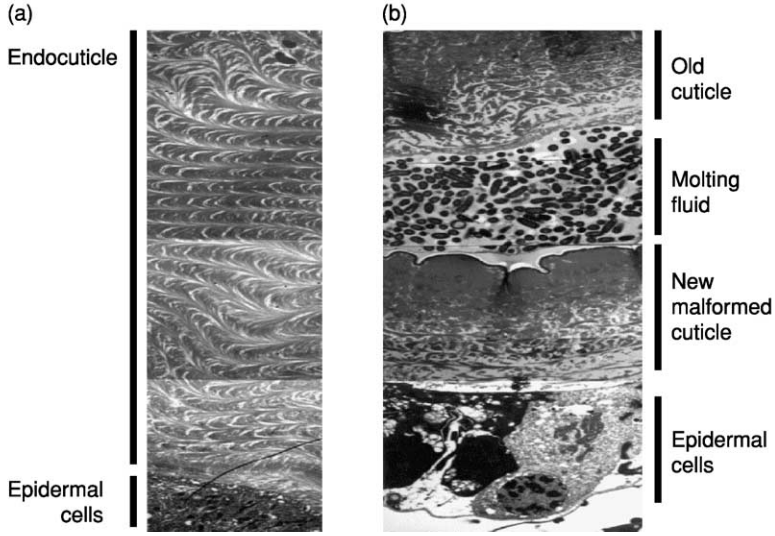

Figure 12 Transmission electron micrographs of the integument of control (a) and halofenozide (fava bean leaves dipped in a 100 ppm solution) ingested (b) second instar Colorado potato beetle larvae (same magnification). In the control integument, the epidermal cells appear normal (not clear in this figure) and the new cuticle is deposited in an ordered lamellate manner. In the integument of halofenozide intoxicated larva, the epidermal cells are highly vacuolated and the new cuticle is malformed, lacking ordered lamellate deposition. Although apolysis of the old cuticle has taken place, it is not shed, and electron dense granulated material (bacterial?) is seen in the ecdysial space. (Both micrographs taken at same magnification).

and microsomes. Subsequently, Williams *et al.* (2002) demonstrated that induction of ecdysteroid 26-hydroxylase by RH-5849, RH-5992 (tebufenozide), and RH-0345 (halofenozide) may be a universal action of bisacylhydrazines in susceptible lepidopteran larvae. These effects were not observed in nonsusceptible larvae of the waxmoth, *Galleria mellonella*, whose ecdysteroid receptor is capable of binding RH-5992 (Williams *et al.*, 2002). The binding in this case may not be sufficient for transactivation of genes that are involved in the molting process, and induced or repressed by 20E.

It is interesting to compare what happens at the molecular level in response to changing hormone levels in control insects compared to bisacylhydrazine intoxicated larvae as shown in **Figure 13**. Bisacylhydrazines, by virtue of their action via the ecdysone receptor, activate genes that are dependent upon increasing titers of 20E. However, those genes that are normally activated either by decreasing titers or absence of 20E are not expressed in the presence of ingested bisacylhydrazine in the hemolymph. During a normal molt cycle, the release of eclosion hormone to initiate the eclosion behavior in the molting larvae is dependent upon clearance of 20E titers in the hemolymph (Truman *et al.*, 1983). The presence of bisacylhydrazines in the hemolymph inhibits the release of eclosion hormone, thus resulting in an unsuccessful lethal molt.

The expression and repression of several genes during a molt cycle in lepidopteran (*M. sexta* and *C. fumiferana*) larvae treated with RH-5992 have been investigated (Retnakaran *et al.*, 1995, 2001; Palli *et al.*, 1995, 1996, 1999). In control larvae, at the time of the rise in titer of 20E, as well as those treated with RH-5992, early genes such as MHR3 (in *Manduca*), CHR3 (in *Choristoneura*), and E75, (in *Drosophila*) are expressed. As 20E titers decline, DDC, which requires a transient exposure to 20E followed by its clearance, is expressed. In RH-5992, intoxicated larvae genes like DDC are not expressed, which prevents tanning and hardening of the already malformed new cuticle. During the intermolt period, when 20E is absent, genes like those for the 14 kDa larval cuticle protein (LCP14) that are normally repressed in the presence of 20E, are expressed. Once again, the prolonged presence of RH-5992 in the hemolymph prevents the expression of LCP14, and perhaps other genes that would normally be depressed in the absence of 20E. As a consequence of all the changes induced or repressed by RH-5992, and other bisacylhydrazine insecticides, the molting process is completely derailed at the ultrastructural, physiological and molecular level leading to precocious lethal molt in susceptible larvae.

Farkas and Slama (1999) studied the effects of RH-5849 and RH-5992 on chromosomal puffing, imaginal disc proliferation, and pupariation in larvae of *D. melanogaster*. In this study, they demonstrated that the two bisacylhydrazine compounds acted like 20E in the induction of early

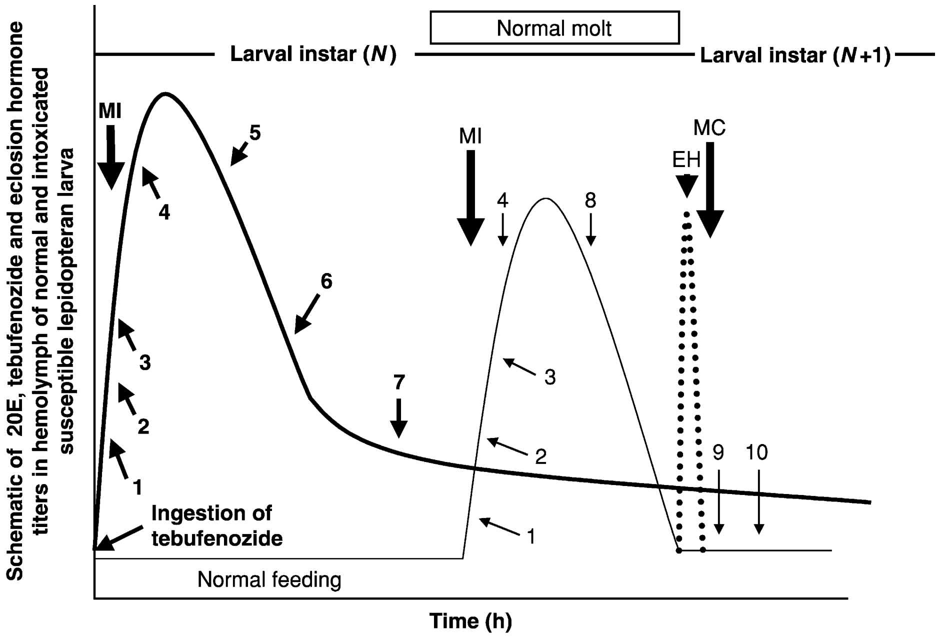

Figure 13 Schematic representation of titers 20E (thin line) and release of eclosion hormone (EH; dotted line), which triggers the ecdysis of the larva to complete a normal molt. The solid bold line represents relative titers of ingested tebufenozide in a susceptible lepidopteran larva (adapted from Dhadialla, unpublished data). Owing to the metabolic stability and amount of tebufenozide in the insect hemolymph, eclosion hormone, the release of which is normally dependent upon the complete decline of 20E, is not released and the intoxicated insect is not able to complete the molt, which leads to premature death. Both methoxyfenozide and halofenozide undergo similar metabolic fate, which is detrimental to intoxicated insect stage. The ecdysone agonists trigger a molt attempt anytime during the feeding stage of a susceptible larval instar. Events that take place during the molt and are dependent upon the increasing and decreasing titers of 20E are also shown. The numbers in bold and regular font represent different events triggered by tebufenozide and 20E, respectively. **1**, 1: Inhibition of feeding; **2**, 2: initiation of new cuticle synthesis; **3**, 3: apolysis of old cuticle from new cuticle resulting in an ecdysial space filled with molting fluid; **4**, 4: head capsule slippage; MI: molt initiated; MC: molt completed; **5**: derailment of the molting process; **6**: eclosion hormone is not released, and the larva stays trapped in its old cuticle and slipped head capsule covering the mouth parts (refer to Figure 9) causing it to starve; **7**: molt attempt is lethal and the ecdysone agonist intoxicated larvae dies of starvation, hemorrhage, and desiccation; 8: cuticle formation continues and molting fluid starts to be resorbed; 9: molt attempt is completed after release of EH and larva ecdyses into the next larval stage; 10: new cuticle hardens and the mouth parts are sclerotized so that the larva may continue its growth and development into the next stage.

chromosomal puffs (74EF and 75B), and regression of pre-existing puffs (25AC, 68C) in larval salivary glands. In the chromosomal puff assay, the ED_{50} for bisacylhydrazine compounds were, however, an order of magnitude less than for 20E. Results of additional experiments in this study using different assays, i.e., glycoprotein glue secretion, imaginal disc evagination, and rescue of phenotypic expression in ecdysone deficient mutants showed the potencies of the bisacylhydrazines were two orders of magnitude lower than for 20E. In spite of the quantitative differences in the assays used, the results confirmed the ecdysone-mimetic action of the two bisacylhydrazines.

In a study to understand the role of ecdysteroids in the induction and maintenance of the pharate first instar diapause larvae of the gypsy moth, *Lymantria dispar*, Lee and Denlinger (1997) demonstrated that a diapause specific 55 kDa gut protein could be induced in ligature isolated larval abdomens with injections of either 20E or RH-5992. They also demonstrated that the effect of KK-42, an imidazole derivative known to inhibit ecdysteroid biosynthesis, to prevent prediapausing pharate first instar larvae from entering diapause could be reversed by application of 20E or RH-5992. In this case, RH-5992 was two orders of magnitude more active than 20E.

Using 1,5-disubstituted imidazoles, Sonoda *et al.* (1995) demonstrated that the inductive effects of these compounds on precocious metamorphosis of *Bombyx mori* larvae could be reversed by tebufenozide.

6.3.2.4. Basis for Selective Toxicity of Bisacylhydrazine Insecticides

Unlike halofenozide, which is toxic to both coleopteran and lepidopteran larvae, both tebufenozide and methoxyfenozide are selectively toxic to lepidopteran larvae with a few exceptions of toxicity to

dipteran insects, like the midge, *C. tentans* (Smagghe *et al*., 2002) and the mosquito species (Darvas *et al*., 1998). This, at first, was a surprise, especially after the discovery that bisacylhydrazines are true ecdysone agonists, the activity of which, like that of 20E, is manifested via interaction with the ecdysone receptor complex. There are three basic reasons why an ingested insecticide may be differentially toxic to different insects: (1) metabolic differences between susceptible and nonsusceptible insects; (2) lack of transport to the target site in nonsusceptible insects; and (3) target site differences between susceptible and nonsusceptible insects.

Smagghe and Degheele (1994) found no differences in the pharmacokinetics and metabolism of ingested RH-5992 in two susceptible species, *Spodoptera exigua* and *S. exempta*, and a nonsusceptible insect, *Leptinotarsa decemlineata*. Similar results were obtained when the pharmacokinetics and metabolism of RH-5992 were investigated in larvae of susceptible *S. exempta* and the nonsusceptible Mexican bean beetle, *Epilachna verivesta* (Dhadialla and Thompson, unpublished results).

In competitive displacement EcR binding assays, it became apparent that one of the reasons for the differential selectivity of tebufenozide and methoxyfenozide might be due to differences in the LBDs of EcRs from different insects. While 20E binds to EcR complexes from insects from different orders with similar affinities, the affinity of tebufenozide and methoxyfenozide is very disparate for insects even within an insect order (**Table 2**). Hence, the very high affinity of tebufenozide and methoxyfenozide to lepidopteran EcR complexes correlates very well with their toxicity to larvae within this order, as well as those few amongst the Diptera. However, the same logic does not explain the toxicity of halofenozide and lack of toxicity of tebufenozide to coleopteran larvae, especially when the affinity of tebufenozide is higher than that of halofenozide for binding to EcRs from a coleopteran insect. Perhaps, in this case, the low binding affinity of halofenozide is compensated for by its greater metabolic stability (Smagghe and Degheele, 1994; Farinos *et al*., 1999).

To determine if there are additional reasons at the cellular level for the selective toxicity of tebufenozide, Sundaram *et al*. (1998) made use of four lepidopteran and dipteran cell lines all of which are responsive to 20E indicating the presence of functional EcRs. A lepidopteran cell line from *C. fumiferana* midgut cells (CF-203) and a dipteran cell line (DM-2) derived from *D. melanogaster* embryos responded to 20E in a similar dose-dependent induction of the transcriptional factor, hormone receptor 3 (HR3) CHR3 and DHR3 recspectively, which represents one of the early 20E inducible genes in the ecdysone signaling pathway. The lepidopteran CF-203 cells could produce CHR3 mRNA at 10^{-10} M RH-5992 concentration, as opposed to 10^{-6} M of this compound required for induction of very low amounts of DHR3 transcripts. In further experiments using ^{14}C-RH-5992, the authors were able to show that CF-203 cells accumulated and retained sixfold higher amounts of the radiolabeled compound than DM-2 cells over the same incubation period. Similar results were obtained with another lepidopteran cell line (MD-66) derived from *Malacosomma disstria*, and a dipteran cell line (Kc) from *D. melanogaster* embryos. This significantly higher retention of radiolabeled RH-5992 in lepidopteran cells compared to dipteran cells was in contrast to similar levels of retention of tritiated ponasterone A, a potent phytoecdysteroid. The extremely low amounts of RH-5992 in dipteran cells was due to an active efflux mechanism that was temperature-dependent and could be blocked with 10^{-5} M oubain, an inhibitor of Na^+, K^+-ATPase.

In developing a yeast based ecdysteroid responsive reporter gene assay, Tran *et al*. (2001) had to use a yeast strain that was deficient in the *pdr5* and *snq2* genes, both of which are involved in multiple drug resistance, to increase the sensitivity of the transformed strain to both steroidal and nonsteroidal ecdysone agonists. Subsequently, Retnakaran *et al*. (2001) demonstrated that while the wild-type yeast *Saccharomyces cervisiae* actively excluded tebufenozide, the *pdr5* deleted mutant strain retained significantly higher amounts of radiolabeled tebufenozide (Hu *et al*., 2001; Retnakaran *et al*., 2001). Retransformation of the mutant strain with the *pdr5* gene enabled the active exclusion of radiolabeled tebufenozide, thus once again suggesting a role for an ATP binding cassette transporter.

Some general conclusions can be drawn from the above studies regarding the selective insect toxicity of tebufenozide and methoxyfenozide. While the absence of significant differences in the pharmacokinetics and metabolism of these compounds in susceptible and nonsusceptible insects is not directly responsible for selective toxicity, it is indirectly, because the hormone levels of tebufenozide, after its ingestion by lepidopteran larvae, are about 2000-fold higher than the K_d equivalent for the lepidopteran EcR. The selective toxicity of tebufenozide and methoxyfenozide to lepidopteran larvae is probably due to the clearance of these agonists as shown in resistant cell lines where they are actively pumped out. It would be interesting to investigate if cells derived from *C. tentans* and mosquito tissues,

like lepidopteran cells, are devoid of an active mechanism to eliminate tebufenozide and methoxyfenozide, because ecdysone receptors from both these dipterans have high affinities for bisacylhydrazines (Kapitskaya *et al*., 1996; Smagghe *et al*., 2002) and are susceptible to tebufenozide (Smagghe *et al*., 2002).

6.3.2.5. Spectrum of Activity of Commercial Products

6.3.2.6.1. Chromofenozide (MATRIC®; KILLAT®; ANS-118; CM-001) Jointly developed by Nippon Kayaku Co. Ltd (Saitama, Japan), and Sankyo, Co. Ltd. (Ibaraki, Japan), chromofenozide is the latest amongst the nonsteroidal ecdysone agonist insecticides registered for control of lepidopteran pests on vegetables, fruits, vines, tea, rice, arboriculture, ornamentals, and other crops in Japan (Table 6). Chromofenozide has relatively safe mammalian, avian, and aquatic organism toxicology (Table 7). It also has no adverse effects on nontarget arthropods, including beneficials.

6.3.2.5.2. Halofenozide (MACH II; RH-0345) Unlike tebufenozide, methoxyfenozide, and chromofenozide, halofenozide is more soil systemic and has a broader pest spectrum of activity (Lepidoptera and Coleptera; Table 6). It was developed for control of beetle grub and lepidopteran larval pests of turf in lawns and on golf courses.

Halofenozide gave excellent control of the Japanese beetle (*Popillia japonica*) and the oriental

Avian: mallard duck, LC_{50} (8-day dietary)	>5000 mg kg^{-1}	>5620 mg kg^{-1}		>5000 mg kg^{-1}
Bobwhite quail, LC_{50} (8-day dietary)	>5000 mg kg^{-1}	>5620 mg kg^{-1}	>5000 mg kg^{-1} (Japanese quail, 14-day)	4522 mg kg^{-1}
Aquatic: bluegill sunfish, acute LC_{50} (96 h)	3.0 mg l^{-1}	>4.3 mg l^{-1}		>8.4 mg l^{-1}
Daphnia magna, acute EC_{50} (48 h)	3.8 mg l^{-1}	3.7 mg l^{-1}	>189 mg l^{-1} (3 h)	3.6 mg l^{-1}
Honeybee (oral and contact), acute LD_{50}	>234 μg bee^{-1}	>100 μg bee^{-1}	>100 μg bee^{-1} (contact) >133 μg bee^{-1} (oral)	>100 μg bee^{-1}
Earthworm, LC_{50} (14 days)	1000 mg kg^{-1}	>1213 mg kg^{-1}	>1000 mg kg^{-1}	980 mg kg^{-1}

beetle (*Exomala orientalis*) when applied at 1.1 kg active ingredient (a.i.) ha^{-1} to a mixed field population on turf plots (Cowles and Villani, 1996; Cowles *et al.*, 1999). In the same study, higher rates (1.7–2.2 kg a.i. ha^{-1}) were required to control the European chafer, *Rhizotrogus (Amphimallon) majalis (Razoumowsky)*, population. The Asiatic garden beetle, *Maladera castanaea* (Arrow), was not sensitive to any of the doses of halofenozide tested.

The recommended rates for the control of lepidopteran larvae (such as cutworms, sod webworms, armyworms, and fall armyworms) and beetle grubs (Japanese beetle, northern and southern masked chafer, June beetle, Black turfgrass ataenius beetle, green June beetle, annual bluegrass weevil larvae, bill bugs, aphodius beetles, European chafer, and oriental beetle) are 12 kg a.i. ha^{-1} and 18–24 kg a.i. ha^{-1}, respectively.

6.3.2.5.3. Tebufenozide (MIMIC; CONFIRM; ROMDAN; RH-5992) and methoxyfenozide (RUNNER; INTREPID; PRODIGY; RH-2485) Tebufenozide, at low use rates, shows remarkable insect selectivity for the control of lepidopteran larvae, including many members of the families Pyralidae, Pieridae, Tortricidae, and Noctuidae, which are pests of tree fruit, vegetables, row crops, and forests (**Table 6**; Le *et al.*, 1996; Dhadialla *et al.*, 1998; Carlson *et al.*, 2001). Laboratory studies have shown the following: tebufenozide administered through artificial diet or by leaves treated with tebufenozide is efficacious against *C. fumiferana* (Retnakaran *et al.*, 1999), corn earworm and fall armyworm (Chandler *et al.*, 1992), and beet armyworm (Chandler, 1994); both tebufenozide and methoxyfenozide are efficacious against laboratory reared and field populations of codling moth, *Cydia pomonella* (Pons *et al.*, 1999; Knight *et al.*, 2001), laboratory reared and multi-resistant cotton leafworm, *Spodoptera littoralis* (Smagghe *et al.*, 2000b), field populations of filbertworm, *Cydia latiferreana*, on hazelnut, and against *D. grandiosella* (Trisyono and Chippendale, 1998).

Tebufenozide has been used very successfully for the control of *C. fumiferana*, which is the most destructive insect defoliator of spruces, *Picea* sp., and balsam fir, *Abies balsamea* (L.) Mill, in North American forests (Sundaram *et al.*, 1996; Cadogan *et al.*, 1997, 1998, 2002). Cadogan *et al.* (1998) used a 240 g l^{-1} formulation of commercial tebufenozide (MIMIC® 240LV) mixed with water and a tracer dye (Rhodamine WT), which was sprayed onto the trees using a light-wing aircraft, to determine the foliar deposit of the insecticide and its efficacy against *C. fumiferana*. Single applications of 1 or 2 L ha^{-1} resulted in a 61.4–93.6% or 85.6–98.3% reduction, respectively, of the spruce budworm populations. Following double applications, the mean population reductions ranged from 93.6 to 98.3% compared to mean population reductions of 61% in untreated control fields. Defoliation in untreated control plots was about 92% and in plots with single or double spray applications, defoliation was 40–62% or 31–62%, respectively. These results indicated that a double spray application was most efficacious.

MIMIC 240LV has also provided effective control of Jackpine budworm, *Choristaneura pinus*, and *Lymantria dispar* in North American forests, as well as control of processionary caterpillar, *Thaumetopomea pityocampa*, and European pine shoot moth, *Rhyaciona buoliana*, in forests in Spain and Chile, respectively (Lidert and Dhadialla, 1996; Butler *et al.*, 1997).

Two of the major lepidopteran pests of tree-fruits are codling moth and leaf rollers, which have been controlled by frequent applications of azinphos-methyl and other organophosphate insecticides (Riedl *et al.*, 1999). With increasing requirements to use more selective insecticides without effecting biological control of other pests, much attention has been paid to the use of IGRs like chitin synthesis inhibitors, JHAs, and agonists of 20E. The effectiveness of tebufenozide against larvae of the codling moth, *C. pomonella*, has been tested both under laboratory and field conditions (Pons *et al.*, 1999; Knight, 2000). Pons *et al.* (1999) found that tebufenozide has ovicidal and larvicidal but not adulticidal activity against *C. pomonella*. Tebufenozide was about 73 times more effective when presented to neonate larvae in artificial diet as compared to treated apples; possibly because once the neonates have burrowed their way into the apples they are no longer exposed to the insecticides. However, in tebufenozide treated artificial diets, the susceptibility to the insecticide decreased with increasing age. Because of the feeding behavior of codling moth larvae, which generally do not feed and do not ingest large amounts of foliage or fruit as they burrow into the core of the fruit, the exposure to the insecticides is very limited. However, the reproductive and ovicidal effects of tebufenozide may be more important than its larvicidal effects (Knight, 2000). Knight (2000) found that in 30 field trials, tebufenozide exhibited both residual and topical ovicidal effects for codling moth egg masses laid on leaves. Similar results were obtained by Pons *et al.* (1999).

These studies indicated that the timing of tebufenozide sprays was important in not only preventing

codling moth injury to the apples, but also in controlling oblique banded leaf rollers for which both tebufenozide and methoxyfenozide have been shown to have lethal and sublethal effects (Riedl and Brunner, 1996; Sun *et al*., 2000). Knight (2000) proposed that delaying the first application of tebufenozide until after petal fall in apple for *Choristoneura rosaceana* (Harris) would correspond to an approximate codling moth timing of 30-degree days at which time this insect would be susceptible as well. This strategy, which targets the adults and eggs, was effective in the control of codling moth.

Both tebufenozide and methoxyfenozide are active primarily by ingestion, but also exhibit selective contact and ovicidal activity (Trisyono and Chippendale, 1997; Sun and Barrett, 1999; Sun *et al*., 2000).

6.3.2.6. Ecotoxicology and Mammalian Reduced Risk Profiles

Both tebufenozide and methoxyfenozide have been classified by the US Environmental Agency (EPA) as reduced risk pesticides because of their low acute and chronic mammalian toxicity, low avian toxicity, and their safety to most beneficial arthropods and compatibility with integrated pest management programs. Both tebufenozide and methoxyfenozide are toxic primarily to lepidopteran pests, but they are also toxic to a few dipteran (*C. tentans*, mosquitos) pests. Of the 150 insect species tested, both tebufenozide and methoxyfenozide were found to be safe to members of the insect orders Hymenoptera, Coleoptera, Diptera, Heteroptera, Hemiptera, Homoptera, and Neuroptera (Glenn Carlson, unpublished data). When used at rates that are 18- to 1500-fold greater than that producing 90% mortality in lepidopteran larvae, both tebufenozide and methoxyfenozide had little or no effect on a panel of non-lepidopteran pests (Coleoptera, Homoptera, mites, and nematodes; Trisyono *et al*., 2000; Carlson *et al*., 2001; Medina *et al*., 2001). Similarly, laboratory and/or field studies have shown that the two insecticides have little or no adverse effect on a wide range of non-lepidopteran beneficial insects, like honeybees and predatory insects/mites, when applied at rates used for control of lepidopteran larvae.

In 1998, methoxyfenozide became one of the only four pesticide products to be awarded the "Presidential Green Chemistry Award," which was established by the US Government during 1995 to recognize outstanding chemical processes and products that reduce negative impact on human health and the environment relative to the currently available technology.

The ecotoxicological and mammalian toxicity data for the four commercial ecdysone agonist insecticides are shown in **Tables 7 and 8**. These data clearly show the low mammalian, avian, and aquatic toxicity of these insecticides.

6.3.2.7. Resistance, Mechanism, and Resistance Potential

Tebufenozide is the first nonsteroidal ecdysone agonist with commercial application and has been used in Western Europe since the mid 1990s. In the USA, the first uses occurred concurrently in 1994 in Alabama and Mississippi under Section 18 exemptions (Walton *et al*., 1995; Dhadialla *et al*., 1998).

Resistance to tebufenozide was documented for the first time in the codling moth *C. pomonella* around Avignon in southern France (Sauphanor and Bouvier, 1995; Sauphanor *et al*., 1998b) and in the greenheaded leafroller, *Planotortrix octo*, in New Zealand (Wearing, 1998). A small survey with the beet armyworm, *S. exigua*, collected in different greenhouses in Western Europe (Spain, Belgium, The Netherlands) showed lack of resistance development to tebufenozide (Smagghe *et al*., 2003b). In this same period, Smagghe *et al*. (1999a) kept a laboratory strain of *S. exigua* under continuous pressure with sublethal concentrations of tebufenozide over 12 generations, and in the sixth generation a significantly lower toxicity (about five-fold) was observed. In addition, retention and

Table 8 Mammalian reduced risk profile of bisacylhydrazine insecticides

	Tebufenozide	*Methoxyfenozide*	*Chromofenozide*	*Halofenozide*
Acute oral LD_{50} (rat, mouse)	>5000 mg kg^{-1}	>5000 mg kg^{-1}	>5000 mg kg^{-1}	2850 mg kg^{-1}

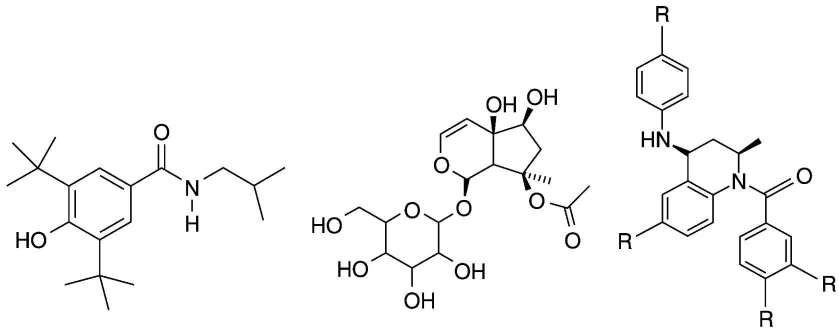
Reproduction (rat)	No effect	No effect	No effect	No effect



metabolic fate studies showed the importance of oxidative metabolism, leading to a rapid clearance from the body. Interestingly, a decrease in oviposition was noted with the lower toxicity indicating a possible fitness cost related to development of resistance (Smagghe and Degheele, 1997; Smagghe *et al.*, 1998). More recently, Moulton *et al.* (2002) reported resistance to tebufenozide in third instar larvae, which reached levels of 150-fold in a selected strain of *S. exigua* from Bangbuathong (Thailand) as compared with a laboratory reference strain. In this region of Thailand, many insecticides including organophosphates (OPs), pyrethroids, benzoylphenylurea (BPUs), and *Bacillus Thurigiensis* (Bt) formulations, and even new IGRs have been rendered ineffective due to ill-advised agricultural practices, most notably dilution of insecticide residues on leaves by overhead drench irrigation (Moulton *et al.*, 2002). This practice is likely to be responsible for the high incidence of insecticide multiresistance in this area and the highly accelerated rate of resistance development. When this Thailand strain was dosed with methoxyfenozide, 120-fold lower toxicity was observed. These selection assays with tebufenozide and methoxyfenozide showed a reduction in toxicity for both compounds, suggesting at least some commonality of resistance mechanism (Moulton *et al.*, 2002). A greenhouse raised strain of *S. exigua*, in southern Spain was also found to be resistant to tebufenozide and methoxyfenozide. Although the level of resistance was lower in this second strain, it was high enough to allow studies on the mechanism(s) of resistance. In general, a higher breakdown activity leads to lower levels of the parent toxophore. For tebufenozide and methoxyfenozide the major first phase route of detoxification was through oxidation (Smagghe *et al.*, 1998, 2003). In addition, piperonyl butoxide, a P450 inhibitor, significantly synergized the toxicity of tebufenozide and methoxyfenozide, whereas DEF, an esterase inhibitor, was ineffective (Smagghe *et al.*, 1998, 1999), indicating that a lower toxicity was more likely from an increase in oxidative activity, rather than in esterase activity. At the cellular level, Retnakaran *et al.* (2001) reported that tebufenozide accumulated selectively in lepidopteran Cf-203 (*C. fumiferana*) cells in contrast to dipteran Dm-2 cells (*D. melanogaster*), which actively excluded the compound (see Section 6.3.2.4 for more details). Perhaps such exclusion systems may also account for the fact that older instars of the white-marked tussock moth (*Orgyia leucostigma*) are resistant to tebufenozide (Retnakaran *et al.*, 2001). The characterization of all such possible resistance processes is essential to provide information that is helpful to prevent resistance from developing towards this valuable group of IGRs. But more information is needed with additional strains collected from the field, especially where growers have severe pest control problems, before a general interpretation can be formulated on resistance risks for this new type of IGRs in the field.

While the available data suggest oxidative metabolism as the primary reason for development of resistance to tebufenozide and methoxyfenozide, there is no evidence so far that suggests that target site modification could be involved as another route to resistance development in field or laboratory insect populations. However, at the cellular level, there is evidence that there could be alterations in the target site(s). Using insect cell lines, Cherbas and co-workers were the first to report that *in vitro* cultured Kc cells of *D. melanogaster* did not respond to 20E after continuous exposure (Cherbas, personal communication). Similarly, Spindler-Barth and Spindler (1998) reported that cells of another dipteran, *C. tentans*, maintained in the continuous presence of increasing concentrations of 20E or tebufenozide over a period of 2 years, developed resistance to both compounds. In these resistant subclones, all 20E regulated responses that are known to occur in sensitive cells were no longer detectable, suggesting that the hormone signalling pathway itself was interrupted (Spindler-Barth and Spindler, 1998; Grebe *et al.*, 2000). Further ligand binding experiments with extracts containing ecdysone receptors from susceptible and resistant cells indicated that ligand binding to EcR from resistant clones was significantly decreased. Moreover, an increase in 20E metabolism and a reduction in receptor concentration were noted in some clones. Similar effects have also been observed in another study using imaginal discs of *S. littoralis* selected for resistance to tebufenozide (Smagghe *et al.*, 2001).

While resistance to ecdysone agonist insecticides is inevitable, it can be prevented from occurring sooner with good resistance monitoring programs.

6.3.2.8. Oher Chemistries and Potential for New Ecdysone Agonist Insecticides

After the discovery of the first three bisacylhydrazine insecticides by scientists at Rohm and Haas Company, Spring House, PA, USA, a number of laboratories initiated such efforts to discover new and novel chemistries with ecdysone mode of action and different pest selectivity. Mikitani (1996) at Sumitomo Company, Japan, discovered a benzamide, 3,5,-di-*t*-butyl-4-hydroxy-N-isobutyl-benzamide

(1) **(2)** **(3)**

Figure 14 Chemical structures of new ecdysone agonists reported in literature: (**1**) 3,5-di-*t*-butyl-4-hydroxy-*N*-isobutyl-benzamide (DTBHIB) from Sumitomo; (**2**) 8-*O*-acetylhrapagide from Merck Research Laboratories, Westpoint, PA, USA and (**3**) tetrahydroquinoline from FMC Corporation, Princeton, NJ, USA. In (3) R = halide.

(DTBHIB; **Figure 14**) and Elbrecht *et al.* (1996) at Merck Research Laboratories, Westpoint, PA, USA, reported the isolation of an iridoid glycoside, 8-*O*-acetylharpagide (**Figure 14**), from *Ajuga reptans*. Both these compounds were reported to induce 20E-like morphological changes in *Drosophila* Kc cells, as well as competitively displace tritiated ponasterone A from *Drosophila* ecdysteroid receptors with potencies similar to that of RH-5849, the unsubstituted bisacylhydrazine. However, the insecticidal activity of these compounds was not described. Attempts to replicate the results of Mikitani (1996) using DTBHIB and analogs failed to demonstrate that these compounds were competitive inhibitors of tritiated ponasterone A binding to DmEcR/DmUSP produced by *in vitro* transcription and translation (Dhadialla, unpublished observations). On the other hand, Dinan *et al.* (2001) demonstrated that the results obtained by Elbrecht *et al.* (1996) were due to co-purification of ecdysteroids in their 8-O-acetylharpagide preparation. When used as a highly purified preparation, Dinan *et al.* (2001) found that 8-*O*-acetylharpagide was not active as an agonist or an antagonist in *D. melanogaster* BII cell bioassay, and neither did it compete with tritiated ponasterone A for binding to the lepidopteran ecdysteroid receptor complex from *C. fumiferana*.

Finally, scientists at FMC discovered a new tetrahydroquinoline (THQ) class of compounds (**Figure 14**) that competitively displaced tritiated ponasterone A from both dipteran (*D. melanogaster*) and lepidopteran (*H. virescens*) EcR and USP heterodimers (unpublished data). Interestingly, the most active analogs of this class of compounds bound the DmEcR/DmUSP with much higher affinity than the HvEcR/HvUSP. This is the reverse of what was observed with bisacylhydrazines. When tested for ligand binding to EcR/USP proteins from *L. migratoria, B. argentifoli, and T. molitor*, to which bisacylhydrazines show no measurable affinity, members of the THQ were found to bind with measurable affinity (μM range; Dhadialla and colleagues, unpublished results). Further work on this chemistry was continued at Rohm and Haas Company, Spring House, PA, USA, and its subsidiary, RheoGene LLC, Malvern, PA, USA, which resulted in the synthesis of a number of analogs that were active in transactivating reporter genes fused to different insect EcRs and heterodimeric partners (*L. migratoria* RXR, and human RXR) in mouse NIH3T3 cells (Michelotti *et al.*, 2003).

The discovery of THQs with ligand binding activities to various EcRs (Michelotti *et al.*, 2003), some of which do not interact with bisacylhydrazines, and the interpretation of X-ray crystal structure results of liganded HvEcR/HvUSP (Billas *et al.*, 2003) provides good evidence for the potential to discover new chemistries with ecdysone agonist activities. It should also be possible to design chemistries that specifically interact with EcR/USPs from a particular insect order.

6.3.2.9. Noninsecticide Applications of Nonsteroidal Ecdysone Agonists; Gene Switches in Animal and Plant Systems

A number of researchers started to explore the utilization of the ecdysone receptor as an inducible gene switch due to the knowledge that neither mammals nor plants have ecdysone receptors, and the discovery of bisacylhydrazine as true ecdysone agonists with reduced risk ecotoxicology and mammalian profiles. Gene switches are inducible gene regulation systems that can be used to control the expression of transgenes in cells, plants, or animals. There is a recognized need for tightly regulated eukaryotic molecular gene switch applications, such as for gene therapy, and in understanding the role played

by specific proteins in signaling pathways, cell differentiation, and development (Allgood and Eastman, 1997). Other applications include large-scale production of proteins in cells, cell-based high-throughput screening assays, and regulation of traits in both plants and animals. Unlike all other previous and current insecticides, commercial nonsteroidal ecdysone agonists are the first class of insect toxic chemistry that has led to such a high level of interest and utility outside the insecticide arena. The following is a brief overview of the use of bisacylhydrazine insecticides and EcRs as gene switches in mammalian and plant systems.

6.3.2.9.1. Gene switch in mammalian systems Christopherson *et al.* (1992) demonstrated that DmEcR could function as an ecdysteroid-dependent transcription factor in human 293 cells cotransfected with an RSV-based expression vector that encoded DmEcR and a reporter gene, which contained four copies of *Drosophila* Hsp27 linked to a MTV promoter-CAT construct. They demonstrated that the activity of DmEcR could not be activated by any of the mammalian steroid hormones tested. Even amongst the ecdysteroids, the phytoecdysteroid muristerone A was the best transactivator of the reporter gene, while 20E was not as effective. These authors further demonstrated that chimeric receptors containing the LBD of DmEcR and the DBD of glucocorticoid receptor could also function when cotransfected with plasmids containing glucocorticoid receptor response elements fused to a reporter gene. Subsequently, No *et al.* (1996) demonstrated that an EcR-based gene switch consisting of DmEcR, *Homo sapiens* RXR, and appropriate response elements fused to a reporter gene in mammalian cells or transgenic mice could be transactivated with micromolar levels of muristerone A. Muristerone was shown to maintain its activity when injected into mice and was not found to be toxic, teratogenic, or inactivated by serum binding proteins. Moreover, overexpression of modified DmEcR and RXR did not appear to to be toxic, at least in transfected cells. This study, like an earlier one (Yao *et al.*, 1995), demonstrated that HsRXR could substitute for its insect homolog and heterodimer partner for EcR, USP. However, in all these studies, the range of activating ligands was limited to ecdysteroids and, in particular, to muristerone A. In addition, RXR, which is present in almost all mammalian cells, was found not to be as good a partner for EcR as USP. Hence, very high endogenous levels were necessary for stimulation with muristerone A to occur.

With the availability of EcR and USPs from other insects, especially lepidopteran insects, and understanding the high affinity of nonsteroidal ecdysone agonists like tebufenozide and methoxyfenozide for lepidopteran EcRs/USPs, Suhr *et al.* (1998) demonstrated that the *B. mori* EcR (BmEcR), unlike DmEcR, could be transactivated to very high levels in mammalian cells with tebufenozide without adding an exogenous heterodimer partner like RXR. The endogenous levels of RXR were enough to provide the high transactivation levels. The work by Suhr *et al.* (1998) further demonstrated that while the D domain (hinge region) of EcR was necessary for high-affinity heterodimerization with USP, both D and E (LBD) domains were necessary for high-affinity interaction with RXR. By creating chimeric EcR using parts of E-domains from BmEcR and DmEcR, these investigators showed that a region in the middle of the E-domain (amino acids 402 to 508) in BmEcR constituted the region conferring high specificity for tebufenozide. Subsequent research by others has mainly focused on using EcRs and USPs from other insects as well as using different promoters for expression of the transfected genes (Kumar *et al.*, 2002; Dhadialla *et al.*, 2002; Palli and Kapitskaya, 2002; Palli *et al.*, 2002, 2003). Based on EcR homology modeling studies and site-directed mutagenesis of selected amino acid residues, Kumar *et al.* (2002) found that a CfEcR mutant, which had an A110P mutation in the LBD, was responsive only to nonsteroidal ecdysone agonists, including methoxyfenozide, but not to any of the ecdysteroids tested. This demonstrated that the affinity and functional specificity of an EcR for a ligand can be altered, thus offering the possibility of using multiplexed EcR-based gene switches that could regulate different traits with different ligands. Palli *et al.* (2003) developed a two-hybrid EcR based gene switch, which consisted of constructs containing DEF domains of CfEcR fused to the GAL4 DNA binding domain, and CfUSP or *Mus musculus* retinoid X receptor (MsRXR) EF domains fused to the VP16 activation domain. These constructs were tested in mammalian cells for their ability to drive a luciferase gene placed under the control of GAL4 response elements and synthetic TATAA promoter. This combination gave very low level basal activation of the reporter gene in the absence of the inducer. In the presence of the inducer, there was a rapid increase in the expression of the luciferase reporter gene, reaching levels as high as 8942-fold greater than basal level by 48 h. Withdrawal of the ligand resulted in 50% and 80% reduction of the reporter gene by 12 h and 24 h, respectively.

These studies clearly demonstrate the potential of utilizing EcR based gene switches that can be activated by ecdysteroids and nonsteroidal ecdysone agonists like tebufenozide, methoxyfenozide, and others. The fact that both tebufenozide and methoxyfenozide are registered as commercial insecticides, and have proven reduced risk mammalian and ecotoxicology profiles, makes them very attractive as inducers of the EcR based gene switches. The work of Kumar *et al.* (2002) clearly demonstrates the potential of mutating EcR to change its ligand specificity, thus opening additional possibilities of extending the use of the EcR gene switch in a multiplexed manner.

6.3.2.9.2. Gene switch for trait regulation in plants The reader is referred to very good recent reviews on this topic that not only describe the EcR-based chemically inducible gene regulation systems, but also other systems that have utility in plants (Jepson *et al.*, 1998; Zuo and Chua, 2000; Padidam, 2003). This section is restricted to descriptions of EcR-based gene switch systems.

In the mid-1990s, a number of agricultural companies initiated research to exploit the use of the EcR-based gene switch and nonsteroidal ecdysone agonists like tebufenozide as chemical inducers for regulation of traits (for example, fertility, flowering, etc.) in plants. Initial work was done using DmEcR and DmUSP as components of the gene switch (Goff *et al.*, 1996). In this case, the researchers used chimeric polypeptides (GAL4 DBD fused to LBD of DmEcR and VP16 activation domain fused to DmUSP) to activate the luciferase reporter gene fused to GAL4 response element in maize cells. In the presence of 10 μM tebufenozide, about 20- to 50-fold activation of luciferase expression was obtained. Subsequently, a number of researchers developed variants of EcR gene switches using different chimeric combinations of heterologous DBD, LBDs from different lepidopteran EcRs, and transactivation domains that could interact with appropriate response elements to transactivate a reporter gene in a ligand-dependent manner (Martinez *et al.*, 1999a; Unger *et al.*, 2002; Padidam *et al.*, 2003). For example, Jepson *et al.* (1996) and Martinez *et al.* (1999b) used chimeric *H. virescens* EcR (HvEcR) composed of glucocorticoid receptor transactivation and DBD fused to LBD of HvEcR and *GUS* reporter gene fused to glucocorticoid receptor response element for transfection of maize and tobacco protoplast. In both cases, weak transactivation of the *GUS* reporter gene was obtained with tebufenozide and muristerone A, though the response with the latter was much lower than with tebufenozide. However, 10 μM and higher concentrations of the two ligands were required to transactivate the reporter genes.

Padidam *et al.* (2003) used a chimeric *C. fumiferana* EcR (CfEcR) composed of a CfEcR LBD, GAL4 and LexA DBDs, and VP16 activation domains that could be activated with methoxyfenozide in a dose-dependent manner from a GAL4- or LexA-response element to express a reporter gene. These researchers used *Arabidopsis* and tobacco plants for transformation with the gene switch components and obtained several transgenic plants that had little or no basal level of expression in the absence of methoxyfenozide. In the presence of methoxyfenozide, reporter expression was several fold higher than in the absence of methoxyfenozide. The above studies provided ample evidence of the utility of EcR gene switch, especially those that utilize EcR from a lepidopteran species, and tebufenozide and methoxyfenozide as chemical inducers for trait regulation in plants.

Demonstration of the utility of EcR-based gene switch for trait regulation in maize was demonstrated by Unger *et al.* (2002). A mutation in maize (MS45), which results in male-sterile phenotype, could be reversed by complementation to gain fertility using methoxyfenozide-dependent chimeric receptor gene switch to express the wild-type MS45 protein in tapetum and anthers. These researchers used the EcR LBD from, *O. nubialis* to generate a chimeric receptor. The chimeric receptor was introduced into MS45 maize with the MS45 gene fused to the GAL4 response element, which in the absence of methoxyfenozide were male sterile. However, application of methoxyfenozide to plants containing either a constitutive promoter or anther specific promoter resulted in the restoration of fertility to MS45 plants grown in either the greenhouse or the field.

It is interesting to note that in all the above studies, except those by Goff *et al.* (1996), reporter transactivation response to tebufenozide, methoxyfenozide, or muristerone A via the EcR gene switch was obtained without the requirement of an exogenous heterodimeric partner (USP or RXR), suggesting that there may be other factor(s) in plants that can substitute for USP as a partner for EcR, or that EcR can function as a homodimer. However, as far as is known, there is no evidence of EcR binding an ecdysteroid or nonsteroid ligand in the absence of USP or RXR. Irrespective, these studies provide ample demonstration of the utility of EcR-based gene switch, which can be regulated with an ecdysteroid or a nonsteroidal ecdysone agonist. The use of nonsteroidal ecdysone agonists, like any of the commercialized products, is attractive because

their reduced risk for the environment and mammals, birds, aquatic animals, and beneficial arthropods has been found to be acceptable. The specificity and the high affinity with which the bisacylhydrazines bind ecdysteroid receptors also offers the opportunity to utilize different ligands and ecdysone receptors to regulate more than one trait in a plant or an animal system.

6.3.2.10. Conclusions and Future Prospects of Ecdysone Agonists

The discovery of bisacylhydrazine insecticides with a new mode of action, very high degree of selective insect toxicity and reduced risk to the environment, has spurred a lot of interest in this mode of action and chemistry. The biochemical and molecular information on insect EcRs from different orders of insects, crystal structures of liganded HvEcR/HvUSP, and of DmUSP and HvUSP, and the discovery of new non-bisacylhydrazine chemistries, offers potential for the discovery of other new and novel chemistries with ecdysone mode of action and those that would be selectively toxic to nonlepidopteran and coleopteran pests. Although the existing bisacylhydrazine insecticides are most efficacious when ingested, the use of this type of control method could be extended to act against other types of pests if ways could be found for these insecticides to be effective via topical or systemic applications. These bisacylhydrazine insecticides, because of their new mode of action, insect selectivity, and reduced risk ecotoxicology and mammalian profiles, are ideally suited for use in integrated insect management programs.

An altogether different benefit from the discovery of nonsteroidal ecdysone agonists as insecticides has been in the area of gene switch applications in plants and animals. In this particular application, it may be possible to alter the molecular structure of ecdysone receptor LBDs to accommodate new chemistries as gene switch ligands. This is an exciting active area of research that, if successfully applied, offers a number of opportunities in trait and gene regulation in both plant and animal systems. The search for new and novel chemistries that target ecdysone receptors will continue to be a fruitful area of research for several years.

6.3.3. Juvenile Hormone Analogs

Kopec (1922) extirpated the brain of a caterpillar and demonstrated that this prevented pupation; he attributed this phenomenon to a humoral factor produced by the brain. This discovery heralded the study of hormonal regulation of metamorphosis in insects. Wigglesworth (1936) later described the secretion of a hormone that prevents metamorphosis from a pair of glands, the corpora allata (CA) attached to the base of the brain; he called it the "status quo" or juvenile hormone (JH). A few years later, Fukuda (1994) described the prothoracic glands as the source of the molting hormone or ecdysone, which was later characterized as a steroid hormone (Butenandt and Karlson, 1954). At about the same time, the physiology of JH was elegantly worked out by Williams (1952). The chemical characterization of its structure, however, eluded researchers until 1967 when Röller and co-workers finally showed that it was a sesquiterpene, epoxy farnesoic acid methyl ester. At this time, Williams (1967) made the now famous statement, "third generation pesticides" in describing the use of JHs as environmentally safe control agents to which the insect will be unable to develop resistance, the first and second generation pesticides being the inorganic and the chlorinated hydrocarbons, respectively. The development of highly potent synthetic analogs of JH, which were several fold more active than the native hormone, gave credence to William's claim (Henrick *et al*., 1973).

This section describes the biological activity of JH and its analogs as well as their modes of action as understood today. Some of the major uses of JHAs for pest management are cataloged and finally prospects for future development are mentioned.

6.3.3.1. Juvenile Hormone Action

Juvenile hormone has a unique terpenoid structure and is the methyl ester of epoxy farnesoic acid (see also **Chapter 3.7**). This sesquiterpene exists in at least six different forms (**Figure 15**). JH III is the most common type and is present in most insects. Five different JHs, JH 0, I, II, III, and 4-methyl-JH I, have been described in lepidopterans. The bis-epoxide of JH, JH B_3, is found along with JH III in higher Diptera (Cusson and Palli, 2000). Various studies show that JH III is the main JH in most insects whereas JH I and II are the principal ones in Lepidoptera. Biosynthesis of JH proceeds through the mevalonate pathway with acetyl coenzyme A (acetyl CoA) serving as the building block. Propionyl CoA is used wherever ethyl side chains occur. Epoxidation and esterification are the terminal steps in the biosynthetic process (Schooley and Baker, 1985; Brindle *et al*., 1987).

JH secretion by the corpus allatum is regulated by two neurohormones, the allatotropins that stimulate secretion and the allatostatins that inhibit production. Severing the nerve connections or extirpating the neurosecretory cells results in the loss of

control (Tobe and Stay, 1985; Tobe *et al*., 1985; Lee *et al*., 2002). JH is cleared from the hemolymph by JH esterase, which selectively cleaves the methyl ester inactivating the hormone (Wroblewski *et al*., 1990; Feng *et al*., 1999). JH being highly lipophilic is made soluble by JH binding proteins (JHB) to facilitate transportation to the target sites as well as protect it from degradation from nonspecific esterases (Goodman, 1990). The receptor rich structure of the corpus allatum from the female cockroach, *Diploptera punctata*, is illustrated in **Figure 16** (Chiang *et al*., 2002).

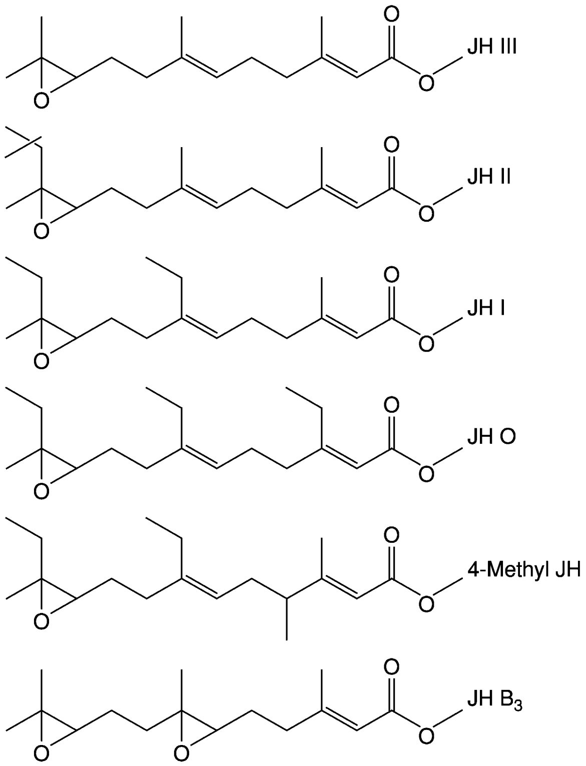


Figure 15 Chemical structure of naturally occurring JHs.

JH is perhaps one of the most pleiotropic hormones known and functions in various aspects of metamorphosis, reproduction, and behavior (Riddiford, 1994, 1996; Wyatt and Davey, 1996; Cusson and Palli, 2000; Palli and Retnakaran, 2000; Hiruma, 2003; Riddiford *et al*., 2003).

The major function of JH is the maintenance of the larval status or the so-called juvenilizing effect. During the last larval instar in lepidoptera there is an absence of JH during the commitment peak of 20E, which results in the reprogramming of metamorphosis towards pupation (**Figure 17**). In the absence of JH, this ecdysone peak induces the expression of the broad complex gene (*BrC* or *Broad*), which is a transcription factor that initiates the larval–pupal transformation through several microRNAs (miRNAs) (Zhou and Riddiford, 2002; Sempere *et al*., 2003). In adults, JH secretion resumes and is responsible for yolk protein (vitellogenin) synthesis and transport into the ovaries (Wyatt and Davey 1996). In addition, JH is also responsible for adult diapause where the ovaries do not develop due to the absence of JH and this effect

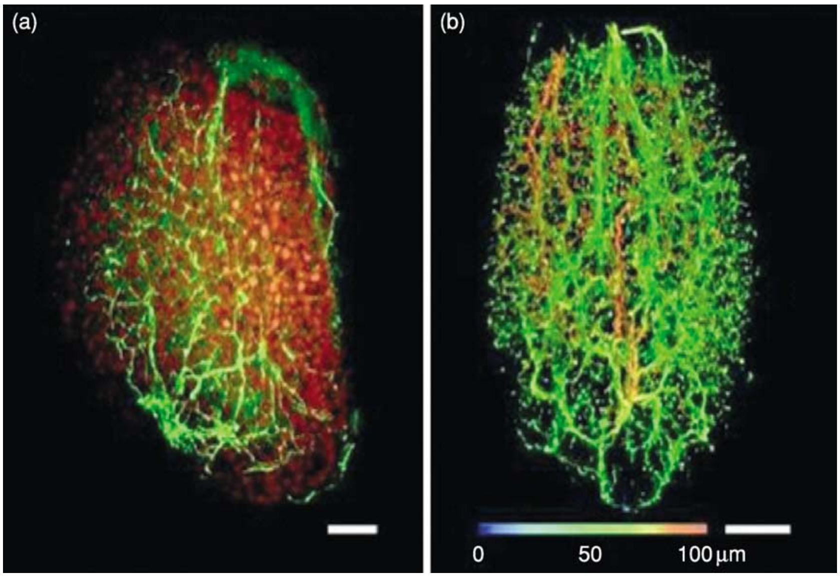

Figure 16 Corpus allatum of female cockroach, *Diploptera punctata*. (a) *N*-methyl-D-aspartate subtype of glutamate receptors (NMDAR) in the nerve fibers (green) involved in JH synthesis and nuclei (red) of parenchyma cells counterstained with propidium iodide. (b) Allatostatin-immunoreactive nerve fibers in the gland (depth code with different colors indicates distance of an object from the surface). Scale bar = 50 μm. can be reversed by applying JH. JH has also been shown to play a role in caste determination, pheromone production, polyphenism, migration, antifreeze protein production, female sexual behavior, male accessory gland secretion, etc. (Wyatt and Davey, 1996).

6.3.3.2. Putative Molecular Mode of Action of JH

The mode of action at the molecular level has not been completely understood at present. Three types of action have been hypothesized and varying degrees of support for each of these modes have been reported. First is the direct action where it directly induces the secretion of a product (Iyengar and Kunkel, 1995; Feng *et al*., 1999). Second is the indirect action where it modulates the action of 20E (Dubrovski *et al*., 2000; Zhou and Riddiford, 2002). In these two instances, the action is at the genomic level where JH has to bind to nuclear receptors to evoke its action. The third involves the role of JH in the transport of vitellogenin into the oocytes through a membrane receptor (Sevala and Davey, 1989). A search for a nuclear as well as a membrane receptor by many investigators over several years has not yielded any concrete results. A nuclear protein isolated from *M. sexta* epidermis using a human retinoic acid receptor as a probe turned out to be an ecdysone-induced transcription factor, a homolog of *Drosophila* hormone receptor 3 (DHR3). A 29 kDa epidermal nuclear protein was found to be a low-affinity JHB (Palli *et al*., 1994; Charles *et al*., 1996). A *D. melanogaster* mutant tolerant to the JHA, methoprene (Met) contained an 85 kDa protein that showed high affinity to JH III (Wilson and Fabian, 1986; Shemshedini *et al*., 1990). The gene was cloned and was identified as a member of the basic helix–loop–helix (bHLH) PAS family of transcriptional regulators (Ashok *et al*., 1998). Attempts to demonstrate the *Met* gene as the JH receptor have only added more confusion to the picture. The ultraspiracle (*USP*) gene, a homolog of the human retinoid-X receptor (RXR) and the heterodimeric partner of the EcR, was demonstrated to be involved in signal transduction of JH III in both yeast (Jones and Sharp, 1997) and Sf9 (Jones *et al*., 2001; Xu *et al*., 2002) cell based assays. In both cases, the cells were transformed with DNA sequences encoding DmUSP, in which JH III application resulted in transactivation. Isolated, recombinant DmUSP specifically bound JH III, and the authors report that *USP* homodimerizes and changes tertiary conformation, including the movement of the LBD α-helix 12 (Jones *et al*., 2001; Xu *et al*., 2002). Xu *et al*. (2002) also reported that ligand binding pocket point mutants of *USP* that did not bind JH III also acted as dominant negative suppressors of JH III activation of reporter promoter, and addition of wild-type *USP* rescued this activation. However, Hayward *et al*. (2003) were not able to demonstrate binding of tritiated JH III to USP from *L. migratoria*. In contrast to results obtained from Jones *et al*. (2001) and Xu *et al*. (2002), the crystal structure

of both HvUSP and DmUSP with a lipophilic ligand revealed the LBD α-helix 12 in an open, antagonist position (Billas *et al.*, 2001; Clayton *et al.*, 2001). While it is unclear whether *USP* is the true nuclear JH receptor, the evidence so far is at best equivocal.

Another approach to eluciding the molecular target(s) of JH action has been the use of JH responsive genes. Several have been identified, such as *jhp21* from *L. migratoria* (Zhang *et al.*, 1996). A response element in the promoter region of this gene binds to a protein, which is thought to be a transcription factor activated by JH (Zhou and Riddiford, 2002). Unfortunately, many of these JH responsive genes appear to be induced by JH at a slow rate, suggesting that they may not be the primary site of regulation. However, there are some genes, such as the JH esterase gene (*JHE*) from a *C. fumiferana* cell line, CF-203, that are induced by JH I within 1 h of administration (Feng *et al.*, 1999). This Cf *jhe* appears to be a primary JH responsive gene, which is induced by JH I and suppressed by 20E in a dose-dependent manner. Work in authors' laboratory has shown that a 30 bp minimal promoter region upstream of the Cf *jhe* transcription start site appears to bind to a nuclear protein isolated from the CF-203 cells (Retnakaran *et al.*, unpublished data). Whether or not it needs to be a high-affinity, low-abundance protein to qualify as a putative JH nuclear receptor is currently under investigation. It has been suggested that JH could act through a membrane receptor as well, as shown by the work of Davey on vitellogenin transport into the oocytes (Wyatt and Davey, 1996). JH acts on the follicle cells of the ovary and makes them contract, causing large spaces to appear between the cells; this process has been termed "patency." This intercellular space formation (patency) permits the vitellogenin from the hemolymph to enter the ovary and gain access to the surface of the oocyte and subsequently enter these cells. This phenomenon was originally described in *R. prolixus* but was later shown in many other species including locusts (Wyatt and Davey, 1996). This membrane-bound receptor appears to be coupled to a G protein and the signal is transduced through a protein kinase system activating an ATPase that permits, among other things, the transport of vitellogenin into the cells (**Figure 18**).

And so the search goes on to unambiguously identify the nuclear and membrane receptors of JH. Characterizing such a receptor would open the

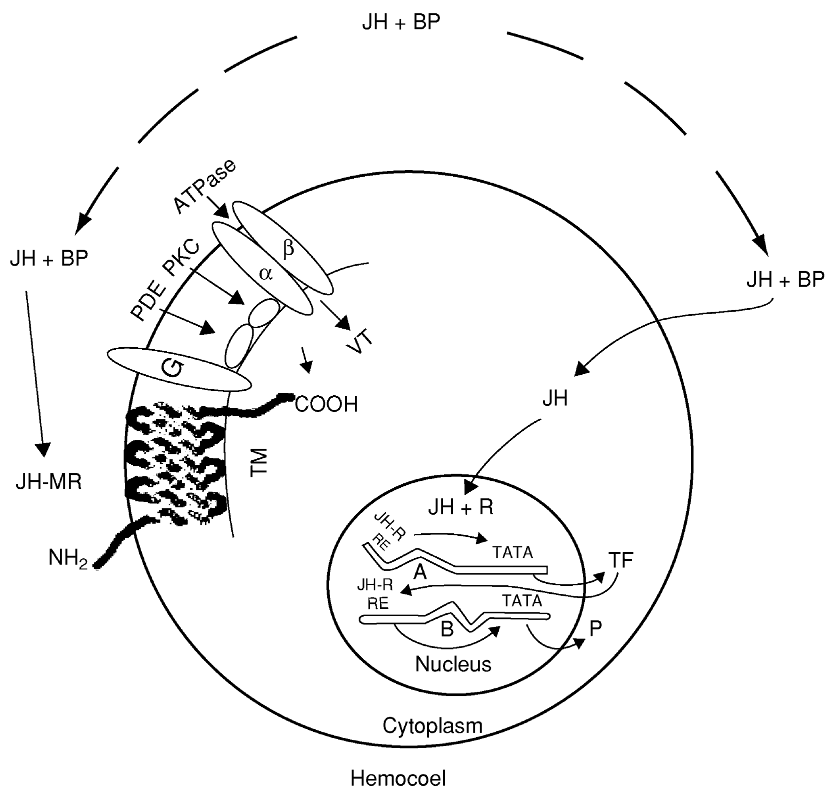

Figure 18 Putative dual receptor mechanism for JH action. A and B are two DNA transcripts; ATPase, Na^+K^+ ATPase with α and β subunits; BP, JH binding protein; G, G protein; JH, juvenile hormone; JH-BP, JH bound to binding protein; JH-MR, JH bound to membrane receptor; PDE, phosphodiesterase; PKC, protein kinase C; RE, hormone response element; TATA, transcription initiation site; TF, transcription factor; TM, transmembrane region. (Reproduced with permission from Wyatt, G.R., Davey, K.G., **1996**. Cellular and molecular actions of JH. II. Roles of JH in adult insects. *Adv. Insect Physiol. 26,* 1–155.)

door for a more rational approach to developing target specific control agents.

6.3.3.3. Pest Management with JHAs

The idea that insects would be unable to develop resistance against JH if it was used as a control agent was one of the driving principles behind the impetus to develop this hormone as an insecticide (Williams, 1967). The difficulty and cost of synthesizing such a complex molecule with a labile epoxide moiety and susceptibility to degradation delayed the realization of this concept. However, it soon became apparent that several synthetic analogs of JH, many of them several fold more active than the native hormone, could be used as control agents. The discovery that some synthetic synergists of insecticides have intense JH activity (Bowers, 1968) was the harbinger for the development of various new analogs with diverse chemical structures. Consequently, the modes of action of these analogs may not necessarily be similar.

Over the years, numerous JHAs have been synthesized and their relative potencies, structure–activity relationships, and differential effects on various species have been studied (Slama *et al*., 1974; Romanuk, 1981). Many naturally occurring JHAs, also called juvenoids, have been isolated from plants such as the "paper factor" from the balsam fir tree (*Abies balsamea*), and juvocimenes from the sweet basil plant (*Ocimum basilicum*) (Bowers and Nishida, 1980). During coevolution, the plants probably developed these JHAs to defend themselves against insects. Some representative examples of these compounds are shown in **Figure 19**.

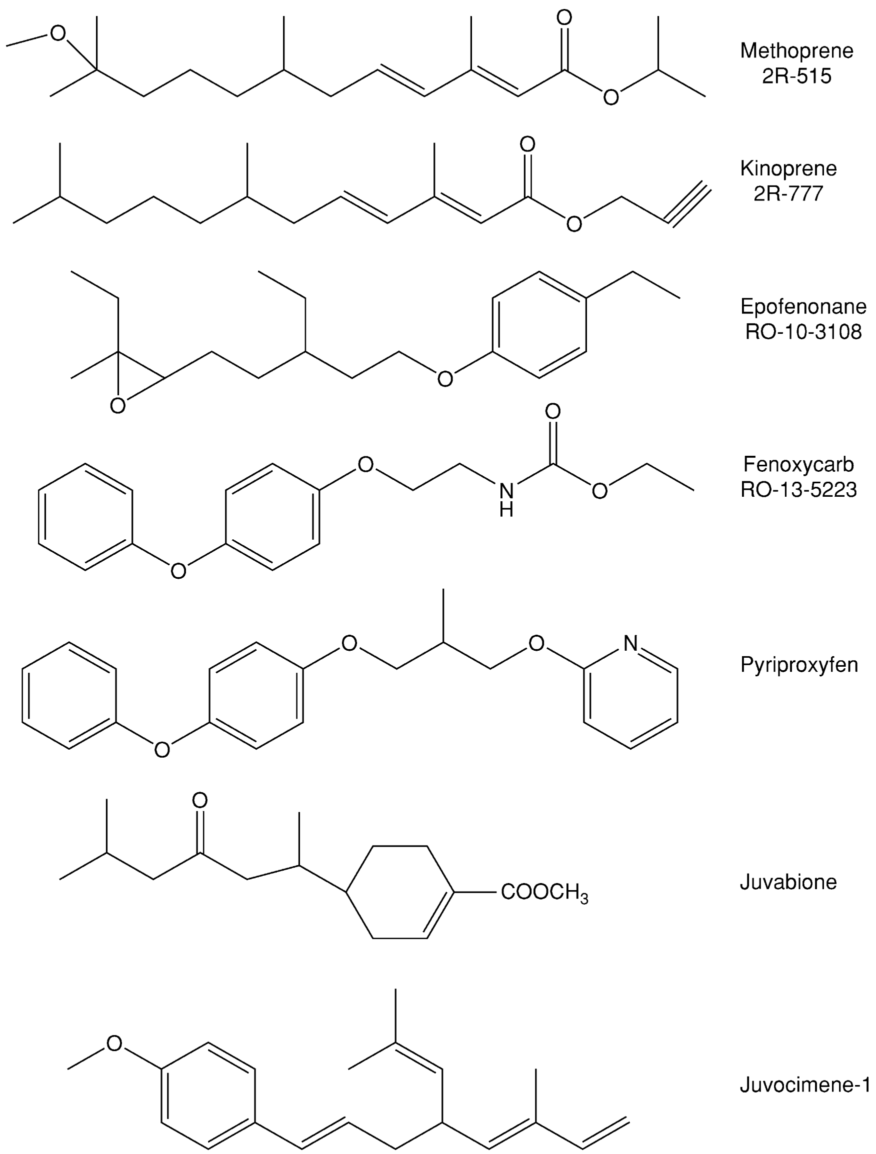

Figure 19 Some synthetic and naturally occurring JHAs.

JHAs can be broadly classified into two groups: the terpenoid JHAs such as methoprene and kinoprene and the phenoxy JHAs such as fenoxycarb and pyriproxyfen, with some such as epofenonane straddling the two (**Figure 19**).

6.3.3.3.1. Biological action of JHAs JHAs mimic the action of natural JH and, as such, can theoretically interfere with all the functions of JH. However, only a few such functions have been capitalized for control purposes (Retnakaran *et al.*, 1985). The organismal effects that have been exploited for control are relatively few, the most common being that seen on the last larval instar. Treatment of the larva in its last instar with JHA severely interferes with normal metamorphosis and results in various larval–pupal intermediates that do not survive (**Figure 20**). This effect, however, is not observed if the last instar larva is treated with the JHA methoprene during the first day or at the pharate stage (prepupal stage) of the stadium. If treated on day 1, the larva molts into a supernumerary larval instar and if it receives JHA at the pharate stage there is no effect (Retnakaran 1973a, 1973b; Retnakaran *et al.*, 1985). Morphogenetic control is ideally suited for controlling insects that are pests as adults, such as mosquitos and biting flies.

JHAs block embryonic development at blastokinesis and act as ovicides (Riddiford and Williams, 1967; Retnakaran, 1970). In some instances, when older eggs are treated, there is a delayed effect that is manifested at the last larval instar when it molts into a supernumerary instar (Riddiford, 1971). This type of ovicidal effect is useful especially in controlling fleas. In some cases where adults are treated, the material gets transferred to the eggs where they block embryonic development (Masner *et al.*, 1968). JHAs induce sterility in both sexes of adult tsetse flies (Langley *et al.*, 1990).

Adult or reproductive diapause is caused by the absence of JH secretion and this condition can be terminated by JHA treatment (De Wilde *et al.*, 1971; Retnakaran, 1974).

6.3.3.3.2. Properties and mode of action of selected JHAs

6.3.3.3.2.1. Methoprene (ALTOSID®, APEXSE®, DIANEX®, PHARORID®, PRECOR®, VIODAT®) Methoprene is perhaps one of the best known terpenoid JHAs developed for pest control. A mutant strain of *D. melanogaster* that was tolerant to methoprene, the so-called *Met* flies, was generated by Wilson and Fabian (1986). These flies were also found to be tolerant to JH III, JH B_3, and several JHAs but not to many classes of insecticides. It was therefore tempting to speculate that this would be an elegant source to discover the JH receptor. An 85 kDa protein isolated from the fat body of wild flies was found to bind with high affinity to JH III. The same 85 kDa protein from *Met* flies showed a sixfold lower affinity for JH III (Shemshedini *et al.*, 1990). When the *Met* gene was cloned, it became

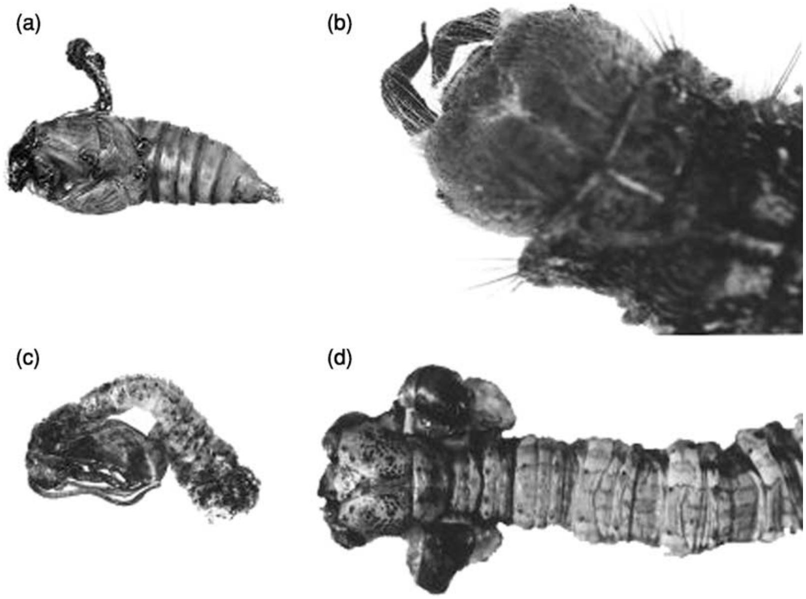

Figure 20 Morphogenetic effects of a JHA, methoprene, on the last larval instar of some lepidopteran insects. (a) A spruce budworm (*Choristoneura fumiferana*) pupa showing larval head and legs; (b) a forest tent caterpillar (*Malacosoma disstina*) showing aberrant mouthparts; (c) a pupa-like larva of the Eastern hemlock looper, *Lambdina fiscellaria*; (d) deformed Eastern hemlock looper larva with everted wing discs.

apparent that it was a bHLH-PAS and belonged to a family of transcriptional regulators, and this gene was not vital for the survival of the flies (Ashok *et al.*, 1998; Wilson and Ashok, 1998). This raises the possibility that JH activity could be exhibited by compounds that may interfere at any step during the synthesis, transportation, and target-site activity. Being extremely pleiotropic, the target-site activity could easily span a wide spectrum of functions. The methoprene-tolerant *Met* gene probably encodes a nonvital insecticide target protein of one type or another (Wilson and Ashok, 1998).

Methoprene is by far the most thoroughly studied JHA. Extensive EPA data collected over several years have shown that this JHA is relatively nontoxic to most nontarget organisms. Methoprene is rapidly broken down and excreted; its half-life in the soil is about 10 days. Mild toxicity to birds and some aquatic organisms has been observed. It has been used as a mosquito larvicide and for controlling many coleopterans, dipterans, homopterans, and siphonopterans (Harding, 1979).

6.3.3.3.2.2. Kinoprene (ENSTAR®) This is also an extremely mild JHA with little or no toxic effects. It breaks down in the environment and is relatively nonpersistent. It is relatively nonhazardous to bees and is nontoxic to birds, fish, and beneficial insects. It is decomposed by sunlight. It has been effectively used for controlling scales, mealy bugs, aphids, whiteflies, and fungal gnats. Its effects are morphological, ovicidal, and it acts as a sterilant (Harding, 1979).

6.3.3.3.2.3. Fenoxycarb (INSEGAR®, LOGIC®, TORUS®, PICTYL®, VARIKILL®) Fenoxycarb was the first phenoxy JHA found to be effective (Grenier and Grenier, 1993). It is unusual in having a carbamate moiety but does not show any carbamate-like toxicity. This JHA is considered slightly toxic to nontarget species, especially aquatic crustaceans, and carries the signal word "caution" on its label. It has been used as an effective control agent against fire ants (as bait), fleas, mosquitos, cockroaches, scale insects, and sucking insects. It is considered a general use insecticide. Unlike methoprene and kinoprene, fenoxycarb can be toxic to some of the beneficial insects such as neuropterans (Liu and Chen, 2001).

6.3.3.3.2.4. Pyriproxifen (KNACK®, SUMILARV®, ADMIRAL®) This JHA is a phenoxy analog similar to fenoxycarb. It is by far one of the most potent JHAs currently available. It is mildly toxic to some aquatic organisms but is nontoxic to bees. Its effects are similar to the other JHAs and causes morphogenetic effects as well as sterility. It has been used effectively in the form of bait for controlling the red imported fire ant (*Solenopsis invicta*) in California. It has been used for controlling aphids, scales, whiteflies, and the Pear psylla, and the tsetse fly (*Glossina morsitans*) in Zimbabwe. In the latter, treatment of both sexes results in pyriproxifen being transferred to the female uterus where the embryo is killed (Langley *et al.*, 1990).

6.3.3.4. Use of JHAs for Pest Management

JJHAs have been successfully used for controlling certain types of pests, especially where the pest is the adult stage. It has not been very effective against most lepidopteran agricultural pests because the larval stage is responsible for crop destruction. While some of the control measures tested since the previous edition of this series (Retnakaran *et al.*, 1985) are described below, **Table 9** summarizes the effects of the various JHA insecticides on agricultural and stored insect pests.

6.3.3.4.1. Control of public health and veterinary insects In most instances, the adult form is the active pest and, therefore, these species can be managed by JHA insecticides. Mosquitos, fleas, cockroaches, fire ants, and tsetse flies are some of the major pests that are vulnerable to JHAs (**Table 10**).

6.3.3.4.2. Anti-JH for pest management Compounds that prevent JH production, facilitate JH degradation, or destroy the corpus allatum all belong to this group. It is a catchall of various compounds that negate the activity of JH. Ideally, such compounds should be very effective pest control agents. Treatment of newly emerged larvae with such a compound would theoretically create miniature pupae, thus abbreviating the destructive part of the insect's life history. Many of the anti-JH compounds turned out to be highly toxic and did not pan out as good control agents. Once the JH receptor is characterized, it can be a target for control. Some of the effects that have been studied with anti-JH compounds are shown in **Table 11**.

6.3.3.5. Effects on Nontarget Invertebrates and Vertebrates

The effects of JHA insecticides have been studied and extensively reviewed (Grenier and Grenier, 1993; Miyamoto *et al.*, 1993; Palli *et al.*, 1995). The phenoxy JHAs, fenoxycarb, and pyriproxifen have been shown to be toxic to a number of dipteran, coleopteran, and hemipteran predators and parasitoids of scale insects (Mendel *et al.*, 1994).

Table 9 Control of agricultural and stored product insects with JHA insecticides

Insect species	*Host*	*Hormone analog*	*Activity*	*Reference*
Nephotettix cincticeps N. nigropictus N. virescens Recilia dorsalis (leafhoppers)	Rice	NC-170 4-chloro-5-(6-chloro-3-pyridylmethoxy)-2-(3,4-dichlorophenyl)-pyridazin-3(2H)-one	Good activity, 100 ppm suppressed population for more than 6 weeks	Miyake *et al.* (1991)
Adoxophyes orana Pandemis heparana Archips podana, Archips rosana (leafrollers)	Apple Orchards	Fenoxycarb and epofenonane	Adequate reduction, reinfestation never resulted in an increase to a harmful population level; good activity	de Reede *et al.* (1985)
Lycoriella mali (mushroom pest)	Compost	Methroprene	Resistance to this compound does not seem to be developing rapidly	Keil *et al.* (1988)
Heliothis virescens (tobacco budworm)	Cotton	Fenoxycarb	Good activity, opens new aspects for the control of lepidopterous pests with this compound	Masner *et al.* (1986)
Rhagoletis pomonella (apple maggot)	Apple	Pyriproxyfen	Good activity	Duan *et al.* (1995)
Ceratitis capitata (Mediterranean fruit fly)	Fruits in general	Methoprene	Good activity prevents adult eclosion	Saul *et al.* (1987)
Adoxophyes orana Pandemis heparana (leafrollers)	Apple orchards	Epofenonane and fenoxycarb	Good activity, the foliar residue remained active for at least 4 weeks and parasites seem to be less susceptible to it than the host itself	de Reede *et al.* (1984)
Manduca sexta (tobacco hornworm)	Tobacco plants	JHAs such as 1,3- and 1,4-bisNCS	Good activity, can disrupt insect growth and development	Ujváry *et al.* (1989)
Ceroplastes floridensis (Florida wax scale)	Guava plants	Fenoxycarb	Insects on treated plants deposited only a small amount of wax	Eisa *et al.* (1991)
Cacopsylla pyricola (Pear psylla)	Pear	Fenoxycarb	May still be a viable strategy for managing this	Krysan (1990)
Melanoplus sanaguinipes, M. differentialis (grasshopper)	Rangelands and crops	Fenoxycarb	Good activity; eliminates egg production and reduces oviposition	Capinera *et al.* (1991)
Spodoptera littura (tobacco cutworm)	Vegetable crops	Pyriproxyfen	Good activity, reduces the number of eggs	Hastakoshi (1992)
Christoneura rosaceana (leafroller)	Fruit trees	Fenoxycarb	Good activity, abnormal development is noted in all treatments	Aliniazee and Arshad (1998)
Cydia pomonella (codling moth)	Apple and pear	Phenoxyphenol pyridine and pyrazine carboxamides *N*-(4-phenoxyphenol) pyridinecarboxamides and *N*-(4-phenoxyphenyl) pyrazinecarboxamides	Good activity, prolongs development	Balcells *et al.* (2000)
Laodelphax striatellus (brown planthopper)	Rice	NC-170 4-chloro-5-(6-chloro-3-pyridylmethoxy)-2-(3,4-dichlorophenyl)-pyridazine-3(H)-one	Good activity, 100 ppm prevents larvae from entering diapause	Miyake *et al.* (1991)
Dacus dorsalis (oriental fruit fly)	Papayas	Methoprene	Good activity, higher doses showed no survival	Saul *et al.* (1987)
Trichoplusia ni (cabbage looper)	Cabbage	Methoprene	Good activity, amount of eggs is reduced	Campero and Haynes (1990)

Table 9 Continued

Insect species	*Host*	*Hormone analog*	*Activity*	*Reference*
Bemisia tabaci (sweet potato whitefly)	Cotton and vegetable crops	Pyriproxyfen	Good activity, strong translaminar effect and acts on all stages	Ishaaya and Horowitz (1992)
Bemisia tabaci (sweet potato whitefly)	Cotton and vegetable crops	insect growth regulators such as buprofezin and pyriproxyfen	activity not well seen	Palumbo *et al.* (2001)
Trialeurodes vaporariorum (greenhouse whitefly)	Greenhouse crops	Pyriproxyfen	Good activity, affects all stages	Ishaaya *et al.* (1994)
Reticulitermes santonensis Reticulitermes flaviceps Coptotermes formosanus (termites)	Wood	Carbamate derivative of 2-(4-hydroxybenzyl) cyclokexanone (W-328)	Good activity, 500 ppm concentration results in significant soldier differentiation	Hrdý *et al.* (2001)
Reticulitermes speratus (termites)		Ethyl(2-(*p*-phenoxy-phenoxy)ethyl)carbamate	Good activity, results in the collapse of the whole termite colony	Tsunoda *et al.* (1986)
Ips paraconfusus Lanier (California beetle)	Logs of ponderosa pine	Fenoxycarb	Good activity, acts as an effective chemosterilant	Chen and Border (1989)
Lipaphis erysimi (mustard aphid)	Leafy vegetables	Pyriproxyfen	Good activity, causes direct mortality, reduces longevity and inhibits progeny formation	Liu and Chen (2000)
Cacopsylla pyricola (Pear psylla)	Pear	Fenoxycarb	Good activity	Lyoussoufi *et al.* (1994)
Reticulitermes speratus (Japanese subterranean termite)	Wood in general	Ethyl (2-(*p*-phenoxy-phenoxy)ethyl)carbamate	Good activity, disturbance of caste differentiation results in collapse of the colony	Tsunoda *et al.* (1986)
Rhyzopertha dominica (lesser grain borer)	Wheat grain	2′,7′,-epoxy-3,7′-dimethyl-undec-2′-enyl6-thyl-3-pyridyl ether	Good activity, 4 ppm resulted in insect mortality	Mkhize (1991)
Tribolium castaneum (red flour beetle), *Rhyzopertha dominica* (lesser grain borer), *Sitophilus oryzae* (rice weevil)–red flour beetle	Wheat flour	Methoprene and pyriproxyfen	Good activity, 20 ppm reduced the population by 80–99%	Kostyukovsky *et al.* (2000)

However, the ectoparasite of the California red scale and Florida wax scale, *Aphytis holoxanthus*, was insensitive to pyriproxifen (Peleg, 1988). Fenoxycarb was also found to be toxic to *Colpoclypeus florus*, a parasitoid of *Adoxophyes orana* and *Pandemis heparana*. Pupation in the predatory coccinellid, *Chilocorus bipustulatus* L., was inhibited when larvae fed on the scale insect, *Chrysomphalus aonidum*, were dipped into a 0.025% solution of fenoxycarb (cited in Grenier and Grenier, 1993). Additional effects of JHA insecticides have been summarized in Table 12.

The toxicological profiles of JHA insecticides for mammalian (rat), aquatic (rainbow trout and Daphnia), predatory, and parasitoid insects have been summarized in Table 13. In general, JHA insecticides have low acute toxicity to fish, birds, and mammals. Both fenoxycarb and pyriproxifen have very low toxicity to adult bees. However, effects on brood development have been observed as a result of worker bees feeding pollen containing fenoxycarb residues to larvae (Wildboltz, 1988).

Last instars of certain aquatic insects are susceptible to JHA insecticides. Morphogenetic abnormalities have been observed in the heteropteran, *Notonecta unifaciata*, and in the dragon flies, *Anax junius* and *Pantala hymenaea*, with applications of fenoxycarb (Miura and Takahashi, 1987). Similarly, pyriproxifen also produced morphogenetic effects when applied to last instars of the

Table 10 Control of some insect pests of public health and veterinary importance with JHA insecticides

Insect species	*Host*	*Hormone analog*	*Activity*	*Reference*
Monomorium pharaonis (pharaoh ant)	Large office buildings, houses, apartment buildings, food establishments and hospitals	Pyriproxyfen	Good activity when used at concentrations of 0.25%, 0.5%, and 1%	Vail *et al.* (1995)
Culex quinquefasciatus Aedes aegypti (mosquitos)	Humans	VCRC/INS/A-23	Activity was good and the compound was found cost effective	Tyagi *et al.* (1985)
Chironomus fusciceps (midge)	Sulfur containing pods near residential areas	Pyriproxyfen	Good activity, at 0.00177 and 0.05369 ppm caused 50 to 90% emergence inhibition	Takagi *et al.* (1995)
Glossian morsitans, G. pallidipes (testse flies)	Cattle and humans	Pyriproxyfen	Good activity, it can replace pesticides	Hargrove and Langley (1993)
Blattella germanica (german cockroach)	Residences	Fenyxocarb and hydroprene	It can reduce the population	King and Bennett (1988)
Anopheles balabacensis (mosquitos)	Humans	Pyriproxyfen	Good activity, 0.005 ppb reduce the egg and sperm production and blood feeding and copulating activity	Iwanaga and Kanda (1988)
Ctenocephalides felis (cat flea)	Cat	Methoprene	Activity is 12.7 and 127 ng cm^{-2}, resulted in 15–5.2% adult emergence. Good control	Moser *et al.* (1992)
Solenopsis invicta (red imported fire ant)		Pyriproxyfen	Good activity, cause 80–85% reduction in colony size	Banks and Lofgren (1991)
Blattella orientalis (oriental cockroach)	Industrial, food manufacturing, and domestic premises	*S*-hydroprene	Good activity	Edwards and Short (1993)
Ctenocephalides felis (cat flea)	Cat	Methoprene	Good activity when cat fleas less than 24 h old were treated	Olsen (1985)
Culex pipiens pallens Culex tritaeniorhynchus	Humans	Pyriproxyfen	Activity remains unclear	Kamimura and Arakawa (1991)
Ctenocephalides felis and Ctenocephalides canis (dog and cat fleas)	Cat and dog	Methoprene and pyriproxifen	Good activity	Taylor (2001)
Culex pipiens (mosquitos)	Humans	4-alkoxyphenoxy- and 4-(alkylphenoxy) alkanaldoxime o-ethers	Good activity	Hayashi *et al.* (1989)
Culex pipiens	Humans	(Phenoxyphenoxy) and (benzylphenoxy) propyl ethers	Good activity	Niwa *et al.* (1989)
Alphitobius diaperinus (mealworm)	Poultry production	Methoprene and fenoxycarb	Good activity	Edwards and Abraham (1985)
Ctenocephalides felis (cat fleas)	Cats	CGA-2545′728	Good activity	Rasa *et al.* (2000)
Ctenocephalides felis (cat fleas)	Cats	Methoprene, pyriproxifen and fenoxycarb	Good activity	Miller *et al.* (1999)

Table 11 Insect control with some anti-JH compounds

Insect species	*Host*	*Hormone analog*	*Activity*	*Reference*
Manduca sexta (tobacco hornworm)	Tobacco, tomato	ETB (ethyl 4-[2-{*tert*-butyl carbonyloxy} butoxy]benzoate)	Some activity, 50 µg of ETB caused formation of larval–pupal intermediates after the fourth instar	Beckage and Riddiford (1983)
Bombyx mori (silkworm)	Mulberry	1-Citronellyl-5-phenylimidazole (KK-22)	Some activity, induction of precocious metamorphosis seems to correlate with prolongation of the larval developmental period in the third instar	Kuwano and Eto (1984)
Blattella germanica (German cockroach)	Household pest	Precocenes	Short-term activity seems to be effective and long-term activity shows that damage to CA is irreversible	Belles *et al.* (1985)
Bombyx mori (silkworm)	Mulberry	Ethoxy (KK-110) and 4-chlor-phenyl (KK-135)	Activity can be inhibited by stimultaneous application of methoprene	Kuwano *et al.* (1990)
Nilaparvata lugens (brown planthopper)	Rice	Precocene II	Activity with an increase in good ovarian growth	Ayoade *et al.* (1995)
Spodoptera littoralis (Egyptian cotton worm)	Cotton	Precocene I and II	Good activity but should be undertaken with care in order to minimize disruptive effects on parasitoids	Hagazi *et al.* (1998)
Hyphantria cunea (Fall webworm)	Hardwood trees	Fluoromevalonate (Fmev, ZR-3516)	Activity was shown as evoking varying degrees of ecdysial disturbance, which resulted in death of the insect	Farag and Varjas (1983)
Oxycarenus lavaterae (Lygaeid)	European forests	Precocenes	Activity shows a high degreee of uniformity	Belles and Baldellou (1983)
Bombyx mori (silkworm)	Mulberry	1-Benzyl-5-[(E)-2,6-dimethyl-1,5-heptadienyl] imidazole (KK-42)	Good activity, 100% precocious pupation	Kuwano *et al.* (1985)
Locusta migratoria migratorioides; Oncopeltus fasciatus; Schistocerca gergaria (locusts)	Various plants	Precocene II	Good activity, ovipositor protrusion, and death at higher concentrations	Degheele *et al.* (1986)
Nilaparvata lugens (Brown planthopper)	Rice	Precocene II (anti-allatin)	Good activity with high rate of mortality	Pradeep and Nair (1989)
Spodoptera mauritia (lawn army worm)	Agricultural crops	Fluoromevalonate (Fmev)	Good activity, induced various morphogenetic abnormalities, death before pupation occurred	Nair and Rajalekshmi (1989)
Drosophila melanogaster (fruit fly)	Various fruits	5-Ethoxy-6-(4-methoxyphenyl)methyl-1,3-benzodioxole J2581	Activity can be reversed by application of JH of methoprene	Song *et al.* (1990)
Diploptera punctata (cockroach)	Various types of diet	1,5-disubstituted imidaxoles	Good activity, powerful inhibitors of the last step of juvenile synthesis	Unnithan *et al.* (1995)
Manduca sexta (tobacco hornworm)	Tomato and tobaco	Farnesol dehydrogenase	Good activity, unique dehydrogenase that should be examined further	Sen and Garvin (1995)
Oncopeltus fasciatus (milkweed bug)	Milkwood	6,7-Dimethoxy-2,2-dimethyl 2*H*-chromene	Activity shows defiency of JH	Bowers and Unnithan (1995)

Continued

Table 11 Continued

Insect species	*Host*	*Hormone analog*	*Activity*	*Reference*
Heliothis virescens and *Trichoplusia ni* (cabbage looper)	Field crops and vegetables	Virus AcJHE-SG (transgenic virus with JH esterase gene)	Good activity, death occurred from contraction-paralysis and disruption of the normal sequence of events at the molt	Bonning *et al.* (1995)
Sogatella furcifera (whitebacked rice planthopper)	Rice	Precocene II	Activtiy showed inductio metathetely by itself occurred	Miyake and Mitsui (1995)
Zaprionus paravittiger (banana fruitfly)	Bananas	Precocene	Good activity, with 0.076, 0.1 ppm in 1 μL of acetone, adult longevity and fecundity were reduced	Rup Pushpinder and Baniwal (1985)
Musca domestica (housefly) *Diploptera punctata* (cockroach)	Various diets	2-(1-Imidazolyl)-2-methyl-1-phenyl-1-propanone and 2-methyl-1-phenyl-2-(1,2,4,-triazol-1-yl)-1-propanone	Activity was seen at 0.2 mM	Bélai *et al.* (1988)
Aphis craccivora (ground nut aphid)	Legumes	Precocene II	Good activity, with 2.0 μg/aphid, precocious metamorphosis was seen	Srivastava and Jaiswl (1989)
Pieris brassicae (cabbage butterfly) and *Leptimotarsa decemlineata* (Colorado potato beetle)	Vegetables and potato	2,2-Dimethylchromene derivatives	Good activity	Darvas *et al.* (1989)
Heliothis zea (corn earworm)	Corn	Precocene II	Good activity, growth and development were inhibited	Binder and Bowers (1991)

Table 12 Effects of JH analog insecticides on beneficial and aquatic species

Parasite/predator/aquatic	*Host/habitat*	*Hormone analog*	*Activity*	*Reference*
Chilocorus nigritus	Citrus red scale	Pyriproxyfen	Harmful to nontargeted species	Magaula and Samways (2000)
Daphnia pulex	Aquatic	Methoprene	Decrease in the incidence of all-male broods and an increase in the incidence of all-female broods	Peterson *et al.* (2000)
Aphanteles congregatus	Tobacco hornworm	Methoprene	Low dose would allow the insect to pupate normally	Beckage and Riddiford (1981)
Copidosoma floridanum	Cabbage looper	Methoprene	Slight activity, inhibited morphogenesis	Strand *et al.* (1991)
Encarsia pergandiella E.transvena, E.formosa	White fly	Pyriproxyfen	Relatively safe to parasitoids	Liu and Stansly (1997)
Moina macrocopa	Aquatic	Methoprene	Low activity on reproduction	Chu *et al.* (1997)
Ceroplastes destructor	Citrus orchards	Pyriproxyfen and fenoxycarb	Arrested the first and second instar	Wakgari and Giliomee (2001)
Chrysoperla rufilabris	Aphids	Fenoxycarb and pyriproxyfen	Ovicidal effect and delay in development	Liu and Chen (2001)
Rhithropanopeus harrishii (mud crab)	Aquatic	Methoprene	No activity was noticed	Celestial and McKenney (1993)

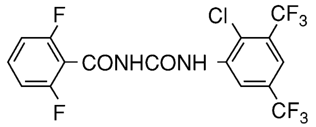
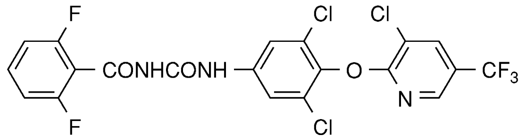
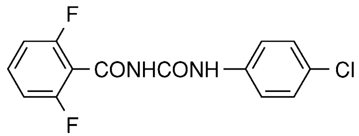
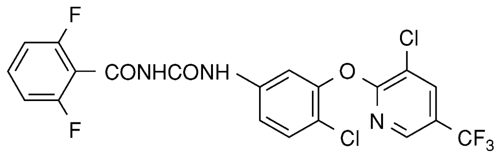
6.3.3.6. Conclusions and Future Research of JHAs

JHAs have not proven to be the wonderful control agents they were purported to be. However, they have advantages for controlling pests of public health. Many of them are environmentally attractive. The anti-JH compounds have, for the most part, remained at the experimental stage. Interfering with JH action will become an attractive option, once the JH receptor is characterized.

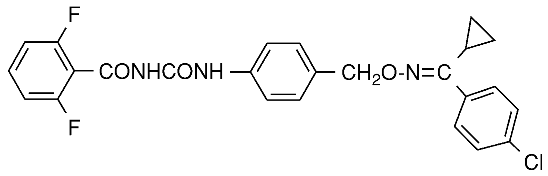


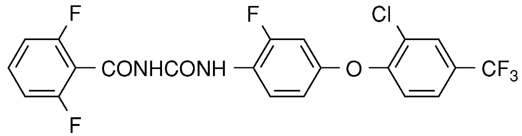


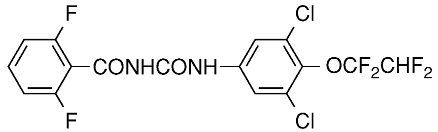


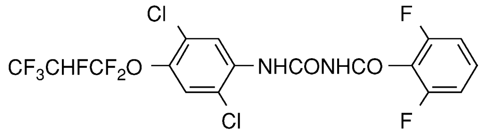


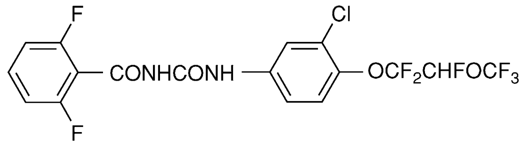
6.3.4. Insecticides with Chitin Synthesis Inhibitory Activity

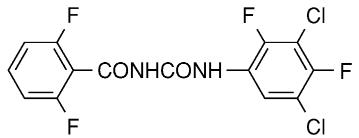


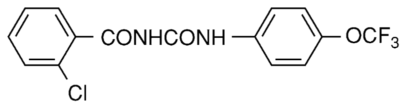








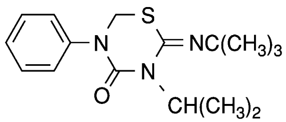




If the insect cuticle, which provides the exoskeletal structure, is disrupted during its formation, it is lethal to the insect. The cuticle needs to be waterproof for protection, soft and flexible to allow movement, extensible in between segments to allow for increase during feeding and growth, and also rigid to provide firm points of muscle attachment as well as for mandibles and claws. The cuticle is the product of a single layer of epidermal cells, and consists of different layers of which the procuticle contains chitin, a major component (30–60%) of insect cuticle. Chitin is a β-1,4-linked aminopolysaccharide homopolymer of *N*-acetylglucosamine (GlcNAc), and is by far one of the most abundant biological materials found on earth. This nitrogenous amino sugar polysaccharide is cross-linked to proteins via biphenyl linkages to form a protective matrix, which consists of a chitin microfibers–protein complex. Chitin biosynthesis, which is not fully understood, is a complex process consisting of a series of enzymatic steps beginning with a glucose unit, which is converted to GlcNAc that is linked with UTP, transported within the cell in combination with dolichol phosphate, and polymerized into chitin. The newly polymerized chitin is covalently linked to proteins to form chitin microfibrils in the cuticle. Polymerization to form chitin is catalyzed by the enzyme chitin synthase (CHS or chitin-UDP-glucosamine-transferase), which occurs in several forms (CHS 1, 2 and 3; EC 2.4.1.16). This enzyme has probably undergone sequential gene duplication and divergence during evolution, resulting in its expression in different forms in diverse species, one of which is the human hyaluronan synthase. It has a conserved amino acid sequence essential for chitin biosynthesis in yeasts, and it has evolved into two types: the fungal form, which occurs as an inactive zymogen requiring proteolysis for activation, and the arthropod form, which is membrane bound. For more details on chitin biosynthesis and cuticle formation, the reader should refer to **Chapter 4.2.** Over the past three decades, the chitin biosynthetic pathway has proven to be important for developing insect control agents that selectively inhibit any of the chitin synthetic steps in insects. Two types of insect regulatory chitin synthesis inhibitors (CSI) have been developed and used as commercial compounds for controlling agricultural pests: the benzoylphenyl ureas (BPUs), and buprofezin and cyromazine (Spindler *et al.*, 1990; Retnakaran and Oberlander, 1993; Londerhausen, 1996; Palli and Retnakaran, 1999).

6.3.4.1. Brief Review of Old Chitin Synthesis Inhibitors

The insecticidal activity of the first BPUs was discovered around 1970 by scientists at Philips-Duphar BV, (now Crompton Corp., Weesp, The Netherlands) and the first commercial compound of this series was diflubenzuron, Dimilin® (Van Daalen *et al.*, 1972; Grosscurt, 1978) marketed by Uniroyal Chemical (Table 14). Diflubenzuron and older CSIs have already been extensively reviewed by Retnakaran *et al.* (1985), Grosscurt *et al.* (1987), and Retnakaran and Wright (1987).



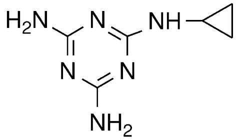


Table 14 Chemical structures of the chitin synthesis inhibitors (CSI), 11 benzoylphenyl ureas (BPUs), and buprofezin and cyromazine, their biological effects and their target pest species

Compound	*Chemical structure*	*Biological effects*	*Uses to control pest species*
Bistrifluron		Inhibition of larval molting leading to death	Whiteflies in tomato (*Trialeurodes vaporariorum* and *Bemisia tabaci*), and lepidopterous insects in vegetables, cabbage, persimmon, apples, and other fruits (e.g., *Spodoptera exigua*, *Plutella xylostella*, *Stathmopoda masinissa*, and *Phyllonorycter ringoniella*) at 75–400 g ha^{-1}
Chlorfluazuron		Acts as an antimolting agent, leading to death of the larvae and pupae	*Heliothis*, *Spodoptera*, *Bemisia tabaci*, and other chewing insects on cotton, and *Plutella*, *Thrips* and other chewing insects on vegetables. Also used on fruit, potatoes, ornamentals, and tea. Applied at 2.5 g hl^{-1}
Diflubenzuron		Nonsystemic insect growth regulator with contact and stomach action. Acts at time of insect molting, or at hatching of eggs	Wide range of leaf-eating insects in forestry, woody ornamentals, and fruit. Controls certain major pests in cotton, soybeans, citrus, tea, vegetables, and mushrooms. Also controls larvae of flies, mosquitos, grasshoppers, and migratory locusts. Used as an ectoparasiticide on sheep for control of lice, fleas, and blowfly larvae. Is suitable for inclusion in integrated control programs. Effective at 25–75 g a.i./ha against most leaf-feeding insects in forestry; in concentrations of 0.01–0.015% a.i. against codling moth, leaf miners, and other leaf-eating insects in top fruit; in concentrations of 0.0075–0.0125% a.i. against citrus rust mite in citrus; and at a dosage of 50–150 g a.i./ha against a number of pests in cotton (cotton boll weevil, armyworms, leafworms), soya beans (soya bean looper complex) and maize (armyworms). Also for control of larvae of mushroom flies in mushroom casing (1 g a.i. m^{-2}); mosquito larvae (25–100 g a.i. ha^{-1}); fly larvae in animal housings (0.5–1 g a.i. m^{-2} surface); and locusts and grasshoppers (60–67.5 g a.i. ha^{-1})
Fluazuron		Systemic acarine growth regulator with contact and stomach action inhibiting chitin formation	Ixodicide for strategic control of the cattle tick *Boophilus microplus* (including all known resistant strains) on beef cattle

Flucycloxuron		Nonsystemic acaricide and insecticide inhibiting the molting process in mites and insects. It is only active against eggs and larval stages. Adult mites and insects are not affected	Eggs and larval stages of Eriophyid and Tetranychid mite species on a variety of crops, including fruit crops, vegetables, and ornamentals. Also controls larvae of a number of insects. Because of its relative selectivity, it is well-suited for integrated control programs. Recommended concentration for control of mites on fruit crops is 0.01–0.015% a.i. On insects, good activity has been found against codling moth, leaf miners, and some leaf rollers in pome fruit, at the same concentration. In ornamentals grown under glass/plastic, lower concentrations can be used. In grapes, the recommended dosage is 125–150 g a.i. ha^{-1}
Flufenoxuron		Insect and acarid growth regulator with contact and stomach action. Treated larvae die at the next molt or during the ensuing instar. Treated adults lay nonviable eggs	Control of immature stages of many phytophagous mites (*Aculus*, *Brevipalpus*, *Panonychus*, *Phyllocoptruta*, *Tetranychus* spp.) and insect pests on pome fruit, vines, citrus fruit, tea, cotton, maize, soybeans, vegetables, and ornamentals
Hexaflumuron		Ingested, systemic insecticide	In agriculture for control of larvae of Lepidoptera, Coleoptera, Homoptera, and Diptera on top fruit, cotton, and potatoes. Major use now is in bait, for control of subterranean termites
Lufenuron		Insecticide/acaricide acting mostly by ingestion; larvae are unable to molt, and also cease feeding	Lepidoptera and Coleoptera larvae on cotton, maize, and vegetables; and citrus whitefly and rust mites on citrus fruit, at 10–50 g ha^{-1}. Also for the prevention and control of flea infestations on pets
Novaluron		Insecticide acts by ingestion and contact, affecting molting. Causes abnormal endocuticular deposition and abortive molting	Under development by Makhteshim Chemical Works for control of Lepidoptera, whitefly, and agromyzid leaf miners in top fruit, vegetables, cotton, and maize
Teflubenzuron		Antimolting agent, leading to death of the larvae and pupae	*Heliothis*, *Spodoptera*, *Bemisia tabaci* and other chewing insects on cotton; and *Plutella*, *Thrips* and other chewing insects on vegetables. Also used on fruit, potatoes, ornamentals, and tea. Applied at 2.5 g hl^{-1}.
Triflumuron		Ingested insecticide, acting by inhibition of molting	Lepidoptera, Psyllidae, Diptera, and Coleoptera on fruit, soybeans, vegetables, forest trees, and cotton. Also used against larvae of flies, fleas, and cockroaches in public and animal health

Continued

Table 14 Continued

Compound	*Chemical structure*	*Biological effects*	*Uses to control pest species*
Buprofezin		Probable chitin synthesis and prostaglandin inhibitor. Hormone disturbing effect, leading to suppression of ecdysis. Persistent insecticide and acaricide with contact and stomach action; not translocated in the plant. Inhibits molting of nymphs and larvae, leading to death. Also suppresses oviposition by adults; treated insects lay sterile eggs	Insecticide with persistent larvicidal action against Homoptera, some Coleoptera, and also Acarina. Effective against Cicadellidae, Deltocephalinae (leafhoppers), and Delphacidae (planthoppers) in rice, at 50–250 g ha^{-1}; Cicadellidae (lady beetle) in potatoes; Aleyrodidae (whitefly) in citrus, cotton, and vegetables, at 0.025–0.075 g ha^{-1}; Coccidae, Diaspididae (scale insects) and Pseudococcidae (mealybugs) in citrus and top fruit, at 25–50 g hl^{-1}; Tarsonemidae in vegetables, at 250–500 g ha^{-1}. Suitable for IPM programs
Cyromazine		Contact action, interfering with molting and pupation. When used on plants, action is systemic: applied to the leaves, it exhibits a strong translaminar effect; applied to the soil, it is taken up by the roots and translocated acropetally	Control of Diptera larvae in chicken manure by feeding to poultry or treating the breeding sites. Also used to control flies on animals. Used as a foliar spray to control leaf miners (*Liriomyza* spp.) in vegetables (e.g., celery, melons, tomatoes, lettuce), mushrooms, potatoes, and ornamentals, at 75–225 g ha^{-1}; also used at 190–450 g ha^{-1} in drench or drip irrigation

Data compiled from Palli, S.R., Retnakaran, A., **1999**. Molecular and biochemical aspects of chitin synthesis inhibition. In: Jollès, P., Muzzarelli, R.A.A. (Eds.), Chitin and Chitinases. Birkhäuser-Verlag, pp. 85–98; Tomlin, C.D.S., Ed., **2000**. The Pesticide Manual, 12th edn. British Crop Protection Council Publications; and Ishaaya, I., **2001**. Biochemical processes related to insecticide actions: an overview. In: Ishaaya, I. (Ed.), Biochemical Sites of Insecticide Action and Resistance. Springer, pp. 1–16.

The discovery of diflubenzuron spawned the discovery and development of a whole array of new analogs by different agricultural companies (Table 14). These include: chlorfluazuron (AIM®, ATABRON®, HELIX®, JUPITER®; Ishihara Sangyo), flucycloxuron (ANDALIN®; Uniroyal Chemical), flufenoxuron (CASCADE®; BASF), hexaflumuron (CONSULT®, RECRUIT®, TRUENO®; Dow AgroSciences LLC), lufenuron (MATCH®; Syngenta AG), teflubenzuron (NOMOLT®, DART®, DIARACT®; BASF) and triflumuron (ALSYSTIN®, BAYCIDAL®; Bayer AG) (Zoebelein *et al.*, 1980; Haga *et al.*, 1982, 1992; Becher *et al.*, 1983; Sbragia *et al.*, 1983; Retnakaran *et al.*, 1985; Anderson *et al.*, 1986; Retnakaran and Wright, 1987; Grosscurt *et al.*, 1987; Sheets *et al.*, 2000; Tomlin, 2000).

6.3.4.2. New Chemistries and Products

In the last decade, some newer BPU analogs were discovered: novaluron (RIMON®), bistrifluron, fluazuron (ACATAK®), and noviflumuron (RECRUIT® III) by Makhteshim Chemicals, Dongbu Hannong Chemical Co., Syngenta AG, and Dow AgroSciences LLC, respectively (Bull *et al.*, 1996; Ishaaya *et al.*, 1996; Kim *et al.*, 2000; Tomlin, 2000; Karr *et al.*, 2004) (Table 14).

Two other IGRs, buprofezin (APPLAUD®) and cyromazine (NEOPREX®, TRIGARD®, VETRAZIN®), with chemistries different from BPUs, but which also interfere with molting and chitin biosynthesis were developed by Nihon Nohyaku and Ciba-Geigy AG (now Syngenta AG), respectively (Table 14; Hall and Foehse 1980; Williams and Berry, 1980; Kanno *et al.*, 1981; Reynolds and Blakey, 1989; Tomlin, 2000).

6.3.4.3. Mode of Action and SAR

Typically, the chemistry and symptoms of the CSIs are unique, and not similar to other insecticides. Studies with diflubenzuron, the most thoroughly investigated compound of the BPUs, revealed that it alters cuticle composition, especially inhibition of chitin, resulting in abnormal endocuticular deposition that affects cuticular elasticity and firmness, and causes abortive molting. The reduced chitin levels in the cuticle seem to result from inhibition of biochemical processes leading to chitin formation. To date, it is not clear whether inhibition of chitin synthetase is the primary biochemical site for the reduced level of chitin, since in some studies BPUs do not inhibit chitin synthetase in cell-free systems (Retnakaran *et al.*, 1985; Grosscurt and Jongsma, 1987; Retnakaran and Wright, 1987; Londerhausen, 1996; Oberlander and Silhacek, 1998; Palli and Retnakaran, 1999). In addition to chitin synthetase inhibition, other modes of action have been suggested for BPUs, such as: (1) inhibit the transport of UDP-GlcNAc across biomembranes; (2) block the binding of chitin to cuticular proteins resulting in inhibition of cuticle deposition and fibrillogenesis; (3) inhibit the formation of chitin due to an inhibition of the protease that activates chitin synthase, and activation of chitinases and phenoloxidases, which are both connected with chitin catabolism; (4) affect ecdysone metabolism, resulting in ecdysone accumulation that stimulates chitinase, which in turn digests nascent chitin; (5) block the conversion of glucose to fructose-6-phosphate; and (6) inhibit the DNA synthesis (Soltani *et al.*, 1984; Retnakaran *et al.*, 1985; Cohen, 1985; Retnakaran and Wright, 1987; Retnakaran and Oberlander, 1993; Mikólajczyk *et al.*, 1994; Zimowska *et al.*, 1994; Oberlander and Silhacek, 1998; Palli and Retnakaran, 1999; Oberlander and Smagghe, 2001). In addition, recent studies using imaginal discs and cell-free systems indicated that BPUs inhibit the 20-hydroxecdysone dependent GlcNAc incorporation into chitin, suggesting that BPUs affect ecdysone dependent biochemical sites, which lead to chitin inhibition (Mikolajczyl *et al.*, 1994; Zimowska *et al.*, 1994; Oberlander and Silhacek, 1998). BPUs act mainly by ingestion, and for the most part they are effective as larvicides, but in some species they also suppress oviposition. They act as ovicides, reducing the egg-laying rate or hindering the hatching process by inhibiting embryonic development. In most cases, the embryo was fully developed in the egg but the larva failed to hatch (Retnakaran and Wright, 1987; Ishaaya, 2001). BPUs were also found to reduce cyst and egg production in two free-living plant nematodes (Veech, 1978; Evans, 1985). In addition to being toxic by ingestion, some BPUs exhibit contact toxicity. Moreover, most BPUs, except hexaflumiron, have no systemic or translaminar activity (Retnakaran and Wright, 1987; Tomlin, 2000; Ishaaya, 2001).

The mode of action of buprofezin resembles that of the BPUs, although its structure is not analogous (Uchida *et al.*, 1985; De Cock and Degheele, 1998; Ishaaya, 2001). The compound strongly inhibits the incorporation of ^{3}H-glucose and GlcNAc into chitin. As a result of chitin deficiency, the procuticle of treated larval stages loses its elasticity and the insect is unable to molt. In addition, buprofezin may work as a prostaglandin inhibitor that may lead to suppression of ecdysis and slightly reduced DNA synthesis. It also exerts its effect on egg-hatch and on the larval stages in the rice planthopper, *Nilaparvata lugens*, and the whiteflies, *Bemesia tabaci and Trialeurodes vaporariorum* (De Cock *et al.*, 1995;

De Cock and Degheele, 1998; Ishaaya, 2001). It has no ovicidal activity but suppresses embryogenesis through adults (**Table 14**).

Although the exact mode of action of the IGR cyromazine, which is predominantly active against dipteran larvae, is not known, evidence has been presented to suggest that its target site for interference with sclerotization is different from that of BPUs (Biddington, 1985). In larvae intoxicated with cyromazine, the cuticle rapidly becomes less extensible and unable to expand compared with the cuticle of untreated larvae. The cuticle may be stiffer because of increased cross-linking between the various cuticle components, the nature of which remains unknown. As summarized in **Table 14**, cyromazine is an IGR with contact action interfering with molting and pupation. It has good systemic activity. When applied to the leaves, it exhibits a strong translaminar activity, and when applied to the soil it is taken up by the roots and translocated acropetally (Hall and Foehse, 1980; Awad and Mulla, 1984; Reynolds and Blakey, 1989; Viñuela and Budia, 1994; Tomlin, 2000).

With classical SAR (Hansch-Fujita), the effects of different substituents on the benzene rings in BPUs were analyzed for larvicidal activity against *Chilo suppressalis*, *S. littoralis*, and *B. mori* (Nakagawa *et al*., 1987, 1989a, 1989b). For the benzoyl moiety, the toxicity was higher with a higher total hydrophobicity, a higher electron withdrawal from the side chain, and a lower steric bulkiness of *ortho*-substituents. In addition, introduction of electron-withdrawing and hydrophobic substituents at the *para*-position of the phenyl (aniline) moiety enhanced the larvicidal activity, whereas bulkier groups were unfavorable. Stacking did not occur between the two aromatic moieties along the urea moiety (Sotomatsu *et al*., 1987). To ascertain the above results, the relative activity of BPUs was determined by measuring the incorporation of [^{14}C]-GlcNAc in larval integuments cultured *in vitro* (Nakagawa *et al*., 1989b). There was a colinear relationship between *in vitro* activities and *in vivo* larvicidal toxicities if the hydrophobic factor(s) participating in transport were considered separately. In addition, integuments of the three Lepidoptera were incubated in conditions with and without the synergists piperonylbutoxide (PB) and *S*,*S*,*S*-tributylphosphorotrithioate (DEF). In the Qualitative Structure–activity Relation (QSAR) equation measured without synergist, an electron-withdrawing effect was favorable to the activity, but an electron-donating group was favorable to the activity in the presence of PB. These results mean that electron-withdrawing groups are playing a role in suppressing the oxidative metabolism. DEF had no significant effect, suggesting that hydrolytic degradation of the phenyl moiety was not of significant consequence as compared to its oxidative degradation. In summary, the SAR results suggested that for BPUs the specific larvicidal spectrum is due to inherent differences in metabolism in addition to differences in the physiochemical substituent effects (Nakagawa *et al*., 1987, 1989a, 1989b; Sotomatsu *et al*., 1987).

6.3.4.4. Spectrum of Activity

Most CSI compounds are very potent against a variety of different pests with the highest activity towards lepidopterous insects and whiteflies. The main commercial applications are in field crops/agriculture, forestry, horticulture, and in the home as summarized in **Table 14** (Retnakaran and Wright, 1987; Tomlin, 2000; Ishaaya, 2001). Novaluron acts by ingestion and contact against lepidopterans (*S. littoralis*, *S. exigua*, *S. frugiperda*, *Tuta absoluta* and *Helicoverpa armigera)*, whitefly, *B. tabaci,* eggs and larvae, and different stages of the leafminer, *Liriomyza huidobrensis*. Bistrifluron is active against various lepidopteran pests and whiteflies an apple, Brassica leafy vegetables, tomato, persimmon, and other fruits (Kim *et al*., 2000). Hexaflumuron and the newer noviflumuron are now used in bait for control of subterranean termites (Sheets *et al*., 2000; Karr *et al*., 2004). As a specialty in the series of CSIs, fluazuron is the only ixodicide with a strong activity against cattle ticks (Kim *et al*., 2000) (**Table 14**).

Buprofezin has a persistent larvicidal action against sucking Homoptera, such as the greenhouse whitefly, *T. vaporariorum,* the sweet potato whitefly, *B. tabaci*, both of which are important pests of cotton and vegetables, the brown planthopper, *N. lugens* in rice, the citrus scale insects, *Aonidiella aurantii* and *Sassetia oleae,* and some Coleoptera and Acarina. In contrast, cyromazine is used for control of dipteran larvae in chicken manure. It is also used as a foliar spray to control leafminers (*Liriomyza* sp.) in vegetables and ornamentals, and to control flies on animals (Hall and Foehse, 1980; Williams *et al*., 1980; Kanno *et al*., 1981; Reynolds and Blakey, 1989; Tomlin, 2000) (**Table 14**).

6.3.4.5. Ecotoxicology and Mammalian Safety

Overall, CSIs have selective insect toxicities and as such are considered “soft insecticides.” For diflubenzuron, the harbinger of all BPUs, its environmental fate has been extensively investigated and was shown to be broken down by various microbial

Table 15 Environmental effects of some CSIs

Compound	*Mammals*	*Fish*	*Crustacae*	*Bees*	*Predators*	*Parasitoids*
Bistrifluron	Rat $LD_{50} > 5\,g\,kg^{-1}$	Carp LC_{50} (48 h) $> 0.5\,mg\,l^{-1}$		$LD_{50} > 100\,\mu g\,bee^{-1}$		
Chlorfluazuron	Rat $LD_{50} > 8.5\,g\,kg^{-1}$	Carp LC_{50} (48 h) $> 300\,mg\,l^{-1}$	*Daphnia* LC_{50} (48 h) $0.9\,\mu g\,l^{-1}$	$LD_{50} > 100\,\mu g\,bee^{-1}$	Highly toxic	No – very little effects
Diflubenzuron	Rat $LD_{50} > 4.6\,g\,kg^{-1}$	Zebra fish, rainbow trout LC_{50} (96 h) $>0.2\,mg\,l^{-1}$	*Daphnia* LC_{50} (48 h) $7.1\,\mu g\,l^{-1}$	Not hazardous $LD_{50} > 100\,\mu g\,bee^{-1}$	Safe – little effects	Safe-little adverse effects
Flucycloxuron	Rat $LD_{50} > 5\,g\,kg^{-1}$	Rainbow trout, sunfish LC_{50} (96 h) $>0.1\,mg\,l^{-1}$	*Daphnia* LC_{50} (48 h) $4.4\,\mu g\,l^{-1}$	$LD_{50} > 100\,\mu g\,bee^{-1}$	No – moderate effects	No – harmful effects
Flufenoxuron	Rat $LD_{50} > 3\,g\,kg^{-1}$	Rainbow trout LC_{50} (96 h) $> 100\,mg\,l^{-1}$			No adverse effects – harmful	No – little adverse effects
Hexaflumuron	Rat $LD_{50} > 5\,g\,kg^{-1}$	rainbow trout: not lethal, *Tilapia* $LC_{50} > 3\,\mu g\,l^{-1}$	*Daphnia* LC_{50} (96 h) $0.1\,\mu g\,l^{-1}$	$LD_{50} > 100\,\mu g\,bee^{-1}$	Very little effects	Harmless, but ectoparasites strongly affected
Lufenuron	Rat $LD_{50} > 2\,g\,kg^{-1}$	Carp, rainbow trout, sunfish LC_{50} (96 h) $> 30–70\,mg\,l^{-1}$		$LC_{50} > 38\,\mu g/bee^{-1}$ $LD_{50} > 8\,\mu g/bee^{-1}$	Safe – harmful	Moderately harmful
Novaluron	Rat $LD_{50} > 5\,g\,kg^{-1}$	Rainbow trout, sunfish LC_{50} (96 h) $> 1\,mg\,l^{-1}$	*Daphnia* LC_{50} (48 h) $58\,\mu g\,l^{-1}$	Nontoxic at recommended rates; $LC_{50} > 100\,\mu g\,bee^{-1}$ $LD_{50} > 1\,mg\,bee^{-1}$	Low toxicity – harmful	Little–harmful effects
Teflubenzuron	Rat $LD_{50} > 5\,g\,kg^{-1}$	Trout, carp LC_{50} (96 h) $>0.5\,mg\,l^{-1}$		$LD_{50} > 1\,mg\,bee^{-1}$	Harmless – highly toxic	No – very little effects
Triflumuron	Rat $LD_{50} > 5\,g\,kg^{-1}$	Rainbow trout LC_{50} (96 h) $>320\,mg\,l^{-1}$	*Daphnia* LC_{50} (48 h) $225\,\mu g\,l^{-1}$	Toxic	Harmless – moderately toxic	Moderately harmful
Buprofezin	Rat LD_{50} $2.4\,g\,kg^{-1}$	Carp, rainbow trout LC_{50} (48 h) $>2.7–1.4\,mg\,l^{-1}$	*Daphnia* LC_{50} (3 h) $50.6\,mg\,l^{-1}$	No effect at $2\,g\,l^{-1}$	Harmless – moderately toxic	Very little effects
Cyromazine	Rat LD_{50} $3.4\,mg\,kg^{-1}$	Carp, rainbow trout, sunfish LC_{50} (96 h) $>90\,mg\,l^{-1}$	*Daphnia* LC_{50} (48 h) $>9.1\,mg\,l^{-1}$	No effect up to $5\,\mu g$	Harmless – moderately toxic	Harmless – moderate effects

Data compiled from Darvas, B., Polgár, L.A., **1998**. Novel-type insecticides: specificity and effects on non-target organisms. In: Ishaaya, I., Degheele, D. (Eds.), Insecticides with Novel Modes of Action: Mechanism and Application. Springer, pp. 188–259; Tomlin, C.D.S. (Ed.), **2000**. The Pesticide Manual, 12th edn. British Crop Protection Council Publications; and Ishaaya, I., **2001**. Biochemical processes related to insecticide actions: an overview. In: Ishaaya, I. (Ed.), Biochemical Sites of Insecticide Action and Resistance. Springer, pp. 1–16.

agents without accumulation in soil and water. The fear that spray run-off into streams may cause widespread mortality of nontarget species has not been realized. Moreover, its chitin synthesis inhibitory action is quite specific, and related biochemical processes, such as chitin synthesis in fungi and biosynthesis of hyaluronic acid and other mucopolysaccharides in chickens, mice, and rats, are not affected. A representative list of the salient environmental effects of CSIs against mammals (rat), vertebrates (fish), crustaceans, bees, predators, and parasitoids is given in **Table 15**. However, owing to selective toxicity towards arthropods, BPUs have, varying degrees of effects on crustaceans as well as beneficial insects, which requires their use with care. In this case, the IOBC/WPRS (International Organization for Biological and Integrated control of Noxious Animals and Plants, West Palaearctic Regional Section, 2004) sequential testing scheme has proven its value for testing the side effects on a species-by-species basis and under (semi-)field conditions (Hassan, 1992). However, since most of the BPU formulations need to be ingested to be effective, topical effects on parasites, predators, and pollinators are minimal. Retnakaran and Wright (1987), Perez-Farinos *et al*. (1998), and Medina *et al*. (2002) claimed that the selectivity of BPUs may result from a relatively low cuticular absorption in residual and direct contact assays. As summarized in **Table 15**, the majority of the CSIs are harmless or exert little adverse effect on bees, predators, or parasitoids, which renders these BPUs acceptable for inclusion in integrated pest management (IPM) programs (Elzen, 1989; Hassan *et al*., 1991, 1994; Vogt, 1994; Van de Veire *et al*., 1996; Darvas and Polgar, 1998; Sterk *et al*., 1999; Tomlin, 2000).

6.3.4.6. Resistance, Mechanism for Resistance and Resistance Potential

Pimprikar and Georghiou (1979) were the first to report very high levels of resistance (>1,000-fold) to diflubenzuron in a housefly population stressed with the compound. Since then, several research groups in different parts of the world have reported resistance to CSIs in Lepidoptera, Diptera, and whiteflies.

In Southeast Asia, selection of diamondback moth, *Plutella xylostella,* from Thailand during six generations with chlorfluazuron and teflubenzuron resulted in resistance levels of 109-fold and 315-fold, respectively (Ismail and Wright, 1991, 1992). While marked cross-resistance between chlorfluazuron and teflubenzuron was demonstrated, there was no evidence of cross-resistance to diflubenzuron, and little or no cross-resistance to flufenoxuron and hexaflumuron. Pretreatment with the synergists PB and DEF increased the toxicity of chlorfluazuron and teflubenzuron up to 34-fold and 28-fold, respectively, suggesting that microsomal monooxygenases and esterases are involved in resistance. In another study with *P. xylostella* from Malaysia, selection with diflubenzuron increased resistance to teflubenzuron, but had no effect on chlorfluazuron (Furlong and Wright, 1994). In this study, while use of PB and DEF suggested the involvement of microsomal monooxygenases and esterases in teflubenzuron resistance, glutathion-*S*-transferase (GSTs) had limited involvement.

As documented by Moffit *et al*. (1988) and Sauphanor *et al*. (1998), the codling moth *C. pomonella* shows very high levels of resistance to diflubenzuron in the USA and France. In southern France, failure in *C. pomonella* control was observed for several years, revealing a 370-fold resistance for diflubenzuron and cross-resistance with two other BPUs, teflubenzuron (7-fold) and triflumuron (102-fold), as well as to the ecdysone agonist, tebufenozide (26-fold) (Sauphanor and Bouvier, 1995). Interestingly, resistance to diflubenzuron was linked to cross-resistance to deltamethrin. In both cases, enhanced mixed-function oxidase and GST activities are involved in resistance, rather than target site modification. In addition, a fitness cost described in both resistant strains was mainly associated with metabolic resistance (Boivin *et al*., 2001). Finally, a lack of relationship between ovicidal and larvicidal resistance for diflubenzuron in *C. pomonella* may be due to different transport properties as well as differential enzymatic metabolism (Sauphanor *et al*., 1998).

In some strains of *S. littoralis*, resistance to diflubenzuron was also increased by a factor of about 300 (El-Guindy *et al*., 1983). El Saidy *et al*. (1989) reported that diflubenzuron and teflubenzuron were hydrolyzed rapidly by all tissues tested, and the gut wall was the most active tissue reaching 61% hydrolytic breakdown for diflubenzuron and 16% for teflubenzuron. Interestingly, profenofos and DEF could inhibit degradation of both BPUs tested under optimal conditions. Ishaaya and Casida (1980) had earlier reported that these organophosphorous compounds can inhibit insect esterases in larval gut integument. The strong synergism activity of DEF and profenofos indicated that the major route of detoxification in *S. littoralis* was through hydrolysis, while oxidative metabolism was found to be of minor importance for resistance.

In the Australian sheep blowfly, *Lucilia cuprina*, resistance to diflubenzuron was inherited in a codominant (S male × R female) or incompletely recessive (R male × S female) manner, and there was also some maternal influence on inheritance of

monooxygenase activities, suggesting that diflubenzuron resistance is polygenic and involves mechanisms additional to monooxygenases (Kotze and Sales, 2001).

McKenzie and Batterman (1998) reported the development of resistance to cyromazine in populations of *L. cuprina*, which, however, had remained susceptible for almost 20 years of exposure. This resistance in *L. cuprina* was controlled by a single gene in each variant and two resistance loci were identified: one (Cyr4) closely linked to the marker "reduced eyes" on chromosome IV, and the other, Cyr5, closely linked to the "stubby bristles" marker on chromosome V (Yen *et al*., 1996). Similarly, in *D. melanogaster*, cyromazine resistance was due to a mutation in a single, but different gene than the one identified in resistant *L. cuprina*. The resistance genes, designated *Rst(2)Cyr* and *Rst(3)Cyr*, were localized to puff positions 64 on chromosome II and 47 on chromosome III, respectively (Adcock *et al*., 1993).

With respect to resistance in *Musca domestica*, Keiding (1999) reviewed the period 1977 to 1994. In this period, only two IGRs, diflubenzuron and cyromazine, were widely used for fly control, either by direct contact application to breeding sites, manure, garbage, etc., or as an admixture in feed for poultry or pigs. Widespread use of diflubenzuron or cyromazine by direct treatment of manure has not led to resistance of practical importance except for resistance to diflubenzuron on a few farms in the Netherlands. However, there are reports showing that the use of either compound mixed with feed has resulted in the development of moderate to high resistance to these compounds. High resistance in adult flies to organophosphates and pyrethroids does not usually confer cross-resistance to the larvicidal effects of diflubenzuron or cyromazine, but cross-resistance between organophosphorous compounds and JHAs (methoprene) has been reported. In Denmark, Keiding *et al*. (1992) came to the same conclusions where housefly control with both compounds was carried out on farms for 1–9 years. On none of the farms was any general increase of tolerance to diflubenzuron found. In the same study, two strains were selected with diflubenzuron and cyromazine where moderate to high resistance developed if the selection pressure was strong, especially when used as feed-through applications on poultry farms where all feed contains diflubenzuron or cyromazine. If the treatment of fly breeding sources is less complete, resistance problems may not develop. More recently, Kristensen and Jespersen (2003) observed resistance in houseflies to diflubenzuron for the first time in Denmark, and some field populations with resistance to cyromazine. A fivefold cyromazine resistant strain was established and this was 3-, 5-, and 90-fold resistant to diflubenzuron, triflumuron, and methoprene, respectively. In reviewing the mechanism of resistance in houseflies to diflubenzuron and cyromazine, Ishaaya (1993) indicated that resistance was due to increased levels of detoxifying enzymes, decreased penetration, and enhanced excretion of the compounds. Cross-resistance between cyromazine and diflubenzuron was observed but the mechanism seems more target site related than metabolic.

For the control of whiteflies, novel compounds like buprofezin were introduced at the beginning of the 1990s (Horowitz *et al*., 1994; De Cock and Degheele, 1998). In Israel, a survey in cotton fields over 4 years (1989–1992) with two or three applications of buprofezin per season indicated a fivefold increase in tolerance in the *B. tabaci*, and the resistance ratio for resistance to pyriproxifen was >500-fold (Horowitz and Ishaaya, 1994). Based on the success of the program in Israel, the usefulness of buprofezin was once again demonstrated in a resistance management program in Arizona to control resistance to pyriproxifen in populations of the whitefly, *Bermisia argentifolii* in cotton (Dennehy and Williams, 1997). In another study in southern Spain where highly multiresistant strains of *B. tabaci* showed lower efficacy to buprofezin, pyriproxyfen resistance was not obvious (Elbert and Nauen, 2000). For the greenhouse whitefly, *T. vaporariorum*, which is a major pest problem in protected crops in Western Europe, a >300-fold resistance was scored in a strain collected in northern Belgium (De Cock *et al*., 1995). No cross-resistance was recorded for pyriproxyfen and diafenthiuron, indicating their potential in a resistance management program. In UK greenhouses, Gorman *et al*. (2002) also found very strong resistance to buprofezin in *T. vaporariorum*, and these strains were cross-resistant to teflubenzuron.

The chitin synthesis inhibition site has proven to be important for developing control agents that act against important groups of insect pests and many of these CSIs are environmentally safe. However, details of the exact mode of action of CSIs have not been elucidated so far. Although there were already some incidences of resistance to CSIs in the last two decades in different pest insects, these IGR compounds remain suitable for use as rotation partners in integrated and resistance management programs based on their new and se-

lective mode of action in contrast to broad-spectrum neurotoxins.

At present, it is believed that chitin synthesis has by no means been fully exploited as an attractive target and that opportunities exist to further discover new CSIs. A better understanding of the biosynthetic pathway for chitin synthesis and cuticle deposition, as well as precise mode of action of CSIs would allow for development of better and more efficient high throughput assays for discovery of new and novel CSIs.

6.3.5. Conclusions and Future Prospects of Insect Growth- and Development-Disrupting Insecticides

The three classes of insecticides reviewed in this chapter are much slower acting than those acting on neural target sites. The end user has, of course, been used to seeing insects die within a very short time following application of neuroactive insecticides. The discovery and availability of insecticides that inhibit growth and development of insects brought a paradigm shift from the faster acting neurotoxic insecticides. This change has necessitated educating the distributors and the users on the mode of action of these new insecticides. The bisacylhydrazine insecticides are generally faster acting than the JHA and CSI insecticides. Moreover, an attractive feature of the bisacylhydrazine insecticides is their ability to prevent crop damage by inhibition of feeding within 3–12 h after application.

Of the three classes of insecticides that disrupt growth and development in insects, the mode of action of nonsteroidal ecdysone agonist bisacylhydrazine insecticides is the best understood at the molecular level. This detailed understanding has been possible, both with the cloning and expression of cDNAs encoding EcR and USPs from several insects, and the availability of stable and easy to synthesize bisacylhydrazines. Unlike the JHAs and CSI, the molecular targets for bisacylhydrazine insecticides are not only known but the interaction of some of these insecticides with specific amino acid residues in the ligand binding pocket of the target ecdysone receptor are also known. Moreover, reasons for the selective insect toxicity of bisacylhydrazine insecticides are also well understood. Publication of the crystal structure of unliganded and liganded (with ecdysteroid and bisacylhydrazine) HvEcR/HvUSP, and the discovery of new nonsteroidal ecdysone agonist chemistries like tetrahydroquinolines, provides new tools, and suggests possibilities of discovering new ecdysone agonist insecticides. It should now be possible to use combinatorial chemistry approaches, around leads generated either via *in silico* screening or rational design (based on the three-dimensional structures and interactions of ligand in ligand binding pocket of EcR), to discover new and novel chemistries that target EcRs from specific insect orders. The discovery of additional new, novel, selective, and potent nonsteroidal ecdysone agonists will create opportunities to extend their applications in individually or simultaneously regulating different ecdysone receptor gene switches in plants and animals. Further, the discovery of non steroidal ecdysone agonist bisacylhydrazine insecticides has opened tremendous opportunities to explore both basic and applied biology.

The molecular basis of action of JHA and CSI insecticides is not well understood, although both classes of chemistries were discovered long before the bisacylhydrazine insecticides. The discovery of the JH receptor(s) has been elusive (see **Chapter 3.7**). To complicate matters further, it is not clear if the JHAs use the same molecular target/site as the natural JHs do (Dhadialla *et al*., 1998). Dhadialla *et al*. (1998) alluded to the possibility that the JH receptor may be a complex of two or more proteins, and that JH and JHAs could manifest their action by interacting either with different proteins in the complex or by interacting at different, but effective, sites. Consequently, the research to discover new JH agonist or antagonist chemistries has been slow. An antagonist of JH (different from a precocene type of mode of action) that acts either by inhibiting one of the JH biosynthesis steps or antagonizes the action of JH at the receptor level would be useful. With that, it may be possible to have agonists/antagonists of JH with insect selective toxicity, as has been possible for the ecdysone agonists.

Even though the precise mode of action of CSI insecticides is unknown, many analogs and variants of the original diflubenzuron, Dimilin®, have been synthesized and registered as insecticides. A better understanding of the biosynthetic pathway for chitin synthesis and cuticle deposition, and molecular characterization of the various enzymes involved, as well as the precise mode of action of CSIs, would allow for development of better and more efficient high-throughput assays for discovery of new and novel CSIs.

Finally, in spite of their slower speed of kill of insect pests than the faster acting neurotoxic insecticides, the three classes of insect growth and development disrupting insecticides are well suited for use in insect pest control. They are also suited for resistance management programs due to their novel and different modes of action. The bisacylhydrazine

insecticides are particularly attractive, due to their selective insect toxicity and high degree of mammalian and ecotoxicological reduced risk profiles.

Acknowledgments

The authors would like to thank Natalie Filion, CFS, Ontario, Canada, and Karan Dhadialla, University of Chicago, IL, USA, for sorting and typing the references in the required format. TSD also expresses his deep appreciation to Dow Agrociences LLC., Indianapolis, IN, USA (especially Drs. W. Kleshick and S. Evans) for support and encouragement in undertaking this writing. Part of the research was supported by grants from Gerome Canada and the Canadian Forest Service to AR and colleagues. GS also acknowledges the Fund for Scientific Research Flanders (FWO, Brussels, Belgium).

6.4 Azadirachtin, a Natural Product in Insect Control

A J Mordue (Luntz), University of Aberdeen, Aberdeen, UK
E D Morgan, Keele University, Keele, UK
A J Nisbet, University of Melbourne, Werribee, Australia

6.4.1. Introduction

The dominance of synthetic pesticides, which began with the introduction of DDT in the 1940s, almost displaced completely the natural pesticides used before that time. Only pyrethrum and derris (the active compound is rotenone) survived in specialized uses. In the following half-century the problems of persistence and toxicity of the synthetics grew and regulation followed them. Slowly, one after the other was restricted in use, until we have reached the point where there are no longer available synthetic crop protectants for certain uses. At the same time fundamental research has uncovered entirely new ways of dealing with pests that range from use of pheromone traps through parasitoids to feeding deterrents. Unique among these new discoveries is the compound azadirachtin.

Azadirachtin is a colorless crystalline compound, found in the seeds of the neem tree, *Azadirachta indica* A. Juss. 1830. The compound is of great interest because it is a powerful feeding deterrent for a number of phytophagous insects, and has the power, at parts per million concentration, to inhibit growth and development of all insects ingesting it. This substance, together with a few compounds of closely related structure in the same seeds, provides the most powerful natural pesticide discovered since the era of synthetic pesticides. Its spectrum of activity includes many other arthropods and even annelids and nematodes. Yet it appears to have little or no toxicity for vertebrates. Its isolation, structure determination, synthesis, toxicity, mode of action, spectrum of activity, and practical application have all absorbed the interest of scientists of many disciplines

during the past four decades. Exploration of the properties and uses of azadirachtin continues, with a steady flow of about 45 papers per year appearing on various aspects of the compound.

A resurgence of interest in azadirachtin may be at hand. With the elucidation of its mode of action, which is drawing close, there will be the possibility of studying that site in detail with high-throughput screening methods to search for other molecules with greater field efficacy. Additionally, azadirachtin may prove to be an exciting tool for research scientists studying cellular processes and the cell cycle in invertebrate versus vertebrate cells.

6.4.1.1. The Neem Tree

The modern investigation of the properties of neem seeds began, as often happens, simultaneously in two directions, with the field work of Schmutterer in the Sudan, and laboratory work (unpublished) at the Anti-Locust Research Centre in London. In 1966, Morgan and Butterworth began a systematic search for the substance or substances in neem seeds responsible for the feeding deterrent effect on the desert locust *Schistocerca gregaria*, based on an antifeedant bioassay developed at the Anti-Locust Research Centre (Haskell and Mordue (Luntz), 1969). This work resulted in the isolation of the compound called azadirachtin (Butterworth and Morgan, 1968, 1971). It was soon shown to be effective systemically (Gill and Lewis, 1971), and to have growth-disrupting effects as well (Ruscoe, 1972). Neem products were slow to come to market while powerful synthetics dominated sales, but products are now available in several countries, including the USA, but elsewhere, the toxicity testing rules made for single-compound synthetics still make the licensing of neem products very difficult (Isman, 1997) (see Section 6.4.4).

Other compounds of related chemical structure and similar antifeedant properties have since been isolated from the seeds in smaller quantities. Therefore consideration must be given to the group when discussing the properties of azadirachtin. However, azadirachtin itself remains the most accessible and most abundant compound of the group.

The neem tree appears to be a native of Burma or the Indian subcontinent (Schmutterer, 2002). Indian sources say parts of the neem tree have been used since ancient times as protection against pests, citing the use of neem leaves for protection against bookworm and pests in stored rice, as well as in Ayurvedic medicine (Puri, 1999). The tree belongs to the family Meliaceae, which includes various species of mahogany, but the wood is not of high quality. There are only two other species recognized in the genus: *A. excelsa* (= *A. integrifolia*, locally known as marrango), a native of the Philippine Islands (Schmutterer and Doll, 1993), and the Thai neem tree, *A. siamensis*, very close in appearance to *A. indica*, and formerly thought to be a subspecies, but now awarded full species status. The latter forms hybrids with neem. All contain azadirachtin-like substances with similar properties (Kalinowski *et al*., 1997). Today neem is grown widely across the drier tropics from Australia to Africa, and South and Central America. It is easily grown, widely distributed, exists in large numbers (an estimated 14 million in India alone), so the seeds and their extracts are readily available.

6.4.2. Azadirachtin Research up to 1985

Research on azadirachtin from its discovery to 1985 is best summarized in three international symposia, two held in Germany, in 1980 (Schmutterer *et al*., 1981) and in 1983 (Schmutterer and Ascher, 1984), and one in Kenya in 1986 (Schmutterer and Ascher, 1987). In the 15–20 years following the isolation of azadirachtin, the major biological effects of neem seed extracts were established and shown to be due largely to the active ingredient azadirachtin. The antifeedant effects, insect growth regulatory effects, and sterility effects were established for a wide variety of phytophagous insects, and field trials were carried out to show the effectiveness of neem as a crop protection agent. Early promise of this, together with its large safety margin to vertebrates and potential effectiveness against other pests such as nematodes, led to an upsurge in neem research (Schmutterer and Ascher, 1984, 1987). By 1985 neem pesticides were promoted for use in developing countries by the Deutsche Gesellschaft für Technische Zusamenarbeit (GTZ) as a real alternative in biological and integrated pest control where sufficient raw material was available. In the Western world neem seed, neem oil, and several of their components were being tested in the USA as insect antifeedants and disruptants of normal growth and development. The first commercial neem seed formulation was patented in the USA (Larson, 1985) and granted registration by the Environment Protection Agency. Neem tree plantations for seed supplies were cultivated in the USA, Central and South America, and Australia.

By this time also the broad areas of its mode of action were established although the details were still not fully understood. Insect antifeedancy was shown to be particularly effective in lepidopteran pests compared with others such as the Coleoptera

and Hemiptera and was related to effects on the mouthpart chemoreceptors (Simmonds and Blaney, 1984). Studies on the insect growth regulatory (IGR) mode of action of azadirachtin in, for example, the blowfly *Calliphora vicinia*, the milkweed bug *Oncopeltus fasciatus*, the tobacco hornworm *Manduca sexta*, and the African migratory locust *Locusta migratoria* revealed that ecdysone biosynthesis and catabolism were affected by azadirachtin treatment to cause the major insect growth regulatory effects (Redfern *et al.*, 1982; Sieber and Rembold, 1983; Schlüter *et al.*, 1985; Dorn *et al.*, 1986; Bidmon *et al.*, 1987). In adult insects, such as *L. migratoria*, effects of azadirachtin on egg development were shown to be related to changes in both juvenile hormone (JH) and ecdysone titers (Rembold *et al.*, 1986). In addition to the effects of azadirachtin on JH and ecdysone and the interactions between both hormones, Schlüter (1987) was able to demonstrate in the Mexican bean beetle *Epilachna varivestis* that azadirachtin also affected cells in the process of proliferation and differentiation. Mitosis in the wing disc was blocked from metaphase onwards by azadirachtin injections.

By 1986 azadirachtin was established as an antifeedant, insect growth regulator, and sterilant with a novel mode of action. The basis for its mode of action was known to involve the neurosecretory–neuroendocrine axis and perhaps other sites including particular stages in cell division. Although the full structure had not yet been elucidated or synthetic routes explored, the use of neem extracts to produce insecticides with good market potential was thought to be feasible. Studies to overcome a number of problems preventing commercial use of neem relating to standardization and regulatory matters were still required, as were studies on its possible role in integrated pest management strategies.

6.4.3. Chemistry of Neem Products

Azadirachtin, formula $C_{35}H_{44}O_{16}$, m.p. 160 °C, $[\alpha]_D^{25}$-66°($CHCl_3$, $c = 0.5$) (**Figure 1**) belongs to the large group of plant triterpenoids, and to the narrower group of limonoids, which are frequently found in plants of the Meliaceae. Limonoids are triterpenoids that have their side chains shortened by four carbon atoms and the remaining four atoms cyclized as a furan ring (e.g., nimbin and salannin, and their desacetyl-derivatives; **Figure 1**). The molecule of azadirachtin is unusually highly oxygenated, and in a molecular model the surface is covered by functional

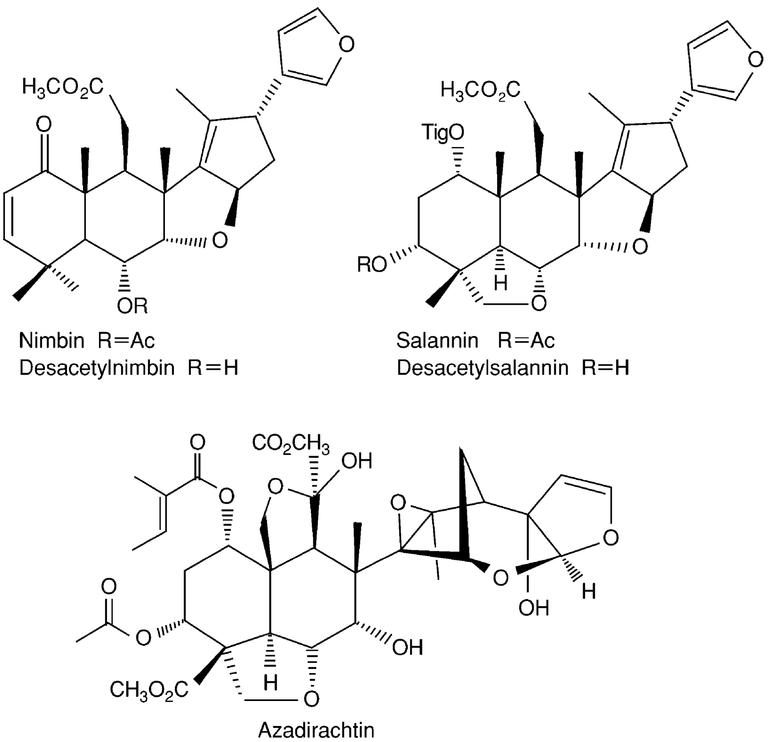

Figure 1 The structure of azadirachtin, together with the principal limonoids (nimbin and salannin, and their desacetyl-derivatives) from the seeds of neem (*Azadirachta indica*). Nimbin possesses almost no antifeedant effect and that of salannin is small compared to azadirachtin.

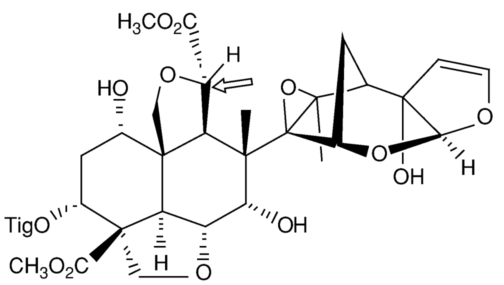
groups. The molecule contains an acetate, a tiglate ester, two methyl esters, a secondary and a tertiary alcohol, an epoxide, a vinyl ether, which is part of an acetal, and a hemiacetal. This overabundance of reactive groups makes its chemistry very difficult (Ley *et al*., 1993). Just how these contribute to its insecticidal properties is not yet understood. Another locust antifeedant called meliantriol of lower activity than azadirachtin was announced shortly before the isolation of azadirachtin (Lavie *et al*., 1967), but its isolation has never been repeated.

Structural studies on azadirachtin began immediately after its isolation, but because of its complexity and the sensitivity of some of the functional groups, progress was difficult. The structure was finally solved 18 years after isolation by a combination of modern nuclear magnetic resonance (NMR) techniques and X-ray crystallography (Bilton *et al*., 1987; Kraus *et al*., 1987; Turner *et al*., 1987). Synthesis of azadirachtin presents a great challenge to organic chemists. Great progress has been made towards it by the groups of Ley (Durand-Reville *et al*., 2002) and others (Nicolaou *et al*., 2002; Fukuzaki *et al*., 2002), but as yet it has not been completed.

6.4.3.1. Neem Limonoids

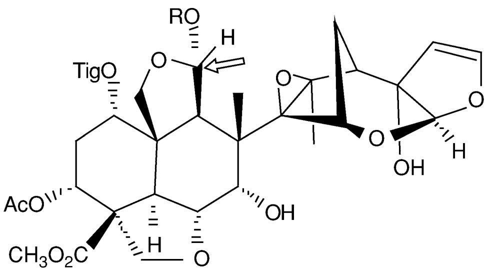
Largely because of the interest in azadirachtin, the triterpenoids of neem have been studied intensively. About 150 such compounds have now been described (Akhila and Rani, 1999), most of them found in very small quantities in various parts of the tree. Only about one-third of them have been tested for biological activity, and none has shown greater activity than the azadirachtin group.

Unfortunately many writers speak of "neem" as if that were a single commodity. The different parts of the neem tree all have different properties and contain different substances. The lack of more accurate description and the frequent lack of analytical data on what is contained in seed extracts have reduced the value of some of the published work on such extracts. The seeds are the only practical source of azadirachtin and its group of compounds. Any of this substance in other parts of the tree is in marginally small concentration.



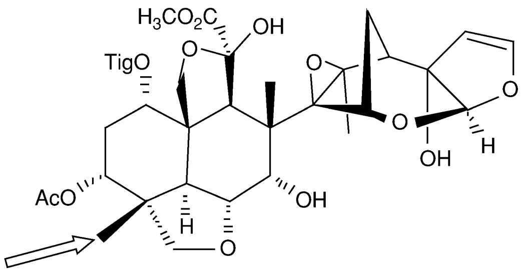
6.4.3.2. Isolation of Azadirachtin

The triterpenoid present in greatest quantity in the seeds is usually salannin (**Figure 1**), a simpler triterpenoid with only weak activity as a feeding deterrent. Azadirachtin, representing 0.1–1.0% (mean 0.6%) of the weight of the seed kernels is next in quantity. The other compounds of azadirachtin-like structure and biological properties occur in progressively smaller amounts. Chemically, they divide into three structural types (**Figure 2**): the azadirachtins, with a hemiacetal group at carbon atom number 11, the azadirachtols, without the hemiacetal, and the meliacarpins, in which the methoxycarbonyl ester at C29 is replaced by methyl. Not all compounds found fit easily into these types and new trace constituents continue to be found (e.g., Luo *et al*., 1999; Malathi *et al*., 2003). Rearrrangement products, known as azadirachtinins (**Figure 3**), of much lower biological activity, are found in the seeds and are also formed during isolation of the limonoids. The names azadirachtin A, azadirachtin B, etc., are sometimes used. These are incorrect names. For the correct chemical names for all these triterpenoids and limonoids, see Kraus (2002). Also present in lesser quantities are nimbin, 3-desacetylnimbin, and 6-desacetylsalannin (Johnson *et al*., 1996) (**Figure 1**), simpler limonoids of lesser activity and interest. Compounds of similar structure are found in the related *Melia* genus. For example, Persian lilac or chinaberry, *Melia azedarach*, contains meliacarpins (**Figure 2**), but the seeds are extremely hard and their extracts are toxic to mammals.



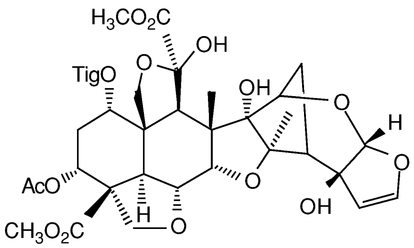
A number of isolation procedures have been described, but all require extraction with solvent from the ground seeds, followed by solvent partition to separate the more polar triterpenoids from the oil. After that, methods differ more, but all require some form of chromatography to separate the individual compounds, either gravity column chromatography (Johnson and Morgan, 1997a), flash columns (Jarvis *et al*., 1999), or preparative high-performance liquid chromatography (HPLC) (Lee and Klocke, 1987; Govindachari *et al*., 1990, 1996). Extraction by supercritical carbon dioxide has been examined, but is not as efficient as solvent extraction (Johnson and Morgan, 1997b; Ambrosino *et al*., 1999). There is a lot of current interest in microwave-assisted chemistry, and a microwave-assisted extraction of seeds has been described (Dai *et al*., 2001).

6.4.3.3. Analysis

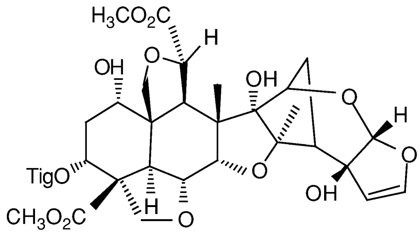


The number of triterpenoids in neem seeds and their similarity in physical properties makes analysis for the important pesticidal compounds both important and difficult. The standard method in use for some time is reverse-phase HPLC with ultraviolet (UV) absorption at short wavelength (214–218 nm) (e.g., Deota *et al*., 2000). Normal-phase supercritical fluid chromatography offers advantages where the equipment is available (Johnson and Morgan, 1997a). A colorimetric method for the whole group of triterpenoids, using vanillin–sulfuric acid has been

3-Tigloylazadirachtol



11-Demethoxycarbonylazadirachtin
(azadirachtin H) R=H
11-Acetyl-11-demethoxycarbonylazadirachtin
(marrangin) R=OAc



3-Acetyl-1-tigloyl-11-hydroxy-meliacarpin
(azadirachtin D)

Figure 2 Examples of minor products related to azadirachtin from neem seeds. The essential difference of structure that makes an azadirachtol or meliacarpin is indicated by an arrow. Marrangin is the chief insecticidal compound of the marrango tree (*Azadirachta excelsa*). The names azadirachtin A, azadirachtin B, etc., are sometimes used. These are incorrect names. For the correct chemical names for all teiterpernoids and limonoids, see Kraus (2002).

(11S)-epimer

3-Tigloylazadirachtolin

Figure 3 Rearrangement products from azadirachtin and 3-tigloylazadirachtol. These compounds, of much lower activity than the others illustrated, are formed by reaction between the epoxide ring and the hydroxyl group at C7.

reported, but this is rather nonspecific (Dai *et al*., 1999), and more specific enzyme-linked immunosorbent assays (ELISAs) have been developed that will give detection from 0.5 to 1000 ppb for azadirachtin and close relatives (Schutz *et al*., 1997, Hemalatha *et al*., 2001). Additionally, monoclonal antibodies to azadirachtin produced by phage display techniques are currently being assessed (Robertson, Mordue (Luntz), Mordue, and Porter, unpublished data). The most accurate and sensitive analytical method, but also the most costly in equipment, is liquid chromatography–mass spectrometry (Schaaf *et al*., 2000; Pozo *et al*., 2003).

6.4.3.4. Stability and Persistence

Azadirachtin is soluble in polar organic solvents (methanol, ethanol, acetone, chloroform, ethyl acetate) and slightly soluble in water ($1.29\,g\,l^{-1}$). Aqueous solutions are usually made by dissolving first in ethanol or acetone and carefully diluting with

water to avoid formation of the glassy mass when the solid is wetted with water, and which then dissolves very slowly. Solutions in organic solvents are stable almost indefinitely (Jarvis *et al*., 1998) but solutions in water at pH 7 or higher are unstable. Aqueous solutions are most stable from pH 4 to 6 (Jarvis *et al*., 1998).

While degradability is one great advantage in agricultural application of neem triterpenoids, the rate of disappearance is a little too high according to some authors. One report says azadirachtin is stable for less than 1 week under ambient conditions (Sundaram, 1996), another says its stability is less than 3 months (Brooks *et al*., 1996). Scott and Kaushik (2000) gave a half-life of 36–48 h in water exposed to sunlight. The DT_{50} (time for 50% of azadirachtin to disappear) in soil at 25 °C was 20 and 31.5 days in unautoclaved and autoclaved soil respectively (Stark and Walter, 1995). Probably the most comprehensive studies on the environmental behavior and stability of azadirachtin have been carried out by the Canadian Forest Service for its use on young trees (Sundaram, 1996). Its persistence on balsam fir and red oak foliage; its dissipation in forest nursery soils; absorption, leaching, and desorption from sandy loam forest soil; photostability on foliage; and rate of hydrolysis in natural waters have all been measured (Sundaram, 1996; Sundaram *et al*., 1997). They have also made efforts to formulate azadirachtin against hydrolysis and UV degradation, but no large-scale study of formulation for stability appears to have been made.

6.4.4. Neem Insecticides in Pest Control

6.4.4.1. Background

Today, after 40 years of discovery, research, and development of neem as a natural pesticide there are well-established products in the organic agriculture and niche markets in both North America and Western Europe. Azadirachtin, the main active ingredient of neem seeds, is an extremely effective antifeedant to many phytophagous insects, and an IGR and sterilant to all insects tested. Other constituents of neem seeds, including the oil, have been shown also to be effective control agents against plant nematodes and fungal pathogens.

The complexity of the azadirachtin molecule and our inability, as yet, to synthesize it has precluded its production as a synthetic pesticide, hence use of the natural product is the only choice. Neem as a botanical pesticide has many excellent attributes that include its broad-spectrum IGR effects, systemic action in some plants, minimal disruption of natural enemies and pollinators, rapid breakdown in the environment, and lack of toxicity to vertebrates. However, its initial promise has not been realized. Problems have arisen during the research and development phase and these relate to its mode of action, where (as with most IGRs) azadirachtin acts slowly and although feeding and crop damage ceases shortly after treatment, pest insects remain alive on treated crops, reducing acceptance by growers and consumers. Neem pesticides have limited persistence on plants and require multiple applications against certain pests when used as a stand-alone treatment. This, together with the cost of production of a consistent, high-quality product with 1% or more of azadirachtin by weight from annual supplies of seeds, results in the cost of neem pesticides to be some three times greater than synthetic pyrethroids (Isman, 2004). Regulatory issues have also featured large in the development of neem and have been a formidable barrier to the successful commercialization of neem-based pesticides. The Environmental Protection Agency of the USA chose to simplify the approval process of neem insecticides by recognizing azadirachtin as the sole active ingredient and deeming the remaining chemical components present in neem kernels to be “inert ingredients” (Isman, 2004). However, Europe and Japan, for example, have required identification and toxicological studies for all major constituents of neem, processes that have greatly delayed its introduction into these and other countries.

Despite these problems neem insecticides are established as valuable components in integrated crop management systems and accepted by organic producers. In California neem insecticides are used on over 60 food crops, particularly lettuce and tomato, and account for 0.25% of insecticide use on tomato (California EPA, 2001, in Isman, 2004). In Europe, Neemazal insecticides (Trifolio-M GmbH) have been cleared for use in Germany after the parent company completed toxicological studies on all compounds present in their neem products. Neem is expected to show continued sales growth in highly developed countries as new markets continue to be developed. Growth in organic food production and the gradual reduction, and ultimate elimination, of synthetic neurotoxic insecticides will both favor expansion of the market for neem. The introduction of neem products specifically formulated for particular crops and crop pests will also aid expansion, as would intensive education of growers.

In developing countries, simple inexpensive formulation of neem extracts must be encouraged as an

important source of pest control at the level of subsistence farming, as long as such unregulated products are not confused with legitimate regulated products of high technical standard.

6.4.4.2. Use in Integrated Pest Management

Azadirachtin exhibits good efficacy against key pests such as whiteflies, leaf miners, fungus gnats, thrips, aphids, and many leaf-eating caterpillars (Immaraju, 1998). Its use is recommended for insecticide resistance control, integrated pest control, and organic pest control programs. Research in community-level interactions with a view to the use of neem-based insecticides in IPM strategies are revealing subtle and complex effects that may or may not be useful. For example, the ability of azadirachtin to inhibit protein synthesis is demonstrated in the obliquebanded leafroller, *Choristoneura rosaceana* by an inhibition of midgut esterases (Smirle *et al*., 1996; Lowery and Smirle, 2000). This is seen also in resistant Colorado potato beetles (*Leptinotarsa decemlineata*) treated with both neem and *Bacillus thuringiensis* (Trisyono and Whalon, 1999) and may be a useful tool in the management of insect populations where insecticide resistance has developed as a result of elevated esterase activity.

Neem has been suggested for use in maintaining beneficial insect levels, as predators and parasitoids are not exposed directly to the insecticide on the plant and are not harmed by it, as shown in the brown citrus aphid and its parasitoid *Lysiphlebus testaceipes* (Tang *et al*., 2002) and the glasshouse whitefly *Trialeurodes vaporariorum* and its paraitoid *Encarsia formosa* (Simmonds *et al*., 2002). However, the indirect exposure of predators or parasitoids by feeding on or developing within prey exposed to azadirachtin may result in classical IGR effects on the beneficial if concentrations are high (Beckage *et al*., 1988; Osman and Bradley, 1993; Raguraman and Singh, 1998; Qi *et al*., 2001). Overall, however, if concentrations of neem insecticides are kept to the recommended levels no harm should ensue, for example, for the diamondback moth *Plutella xylostella* no adverse effects were apparent on the survival and foraging behavior of *Diadegma* parasitoids (Akol *et al*., 2002). There is evidence that larval honeybees have some resistance to azadirachtin in neem, and may also be safe from its effects by a lack of translocation back to the hive in nectar or pollen (Naumann and Isman, 1996).

6.4.4.3. Toxicity to Nontarget Organisms

Azadirachtin has displayed remarkable selectivity in toxicity studies, consistently showing no toxicity to vertebrates until very high concentrations are used. Investigations into mammalian toxicology of pure azadirachtin demonstrated a "no-observed-effect level" of 1500 mg kg^{-1} day^{-1} (the highest quantity tested) when azadirachtin was administered orally to rats for 90 days (Raizada *et al*., 2001). In addition to whole-animal toxicological data, a number of *in vitro* assays of the effects of azadirachtin on several mammalian cell lines have established that the compound is not effective against mammalian cells (measured as effects on proliferation, direct toxicity, and morphological alterations, e.g., micronucleation) until concentrations above 10 μM are used (Reed and Majumder, 1998; Akudugu *et al*., 2001; Salehzadeh *et al*., 2002; Robertson, 2004) (see Section 6.4.7.5).

Similarly with plants, phytotoxicity has been demonstrated particularly at the seedling stage, however, again not until high concentrations are used. Using tobacco seedlings Nisbet *et al*. (1996a) demonstrated toxic effects seen as short-term wilting and long-term deformation at 500 ppm pure azadirachtin. No effects on seedlings were seen at lower doses (1–200 ppm). Using turnip and barley seedlings no significant phytotoxicity was seen with 1–200 ppm azadirachtin (Stamatis, Allen, and Mordue (Luntz), unpublished data), although the dry weight of turnip seedlings 14 days post-treatment with 200 ppm azadirachtin was significantly lower than controls. Cell suspension cultures of *Agrostis stolonifera* when treated with azadirachtin at 150, 250, 500, and 1000 ppm during exponential growth showed significant loss in cell viability (measured as % viable cells in 10 μl cell suspension aliquots using fluorescein diacetate) within 2 h of treatment. The EC_{50} (concentration at which 50% of cells lost viability) at 2 h post-treatment was approximately 300 ppm (400 μM) (Stamatis, Zounos, Allen, and Mordue (Luntz), unpublished data).

6.4.4.4. Resistance

One of many advantages of the azadirachtin group of compounds in practical use is that development of resistance, which has become such a problem with single-compound synthetic pesticides, is delayed by use of the mixture. Resistance and desensitization can be avoided with the mixture of neem triterpenoids. Feng and Isman (1995) showed that the peach potato aphid *Myzus persicae* developed resistance to pure azadirachtin over 40 generations, but the same did not happen with neem seed extract. In another study with *Spodoptera litura* larvae on cabbage, the larvae became desensitized to pure azadirachtin in both choice and nonchoice tests, but did not desensitize to the seed extract, even

though the latter contained the same amount of azadirachtin (Bomford and Isman, 1996).

6.4.4.5. Systemic Action

The discovery by Gill and Lewis (1971) that azadirachtin was effective systemically was largely ignored for some years, but recently, that valuable aspect of its properties has again received attention. The uptake of azadirachtin from solution by cabbage leaves was demonstrated with the cabbage white butterfly *Pieris brassicae* (Arpaia and van Loon, 1993). Tobacco (*Nicotiana clevelandii*) seedlings also absorbed azadirachtin from solution through their roots and its subsequent translocation to leaves caused disturbances in the feeding behavior of the aphid *M. persicae*, resulting in a reduced ability of the aphids to acquire phloem-located viruses from infected seedlings (Nisbet *et al.*, 1993, 1996a). Sundaram *et al.* (1995) showed that neem extract watered around the roots of young aspen (*Populus tremuloides*) was taken up within 3 h and translocated to the stem and foliage within 3 days. Soil drenching of bean plants (*Phaseolus vulgaris*) with neem extract controlled the pea leaf miner *Lyriomyza huidobrensis* (Weintraub and Horowitz, 1997). More recently it has been shown that systemic dispersion of neem extract can be used to control *Ips pini* bark beetle in lodgepole pine (*Pinus contorta*) logs (Duthie-Holt *et al.*, 1999). No works appears to have been done to show whether all the azadirachtin-like compounds are translocated, or whether some more readily than others.

6.4.5. Antifeedant Effects of Azadirachtin

Azadirachtin has marked antifeedant activity against a large number of insect species, its effects being mediated through contact chemoreception (primary antifeedancy) and internal feedback mechanisms (secondary antifeedancy); the latter related to toxic effects on the gut, e.g., enzyme production, cell proliferation, and motility (Timmins and Reynolds, 1992; Nasiruddin and Mordue (Luntz), 1993a; Trumm and Dorn, 2000). Insects vary markedly in their behavioral sensitivity to azadirachtin. The desert locust *Schistocerca gregaria* and many species of Lepidoptera, are among the most sensitive, being deterred by as little as 0.007 ppm (in diets) whereas the Hemiptera and Coleoptera are much less sensitive with EC_{50} values of around 100 ppm or more (e.g., Isman, 1993; Mordue (Luntz) and Blackwell, 1993). Whereas *Schistocerca gregaria* prefers to starve to death rather than ingest azadirachtin, the primary antifeedant effect on aphids of azadirachtin applied systemically in plants occurs at levels far higher than those causing IGR and sterility effects (Lowery and Isman, 1993; Nisbet *et al.*, 1993, 1994; Mordue (Luntz) *et al.*, 1996). Hematophagous insects such as *Culex* mosquitoes are also less sensitive to the antifeedant effects of azadirachtin than to its IGR effects (Su and Mulla, 1998, 1999).

Whereas azadirachtin alone shows toxic IGR and sterilant actions against insects, several compounds in the plant biosynthetic pathway leading to azadirachtin have antifeedant effects against phytophagous insects (Aerts and Mordue (Luntz), 1997). The antifeedant role is an important phenomenon in the overall toxic effects of azadirachtin in those insects that are sensitive to it behaviorally and this phenomenon has been utilized in bioassays to explore the structure–activity relationships of the azadirachtin molecule. Both the decalin and the dihydrofuranacetal fragments of azadirachtin are important in eliciting antifeedant activity. Methylation of the hydroxy substitutions on the molecule and the addition of bulky groups to the dihydrofuran ring decrease antifeedant activity (Blaney *et al.*, 1990; Blaney and Simmonds, 1994; Govindachari *et al.*, 1995; Simmonds *et al.*, 1995).

The primary behavioral antifeedant response of insects to azadirachtin is mediated via neural input from the contact chemoreceptors. Inhibition of feeding behavior results from stimulation of deterrent receptors by azadirachtin often coupled with an inhibition of sugar receptors (Simmonds and Blaney, 1984). In *Spodoptera littoralis, Helicoverpa armigera*, and *H. assulta*, cells sensitive to sucrose and azadirachtin are mainly in the lateral sensillum styloconicum with azadirachtin evoking high impulse discharges (Simmonds *et al.*, 1995; Tang *et al.*, 2000). The firing of sucrose sensitive cells is reduced in the presence of azadirachtin and in some species the firing of the deterrent cells to azadirachtin is also reduced in the presence of sucrose (Simmonds and Blaney, 1996). This phenomenon, known as peripheral interaction, varies among insects and occurs in *S. littoralis* and *S. gregaria* but not in *L. migratoria* (Simmonds and Blaney, 1996). Investigations of the antifeedant mode of action by both electrophysiological recordings and behavioral analysis have shown that both polyphagous and oligophagous insects are behaviorally responsive to azadirachtin with the most responsive species being able to differentiate extremely small changes in the parent molecule (Blaney *et al.*, 1990, 1994; Nasiruddin and Mordue (Luntz), 1993b; Simmonds *et al.*, 1995). In Lepidoptera the antifeedant response is also correlated with increased neural activity of the chemoreceptors. A comparison of antifeedant

effects with physiological effects as measured by electrophysiological responses of taste receptors in lepidopteran larvae, antifeedant behavioral responses in locusts, and [^{3}H]dihydroazadirachtin-binding studies using insect cell lines and homogenates of locust testes is interesting. Results show that all of the effects are linked in terms of the potency of synthetic analogs of azadirachtin. This suggest a causal link between specific binding to membrane proteins and the ability of the azadirachtin molecule to exert biological effects (Mordue (Luntz) *et al.*, 1998).

6.4.6. Neuroendocrine Effects of Azadirachtin

6.4.6.1. Insect Growth Regulation

Over 400 species of insect to date have been shown to be susceptible to the neuroendocrine effects of azadirachtin, exhibiting the now classic symptoms of abnormal molts, larval–adult intermediates, mortality at ecdysis, and delayed molts, often resulting in greatly extended instar lengths. Many papers on a wide variety of insect taxa have allowed detailed descriptions of symptoms to be recorded that show consistency between all insects tested and an ED_{50} (effective dose for 50% of the population) of between 1 and 4 $\mu g\,g^{-1}$ bodyweight (Koul and Isman, 1991; Mordue (Luntz) and Blackwell, 1993; Mordue (Luntz) *et al.*, 1995; Riba *et al.*, 2003). In *O. fasciatus, Epilachna varivestis*, and *L. migratoria* complete molt inhibition has been shown, by radioimmunoassay, to be due to a blockage of ecdysteroid synthesis and release, a delay in appearance of the last ecdysteroid peak, and a slow, abnormal decline in this peak (Redfern *et al.*, 1982; Sieber and Rembold, 1983; Schlüter *et al.*, 1985; Mordue (Luntz) *et al.*, 1986). In *Rhodnius prolixus* a single dose of azadirachtin reduced hemolymph ecdysteroid titers to levels too low for induction of ecdysis (Garcia *et al.*, 1990). This blockage of ecdysteroid production is not due to a direct action of azadirachtin on the prothoracic glands (Koolman *et al.*, 1988) but is caused by two specific actions of azadirachtin. These actions are in the cascade of events leading from brain activation and competency to molt to 20-hydroxyecdysone (20E) production in the hemolymph and its effects on target tissues. First, the release of the morphogenetic brain peptide prothoracicotropic hormone (PTTH) responsible for inducing synthesis and release of ecdysone from the prothoracic glands is blocked in azadirachtin-treated insects. *In vitro* cultures of brain gland complexes or prothoracic glands of *Calliphora vicinia, Bombyx mori, Heliothis virescens*, or *Manduca sexta* in the presence of azadirachtin and PTTH will produce and release normal levels of ecdysone (Bidmon *et al.*, 1987; Pener *et al.*, 1988; Barnby and Klocke, 1990). However, decapitation and ligation experiments in *B. mori, R. prolixus*, and *Peridroma saucia* have shown that release of PTTH is deficient in azadirachtin-treated insects (Koul *et al.*, 1987; Garcia *et al.*, 1990; Koul and Isman, 1991). This deficiency is due to effects on the corpus cardiacum, in terms of release of PTTH and indeed other peptide hormones related to molting such as eclosion hormone or bursicon (Sieber and Rembold, 1983; Mordue (Luntz) *et al.*, 1986; Bidmon *et al.*, 1987; Rembold *et al.*, 1989). Staining of neurosecretion with paraldehyde fuchsin revealed a build-up of material in the corpora cardiaca and neuropilar areas of the brain neurosecretory system in *L. migratoria* (Subrahmanyam *et al.*, 1989).

Experiments on *L. migratoria* with [^{3}H]dihydroazadirachtin revealed heavy labeling within the corpora cardiaca but not in the brain beyond the neurilemma barrier membrane (Subrahmanyam *et al.*, 1989). This suggests, that azadirachtin directly affects the corpora cardiaca by inhibiting the release of hormones, perhaps by operating via effects on neurotransmitters such as acetylcholine, γ-aminobutyric acid (GABA), serotonin, and octopamine (Bidmon *et al.*, 1987; Käuser *et al.*, 1987; Koolman *et al.*, 1988; Banerjee and Rembold, 1992). Also through that axis, azadirachtin has been shown to slow down the rate of synthesis and transport of PTTH by the brain neurosecretory cells, for example in *H. virescens* (Barnaby and Klocke, 1990). Additionally, studies on the ultrastructure of the ring complex of *Lucilia cuprina* after azadirachtin treatment revealed degenerative structural changes of the nuclei of all endocrine glands (prothoracic glands, corpus allatum, corpus cardiacum), suggesting that effects at the transcriptional–translational level were the key to the generalized disruption of neuroendocrine function (Meurant *et al.*, 1994).

Second, in addition to the effect of azadirachtin on PTTH synthesis, transport, and release, azadirachtin has direct effects on the production of ecdysone 20-monooxygenase from the midgut and fat body; the insect cytochrome P450-dependent hydroxylase responsible for the conversion of ecdysone to its more active metabolite, 20E. In *C. vicinia, Drosophila melanogaster, Aedes aegypti*, and *M. sexta*, 20-monooxygenase levels were affected within 1 h of azadirachtin exposure at levels varying between 10^{-4} and 10^{-5} M azadirachtin

(Bidmon *et al.*, 1987; Smith and Mitchell, 1988; Mitchell *et al.*, 1997). Such effects are also clearly demonstrated in *Tenebrio molitor* pupae where ecdysone hemolymph levels were shown to remain relatively constant after azadirachtin treatment (1 µg per insect), whereas there was a highly significant depletion of immunoreactive ecdysteroids (Marco *et al.*, 1990). Variations in successful recovery of development by treatment with exogenous 20E (Pener *et al.*, 1988; Barnby and Klocke, 1990; Marco *et al.*, 1990) support the fact that different target sites for azadirachtin exist and are manifested during growth and molting processes at different times.

In parallel with molting hormone deficiencies in azadirachtin-treated insects, changes in JH also play a significant role in the overall syndrome of azadirachtin poisoning at the molt. That JH hemolymph titers are reduced or delayed is demonstrated in a variety of ways. Azadirachtin inhibits JH-stimulated supernumerary molts in chilled *Galleria mellonella* larvae (Malczewska *et al.*, 1988) perhaps by a blockage of synthesis and release of JH. In the last instar larvae of *M. sexta*, azadirachtin causes supernumerary molts by delaying and extending the JH peak into the critical period for commitment to larval rather than pupal cuticle (Schlüter *et al.*, 1985; Beckage *et al.*, 1988). The importance of timing of hemolymph JH levels with ecdysteroid levels is demonstrated by the selective destruction of larval crochets or hooked setae on the prolegs in *M. sexta* (Reynolds and Wing, 1986; Beckage *et al.*, 1988). The epidermal cells producing such structures require the presence of both ecdysteroids and JH in order to make cuticle and in the absence of JH (e.g., on day 2 of the last larval instar) (Riddiford, 1981) the epidermis loses this ability. Other examples of an imbalance in the presence or absence of ecdysteroid and JH levels are seen in the occurrence of uneverted tanned pupal wing discs in *E. varivestis* (Schlüter, 1987), effects linked with high JH titers such as green hemolymph, brown and green cuticle, lack of black pigment, and supernumerary molts in locusts, *S. littoralis*, and *G. mellonella* (Schmutterer and Freres, 1990; Nicol and Schmutterer, 1991; von Friesewinkel and Schmutterer, 1991; Gelbic and Némec, 2001) and cuticular melanization resulting in black spots related to the absence of JH and low levels of ecdysteroids (Hori *et al.*, 1984; Koul *et al.*, 1987; Malczewska *et al.*, 1988).

It is of interest that azadirachtin potentiates the action of the ecdysteroid agonist RH-2485 in *S. littoralis* (Adel and Sehnal, 2000). There was no effect of azadirachtin on the hyperecdysonic action of high concentrations of diacylhydrazine RH-2485 to induce precocious molting (immediate and fatal molts) thus substantiating the view that azadirachtin does not bind to epidermal ecdysteroid receptors (Koolman *et al.*, 1988). However, azadirachtin was shown to potentiate supernumerary molts in early instar larvae of *S. littoralis* treated with low concentrations of RH-2485, perhaps explained by a slow decline in hemolymph JH levels. Azadirachtin also shows synergy with RH-2485 with regard to deaths at the molt and sterility (Adel and Sehnal, 2000).

6.4.6.2. Reproduction

Adverse effects of azadirachtin on ovarian and testes development, fecundity, and fertility are an important component of overall toxicity and insect control (Karnavar, 1987; Mordue (Luntz) and Blackwell, 1993; Mordue (Luntz), 2000). Sterility effects in females due to interference with vitellogenin synthesis and its uptake into oocytes has been demonstrated in many insects including *L. migratoria*, *O. fasciatus*, *S. exempta*, and *R. prolixus* (Rembold and Sieber, 1981; Dorn *et al.*, 1987; Feder *et al.*, 1988; Tanzubil and McCaffery, 1990). Reduced fecundity has been recorded in the fruit fly *Ceratitis capitata*, the leaf miner *Liriomyza trifolii*, peach potato aphid *Myzus persicae*, *S. exempta, S. littoralis*, and the southern green stink bug, *Nezara viridula* (Parkman and Pienkowski, 1990; Stark *et al.*, 1990; Tanzubil and McCaffrey, 1990; Nisbet *et al.*, 1994; Adel and Sehnal, 2000; Riba *et al.*, 2003); such fertility effects relate to resorption of yolk proteins in developing eggs (Rembold and Sieber, 1981) and lower viability of emerging larvae after treatment of the parental generation (Tanzubil and McCaffery, 1990). In males, fertility reduction is seen in a reduced potency in *O. fasciatus* (Dorn, 1986), a degeneration of spermatocytes in *Mamestra brassicae* (Shimizu, 1988) and blocked cell division in developing spermatocytes in *L. migratoria* leading to significantly smaller mature testes (Linton *et al.*, 1997).

The endocrine events causing reproductive malfunction are very similar to those seen with growth and molting and relate to disruptions in ecdysteroid production by the ovaries and in JH levels in the hemolymph. The latter are most probably caused by alterations to the brain neurosecretory peptides, the allatostatins and allatotropins that control synthesis and release of JH.

Whether production of JH esterase levels, controlling JH catabolism, is affected by azadirachtin is not yet known. In adult female *L. migratoria* ecdysteroid synthesis by the ovaries, together with oogenesis, is inhibited by 10 µg azadirachtin per insect (Rembold and Sieber, 1981), and JH titers

are decreased (Rembold *et al.*, 1986), these effects being associated with an accumulation of neurosecretory material in the corpora cardiaca and brain (Subrahmanyam *et al.*, 1989). In *R. prolixus* reduction in oocyte growth and egg production are caused also by reduced ecdysteroid levels in hemolymph and ovaries (Feder *et al.*, 1988; Garcia *et al.*, 1991). In the cotton stainer bug *Dysdercus koenigii* and the peach potato aphid *Myzus persicae* azadirachtin applied topically or in the diet inhibits and delays embryogenesis, resulting either in many of the embryos remaining at a late stage of development or in the viviparous aphid being born dead with undeveloped appendages (Koul, 1984; Nisbet *et al.*, 1994). It is thought that JH control of embryogenesis and the rate of development of embryos in aphids are important here.

In adult female earwigs, *Labidura riparia*, azadirachtin has been shown to have marked cytological effects on ovaries resulting in severely reduced ovarian development. Due to cyclical reproductive changes in *L. riparia* throughout adult life, relating to the production of eggs (vitellogenesis) and a nonvitellogenic period when the female cares for her eggs, there was the possibility of investigating the specific role of azadirachtin in vitellogenesis control. In this insect JH controls both vitellogenin production in the fat body and stimulates vitellogenin uptake by the ovaries. In addition, ovarian ecdysteroids play a role in vitellogenesis and, at the peak of production, oviposition. They also provide a feedback loop to the brain pars lateralis neurosecretory cells causing release of allatostatins, which block JH synthesis and release enabling successive follicle degenerations during the nonvitellogenic period. Azadirachtin treatment blocks vitellogenesis and corpus allatum activity as seen by ultrastructural studies and concomitantly increases allatostatin build-up in the pars lateralis as measured by antibodies to allatostatin 3 (*Blattella germanica* BLAST-3) (Sayah *et al.*, 1996, 1998). This phenomenon together with the fact that JH treatment rescues the effect of azadirachtin on vitellogenesis suggest that azadirachtin affects those peptides controlling corpus allatum activity in a similar manner to the azadirachtin effects on PTTH and hence ecdysone production during the molt.

Two major conclusions can be drawn regarding the mode of action of azadirachtin on neuroendocrine activity in insects during the molt and reproductive development. First, in both molting and sterility, the processes of synthesis, transport, and release of morphogenetic peptide hormones in the brain are at the center of the mode of action of azadirachtin. Second, in the molt (but not yet proved during reproductive development) the production of important enzymes for controlling hemolymph levels of active hormones (20-hydroxymonooxygenase levels that convert ecdysone to 20E) are inhibited by azadirachtin.

6.4.7. Studies on the Mode of Action of Azadirachtin

6.4.7.1. Studies using Insect Cell Lines

The analysis of direct cytological effects of azadirachtin in whole insects, or even in isolated insect tissues, is complicated by the multiplicity of physiological consequences resulting from the compound (see Section 6.4.6). This complexity has been addressed by analyzing the pharmacology of azadirachtin uptake and binding in cultured *S. frugiperda* Sf9 cells (derived from pupal ovarian tissue) and *D. melanogaster* Kc167 cells (derived from embryonic cells). Such cells rapidly accumulate [^{3}H]azadirachtin from culture medium and are enriched with binding sites compared with many tissue extracts derived from whole insects (Nisbet *et al.*, 1995, 1997; Mordue (Luntz) *et al.*, 1999; Mordue (Luntz), 2002; Robertson, 2004). The effects of azadirachtin on the proliferation and cell cycle events in these cells (Rembold and Annadurai, 1993; Salehzadeh *et al.*, 2002, 2003; Robertson, 2004), accompanied by the above binding studies have given detailed insights into the mode of action of the compound.

Initial studies examining the effects of azadirachtin on the proliferation of Sf9 cells used relatively high concentrations (1 μM) in the culture medium to produce profound effects on cell proliferation (Rembold and Annadurai, 1993; Mordue (Luntz) and Nisbet, 2000). Robertson (2004) has also shown significant reductions in the number of viable cells using the trypan blue exclusion assay within 48 h of treatment with 1 μM azadirachtin for both Sf9 and Kc167 cells. In addition to this effect on cell proliferation, azadirachtin evoked a characteristic cytotoxic effect on cultured cells. Reed and Majumdar (1998) used azadirachtin concentrations of about 0.1 μM in cell culture to demonstrate increases in cell volume, blebbings, blisters, and holes in cell membranes resulting in cytoplasmic extrusions. Since these studies much more refined work has been carried out to discover where in the cell azadirachtin is acting and at what concentration.

6.4.7.2. Effects on Cell Cycle Events

The effects of azadirachtin in blocking cell division have already been established in whole tissues such

as imaginal wing discs of *E. varivestis* (Schlüter, 1985, 1987) and in locust testes, where meiosis was blocked at prometaphase I (Linton *et al*., 1997). Salehzadeh *et al*. (2002) examined the effects of azadirachtin on the proliferation of Sf9 cells using dehydrogenase activity to estimate cell numbers and found an EC_{50} of 0.15 nM after 96 h incubation. Cell proliferation studies using [^{3}H]thymidine uptake during cell division revealed also an inhibition of mitosis in Sf9 cells 24 h post-treatment with an EC_{50} value of 1.5 nM azadirachtin (Robertson, 2004). This nuclear effect was confirmed by Comet assays that directly measure DNA damage. Significant damage was revealed in Sf9 cells within 6 h of treatment; with an EC_{50} value of 5 nM (Robertson, 2004). The reduction in proliferation was related to a time- and concentration-dependent antimitotic effect of azadirachtin on the cells, with concentrations between 10 nM and 5 μM causing the accumulation of mitotic figures, incomplete mitosis, cytokinesis, and an increased proportion of the cells in the G_2/M phase of the cell cycle (Salehzadeh *et al*., 2003). The "G_2" (GAP2) and the "M" (mitosis) stages occur after DNA synthesis and are the stages when the chromosomes separate and cytoplasmic division occurs. These events are dependent upon multiple cellular processes, including the synthesis and functioning of microtubules; a number of compounds (e.g., colchicine) interfere with these processes and inhibit mitosis. Azadirachtin and colchicine inhibit the cell cycle at similar points, an observation that encouraged Salehzadeh *et al*. (2003) to examine the ability of azadirachtin to prevent colchicine-flouroscein from binding to cells previously incubated for 4 h with 10 μM azadirachtin. A 45% reduction in fluorescence was recorded in azadirachtin-treated cells. This led to the conclusion that azadirachtin was binding either directly to tubulin or causing conformational changes that prevented colchicine binding (Salehzadeh *et al*., 2003). While [^{3}H]dihydroazadirachtin is rapidly incorporated by Sf9 cells and binds to the nuclei, it does so in a highly specific, high-affinity, saturable, and essentially irreversible manner (Nisbet *et al*., 1997). Based on these kinetic data, saturation of the azadirachtin-binding element of Sf9 cells requires much lower concentrations or shorter incubation times than 10 μM for 4 h. Thus, it seems unlikely that colchicine and azadirachtin share the same binding site in Sf9 cells; see Schlüter (1987) for a similar conclusion in wing bud development of *E. varivestis* and Billker *et al*. (2002) in microgametogenesis of *Plasmodium berghei*. An alternative explanation for the reduction in colchicine labeling in azadirachtin-treated cells is that the concentration of azadirachtin used, 10 μM, caused cytotoxic damage and reduced the availability of colchicine-binding sites.

6.4.7.3. Binding Studies

There is clearly substantial evidence to show that azadirachtin inhibits cell proliferation in Sf9 cells and that it does so by inhibiting mitotic events that rely on the correct synthesis and assembly of microtubules. [^{3}H]dihydroazadirachtin binds to the nuclei of Sf9 cells (Nisbet *et al*., 1997) and to fractions of homogenates of locust testes with very similar binding properties (Nisbet *et al*., 1995; Mordue (Luntz) *et al*., 1999). The binding sites on locust testes were determined by microautoradiography (Nisbet *et al*., 1996b) and shown to be associated with developing sperm tails, i.e., a region of intense microtubule synthesis. In addition azadirachtin interferes with spermatogenic meiosis in locust testes, arresting meiosis at metaphase I (Linton *et al*., 1997), an effect that could be due to disruption in microtubule synthesis and assembly. Treatment of homogenates of locus testes with nocodazole, which disrupts polymerized microtubules, or prolonged cold-stirring in buffers to promote microtubule depolymerization failed to reduce the binding of [^{3}H]dihydroazadirachtin (Nisbet *et al*., unpublished data).

In systems other than insect cell lines there is good evidence that azadirachtin interferes with microtubule function. In the malarial parasite *P. berghei* azadirachtin does not interfere with the assembly of microtubules during microgametogenesis but confocal laser microscopy and transmission electron microscopy have shown that the formation of mitotic spindles and axonemes was disrupted, i.e., the patterning of microtubules into more complex structures (Billker *et al*., 2002).

In the absence of a good insect cell model for analyzing protein secretion, mammalian cell lines have been used to attempt to understand a possible link between the effects of azadirachtin on protein synthesis, microtubule assembly, and secretory events. Incubation of mouse mammary acini with 0.5 mM azadirachtin reduced overall protein synthesis by about 75% but failed to prevent the secretion of [^{35}S]methionine-labeled proteins in pulse-chase experiments (Nisbet *et al*., unpublished data). The secretion of proteinaceous vesicles from murine mammary epithelial cells is dependent upon the structural integrity of a microtubular network and the existence of tubulins in their polymerized forms. In contrast to the lack of effect of azadirachtin on protein secretion, colchicine and nocodazole treatments of these cells disrupted microtubule assembly and

inhibited protein secretion (Patton, 1974; Rennison *et al.*, 1992). Salehzadeh *et al.* (2003) prepared tubulin from pig brains and repolymerized the protein *in vitro* in the presence of 0.1 mM azadirachtin, but this treatment only reduced polymerization by about 20%. In addition, tubulin and repolymerized microtubules prepared from sheep brains failed to specifically bind [^{3}H]dihydroazadirachtin *in vitro* (Nisbet *et al.*, unpublished data).

6.4.7.4. Effects on Protein Synthesis

Azadirachtin directly inhibits protein synthesis in a variety of tissues where cells are producing enzymes: midgut cells producing trypsin (Timmins and Reynolds, 1992), midgut and fat body cells producing 20-monooxygenases for ecdysone catabolism (Bidmon *et al.*, 1987; Smith and Mitchell, 1988), and midgut and fat body cells producing detoxification enzymes in insecticide-resistant insects (Lowery and Smirle, 2000). These effects in whole insects are seen also in insect cell lines where both cell division and protein synthesis are inhibited in a dose-dependent manner. Using *S. gregaria* injected with azadirachtin, Annadurai and Rembold (1993) were able to study polypeptide profiles of brain, corpora cardiaca, subesophageal ganglion, and hemolymph using high-resolution two-dimensional gel electrophoresis. Using Sf9 cells Robertson (2004) also carried out polypeptide separation with two-dimensional gels with spot analysis by hierarchical and K means clustering. Both groups concluded that differential effects on protein synthesis occurred although overall protein synthesis was reduced. Robertson (2004) showed that in Sf9 cells out of 381 protein spots 52.2% were decreased significantly in intensity, 28.9% were increased in size, and 18.9% were unchanged.

6.4.7.5. Studies Using Mammalian Cell Lines

Azadirachtin is not effective against mammalian cells (measured as effects on proliferation, direct toxicity, and morphological alterations, e.g., micronucleation) until concentrations above 10 μM are reached (Reed *et al.*, 1998; Akudugu *et al.*, 2001; Salehzadeh *et al.*, 2002; Robertson, 2004). On cultured rat dorsal root ganglion neurons, neuronal excitability was altered by modulation of potassium conductances, but only after azadirachtin treatment at 10 μM or higher (Scott *et al.*, 1999). In contrast, the EC_{50} for the effect of the compound on the viability of insect cells (Sf9) *in vitro* is several orders of magnitude lower than that for mammalian cell lines, e.g., 150 pM for Sf9 cells, >10 μM for mouse L929 cells (Salehzadeh *et al.*, 2002). Using mammalian cell lines to investigate azadirachtin mode of action it was shown that azadirachtin inhibited protein synthesis in mouse mammary cells at concentrations above 100 μM but had no effects on protein secretion from these cells (Nisbet *et al.*, unpublished data). Cytosolic concentrations of Ca^{2+} in mouse mammary cells were unaffected by the presence of 500 μM azadirachtin. It is therefore apparent that azadirachtin does not inhibit protein synthesis in mammalian cells as a secondary effect of instantaneous mobilization of calcium stores from the endoplasmic reticulum, as has been demonstrated for other protein synthesis inhibitors, e.g., vasopressin (Reilly *et al.*, 1998), arachidonate, carbachol, or 1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid tetra(acetoxy-methyl) ester (BAPTA/AM) (Wong *et al.*, 1993). It is also clear from the lack of effect on resting calcium levels or protein secretion that azadirachtin does not induce reductions in protein synthesis through general toxicity or structural cellular damage and that the molecule may interfere with a specific cellular event involved in protein synthesis.

6.4.7.6. Resolving the Mode of Action of Azadirachtin

It would appear from current knowledge that azadirachtin may have more than one mode of action. First, it alters or prevents the formation of new assemblages of organelles or cytoskeleton resulting in the disruption of cell division, blocked transport and release of neurosecretory peptides, and inhibition of spermatozoa formation. Second, it inhibits protein synthesis in cells that are metabolically active and have been switched on to produce large amounts of protein such as digestive enzymes by midgut cells, cultured cells with high rates of proliferation, or cell production of mixed function oxidases for detoxification of xenobiotics. At the molecular level azadirachtin may act by altering or preventing transcription or translation of proteins expressed at particular stages of the cell cycle. Future work to elucidate this novel mode of action must now concentrate on the characterization and identification of binding sites using proteomic, microarray, and differential display techniques.

The mode of action of azadirachtin is unlikely to be resolved through the use of mammalian cell lines or proteins. The differences between homologous proteins in mammals and insects may in fact be the key to the specificity of azadirachtin. The use of modern protein purification and production methods should assist in resolving this question. The rapidly expanding range of proteomic tools available for synthesizing short peptides or recombinant polypeptides (e.g., phage display) could pro-

vide a high-throughput method of determining the amino acid residues and conformation required for azadirachtin binding, giving leads to the identity of the binding protein in insects.

Azadirachtin has profound effects on protein synthesis in insect cells and tissues and its antimitotic actions may result from the absence of proteins involved directly in microtubule assembly and function, or proteins involved in posttranslation modifications of these elements (e.g., protein kinases and phosphatases). Thorough stepwise analysis of the protein profile of cells treated with azadirachtin is possible by two-dimensional electrophoresis, such as in the studies initiated by Robertson (2004). This will provide valuable information on the time course of the effects of azadirachtin on the synthesis of individual proteins and even on the posttranslational modification of proteins. Modern molecular techniques to investigate the effects of azadirachtin on gene transcription will be invaluable to investigate this phenomenon. Differential gene expression in azadirachtin-treated cells at time points after treatment could be investigated using RNA arbitrarily primed-polymerase chain reaction (RAP-PCR) or cDNA subtraction to give an indication of which genes are upregulated or downregulated early in the process of the cytotoxic action of azadirachtin. With the advent of high-throughput expressed sequence tag (EST) sequencing and microarray analysis, EST databases could be generated from untreated insect cell lines, printed on microarrays, and hybridized with cDNA derived from treated and untreated cell lines over a wide range of time points after treatment. Ideally, these time-course analyses would be performed in azadirachtin-susceptible *Drosophila* cell lines (Robertson 2004; Mordue, Dhadialla, and Mordue (Luntz), unpublished data), to take advantage of the availability of the full annotated genome for this organism rather than attempting to determine homology with genes from Sf9 cells for example. Recent work has identified a putative Azadirachtin binding proteins with an apparent molecular mass of 591 kD. The protein was identified, by native polyacrylamide gel electrophoresis ligand overlay blots, in nuclear protein extracts from *Drosophila* KC167 cells using BSA-conjugated azadirachtin as a ligand (S.L. Robertson, T.S. Dhandialla, N. Weiting, S.V. Ley, W. Mordue, A.J. Mordue (Luntz), unpublished data).

6.5 The Spinosyns: Chemistry, Biochemistry, Mode of Action, and Resistance

V L Salgado, Bayer CropScience AG, Monheim, Germany
T C Sparks, Dow AgroSciences, Indianapolis, IN, USA

6.5.1. Introduction

The spinosyns and associated spinosoids (semisynthetic analogs of the spinosyns) constitute a new and unique class of insect control agents. The spinosyns are fermentation-derived natural products that are chemically unique (Figure 1). In addition to their unique chemical structure, the spinosyns possess a novel mode of action coupled with an insecticidal efficacy on par with many pyrethroid insecticides, plus a very favorable toxicological profile (Bret *et al*., 1997; Sparks *et al*., 1999). Thus, the spinosyns exhibit many highly desirable attributes for an insect control agent.

The first commercial product, spinosad, was launched in 1997. An extensive discovery effort followed the initial isolation and identification of the first spinosyns. This effort led to the identification of an array of naturally produced spinosyns, as well as a variety of semi-synthetic analogs; the spinosoids.

In this chapter attempts are made to bring together aspects of the discovery of the spinosyns and spinosoids, their chemistry, biology, mode of action, structure–activity relationships, and resistance management. The reader is also referred to several reviews (Crouse *et al*., 1999; Sparks *et al*., 1999; Anzeveno and Green, 2002; Kirst *et al*., 2002b).

6.5.2. Discovery, Structure, and Biosynthesis of the Spinosyns

Among insecticidal insect control agents, natural products have in numerous instances become products or have been the model or inspiration for insecticidal products. At the very least, virtually all significant classes of insect control agents, including

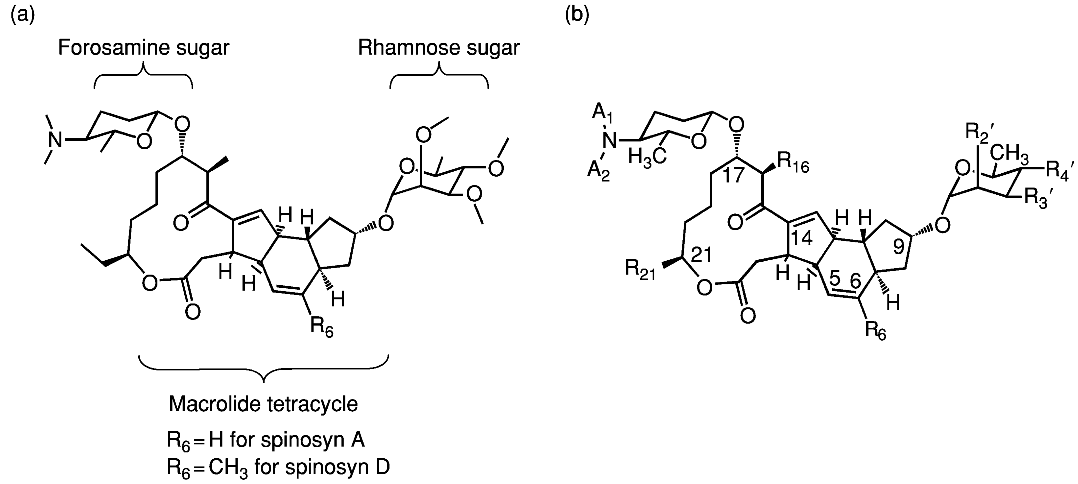

Figure 1 Structures of spinosad and spinosyns/spinosoids.

the organophosphates, carbamates, pyrethroids, neonicotinoids, and many others, can point to a model that exists among nature's chemical laboratory (Addor, 1995). As such, natural products have been and remain a very valuable source of inspiration for the discovery of new insect control agents, thereby providing a source of models, leads, and in some cases the insecticidal products.

There are two key elements to an effective natural products discovery program. The first is new, novel sources of natural products. The second is availability of new bioassays or approaches to screen or filter the natural products and their extracts. Many natural product discovery programs use the same source material coupled with new growth media, new extraction conditions, etc. Thus, new bioassays are central to the exploitation of these existing natural product libraries and hence, the discovery of new insecticidal natural products.

6.5.2.1. The Spinosyns

During the 1980s Lilly Research Laboratories had a program designed to look for rare and unique actinomycetes that were then fed into a whole series of biological screens. In late 1983 a new mosquito larvicide bioassay using early stadium *Aedes aegypti* larvae in 96-well microtiter plates was added to these biological screens. Because of the high throughput and small amount of material needed, a large number of broths could be screened at high sensitivity. An extract from a microorganism cultured from a soil sample collected in the Caribbean was found to be active in this assay (Thompson *et al.*, 1997). Refermentations of the sample (A83543) were active in subsequent mosquito bioassays, but it became of real interest when it showed contact and antifeedant activity against larvae of the southern armyworm (*Spodoptera eridania*) in a plant-based assay, coupled with little activity on spider mites (*Tetranychus urticae*), aphids (*Aphis gossypii*), or corn rootworm (*Diabrotica undecimpunctata*), thus demonstrating some inherent selectivity – a rare occurrence (Thompson *et al.*, 1997). Characterization of the microorganism showed it to be a new species of actinomycete from an unusual genus, *Saccharopolysopra spinosa* (Mertz and Yao, 1990).

From extracts of *S. spinosa*, a series of related A83543 factors, later named "spinosyns," were identified. The spinosyns were found to consist of two sugars, forosamine and 2′,3′,4′-tri-*O*-methylrhamnose, attached to a unique tetracyclic ring system containing a 12-member macrocycle (**Figure 1**). Among macrocyclic lactones, the spinosyns are unique (Kirst *et al.*, 1992; Shomi and Omura, 2002), possessing a structure that is truly novel among insect control agents. Other naturally occurring insecticidal macrocyclic lactones are known (e.g., avermectins, milbemycins), but these are based on entirely different 14-member macrocycles, with modes of action and activity spectra distinct from those of the spinosyns.

As observed with many natural products, the parent (wild type, WT) strain of *S. spinosa* produces a family of closely related spinosyns, which vary in methyl substitution patterns on the forosamine nitrogen, the 2′- and 3′-positions of the rhamnose, and at the C6, C16, and C21 positions of the tetracycle (Kirst *et al.*, 1992) (**Table 1**). The spinosyns produced from the parent strain included spinosyns A–H and J (I was not assigned) (**Table 1**).

Within this mixture, the two major components produced are spinosyn A (primary) and spinosyn D (secondary). An extract of the fermentation broth

containing this naturally occurring mixture is known as spinosad, the active ingredient in a number of products (Tracer®, Success®, SpinTor®, Conserve®) marketed by Dow AgroSciences for insect control. Spinosad received registration from the US Environmental Protection Agency (EPA) for use in cotton insect control in February 1997. As discussed below (see Section 6.5.5.1.1.1), spinosyn A is the most active of the naturally occurring spinosyns from *S. spinosa*, followed closely by spinosyn D (Table 2). Thus, the most insecticidally active naturally occurring spinosyns produced by *S. spinosa* are also those that the microorganism naturally produces in the largest quantity.

Further research around the spinosyns required the availability of significant quantities of material. Because the wild-type parent strain only produced very small quantities of spinosyns, a strain improvement program was instituted to increase the titers of the spinosyns produced. During the process of strain improvement, a number of mutant strains were identified that had nonfunctional 2′- and/or 3′- and/or 4′-*O*-methyltransferases. Since these mutants were unable to methylate the hydroxyl groups on the 2′-, 3′-, or 4′-positions of the tri-*O*-methylrhamnose, a variety of new spinosyns were produced in addition to a few spinosyns seen only as minor factors in the wild-type strain (Sparks *et al.*, 1996, 1999).

The mutant strain possessing a nonfunctional 2′-*O*-methyltransferase produced the already existing spinosyn H (2′-*O*-demethyl analog of spinosyns A) as well as several new spinosyns: Q (2′-*O*-demethyl analog of spinosyn D), R (2′-*O*-demethyl analog of spinosyn B), S (2′-*O*-demethyl analog of spinosyn E), and T (2′-*O*-demethyl analog of spinosyn J). Likewise, a mutant with a nonfunctional 3′-*O*-methyltransferase produced spinosyn J (3′-*O*-demethyl analog of spinosyn A), a minor factor in the wild-type strain, along with the new spinosyns: M (3′-*O*-demethyl analog of spinosyn B), L (3′-*O*-demethyl analog of spinosyn D), and N (the 4′-*N*-demethyl analog of spinosyn L). The mutant possessing a nonfunctional 4′-*O*-methyltransferase produced three new spinosyns: K (4′-*O*-demethyl analog of spinosyn A), O (the 4′-*O*-demethyl analog of spinosyn D), and Y (the 4′-*O*-demethyl analog of spinosyn E) (Sparks *et al.*, 1996, 1999).

Further variations in the methylation of the rhamnose sugar could also be obtained by the addition of sinefungin (Chen *et al.*, 1989), which in *S. spinosa* specifically blocked the 4′-O-methyltransferase during the fermentation process of the wild-type strain (Sparks *et al.*, 1996, 1999). When sinefungin was added to fermentations of the H (nonfunctional 2′-*O*-methyltranferase) and J (nonfunctional 3′-*O*-methyltranferase) mutant strains, several other new spinosyns (P, U, V, W) were produced that were missing methyl groups from the 4′-position in combination with missing methyl groups from either the 2′- or 3′-positions (Sparks *et al.*, 1996, 1999).

In general, the variations in all of the above-mentioned spinosyns center around (1) methylation of the forosamine amino group, (2) presence or absence of *O*-methyl groups on the rhamnose sugar, and (3) presence or absence of alkyl group(s) at the C6, C16, and C21 positions of the tetracyclic ring system. Other factors related to spinosyn A include the C17 pseudoaglycone (PSA), which lacks the forosamine sugar, the corresponding C9 PSA, missing the rhamnose moiety, and the aglycone, where both sugars are absent. The corresponding PSAs and aglycone were also observed for spinosyn D (**Table 1**).

Through the above process of isolating major and minor factors from the wild-type and mutant strains of *S. spinosoa*, more than 20 different spinosyns were identified (Sparks *et al.*, 1996, 1999) (**Table 1**).

6.5.2.2. The 21-Butenyl Spinosyns

Like Eli Lilly and Company, Dow AgroSciences has also had a long-standing natural products screening program. During the mid-1990s a high-throughput

screening (HTS) program was established that used a number of target insect pests including lepidopterous larvae, such as beet armyworm (*Spodoptera exigua*), in a 96-well format, as the primary natural products screening tool. This was accompanied by a number of secondary assays to further characterize extracts that were found to be active in the primary screen. One particular multiyear effort, to screen a very large number and variety of actinomycete broth extracts, relied on a novel bioassay as the secondary assay. From this screening effort an extract was found that was not only active in the primary diet-based screen, but that, on further testing, also exhibited interesting contact activity coupled with symptomology that was very reminiscent of the spinosyns. Further separation and isolation coupled to detailed physical characterization (nuclear magnetic resonance (NMR), liquid chromatography–mass spectroscopy (LC–MS), etc.) of this extract showed that the activity was indeed due to a spinosyn-like entity (Lewer *et al*., 2001, 2003). However, there were some structural differences relative to the then known spinosyns. The dominant, distinctive feature was the presence of a 2-butenyl group at the C21 position of the macrocyclic ring system in place of the heretofore typical ethyl-group of the spinosyns (Lewer *et al*., 2003) (**Figure 2**). The primary factor isolated from the mixture of 21-butenyl factors was the 21-butenyl homolog of spinosyn A (**Figures 1** and **2**, **Table 1**). To date more than 30 additional factors have been isolated, identified, and characterized (Lewer *et al*., 2003). These 21-butenyl spinosyns constitute a new family of spinosyns, for which research on the isolation, characterization, and chemistry is continuing (Crouse *et al*., 2002). Characterization of the microorganism that produces the 21-butenyl spinosyns showed it to be a new species of *Saccharopolyspora* closely related to, but distinct from, *S. spinosa*, which has been named *Saccharopolysopra pogona* (Lewer *et al*., 2003).

6.5.2.3. Spinosyn Biosynthesis

The spinosyns are 12-member macrocyclic lactones (macrolides). Based on incorporation studies using ^{13}C-labeled acetate, propionate, butyrate, and isobutyrate, the biosynthesis of the tetracycle of the spinosyns is consistent with a polyketide synthase-based (PKS) pathway (Kirst *et al*., 1992). As a macrolide, the spinosyns differ from the norm in that the spinosyn PKS pathway ultimately leads to the introduction of three intramolecular carbon–carbon bonds to form the spinosyn tetracycle (Waldron *et al*., 2001) (**Figure 3**). To this tetracycle a neutral sugar, rhamnose, is coupled at the C9 position, and then subsequently methylated via three O-methyltransferases. The final steps involve the addition of an amino sugar to the tetracycle at the C17 position. The amino sugar, forosamine, is also methylated prior to attachment to the spinosyn tetracycle – in this case at both positions of the nitrogen (Kirst *et al*., 1992; Waldron *et al*., 2000, 2001) (**Figure 3**).

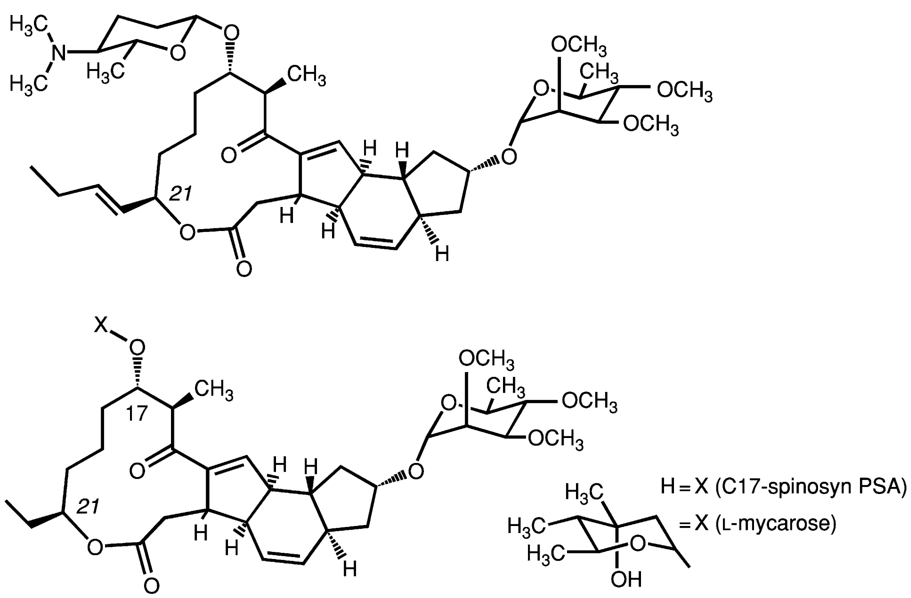

Figure 2 Structures for 21-butenyl spinosyn A (top), the spinosyn A C17-pseudoaglycone (PSA, bottom; X = H) and the C17 L-mycarose biotransformation product.

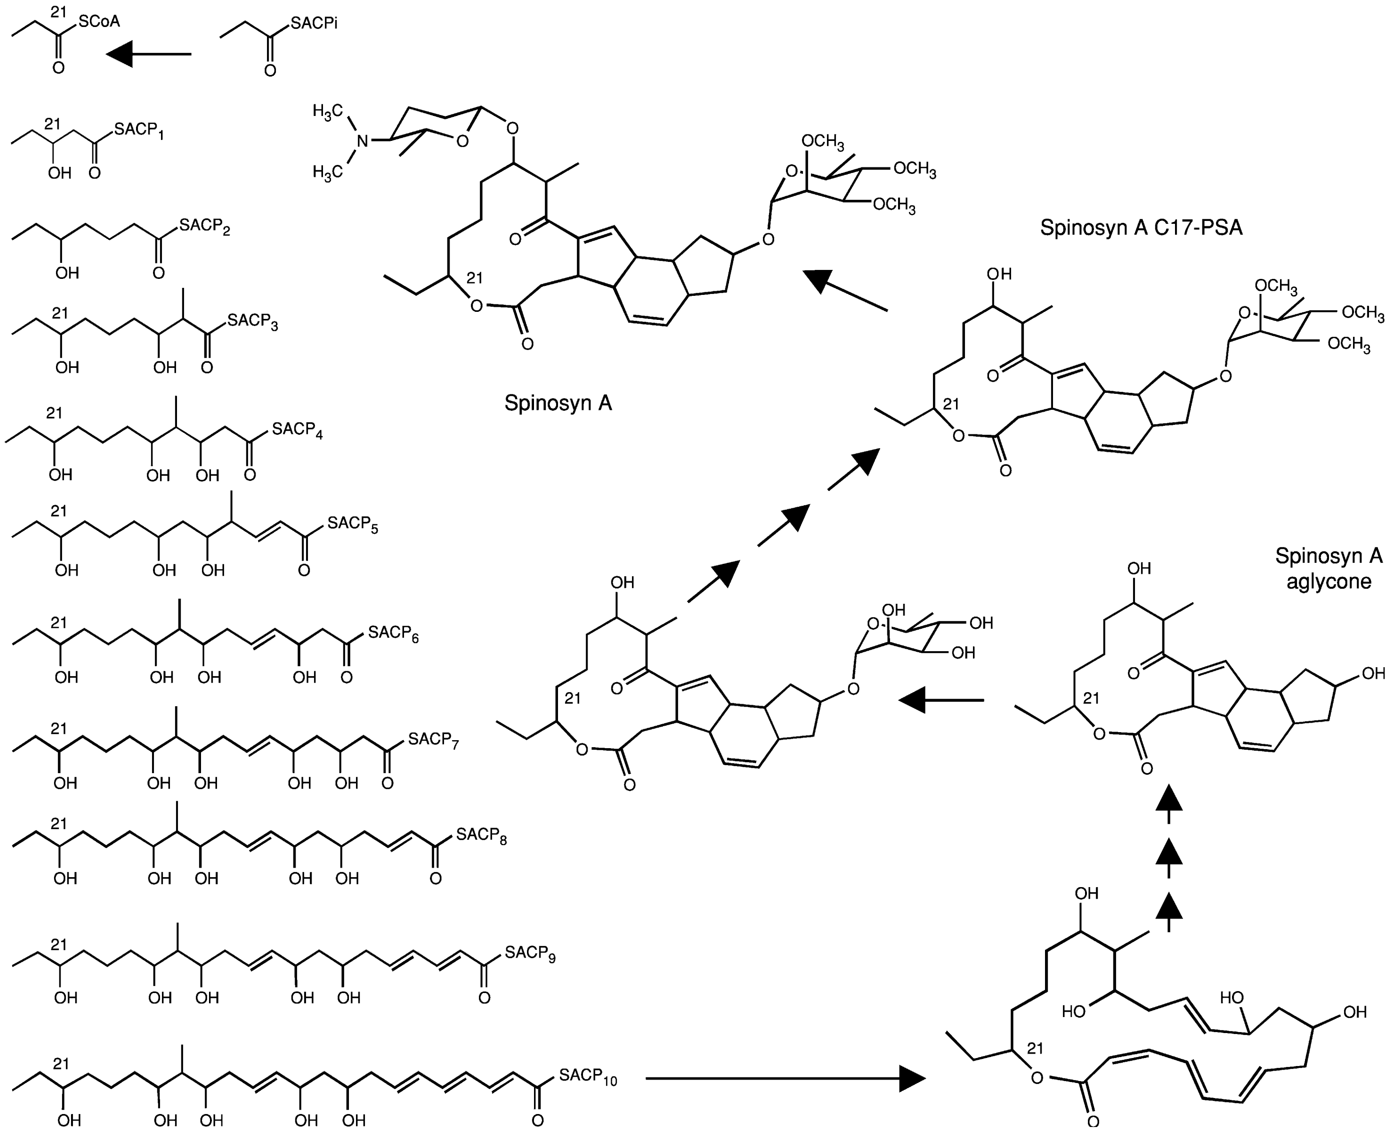
A large synthetic effort has gone into the modification of the forosamine and rhamnose moieties, as well as the core tetracycle (Crouse and Sparks, 1998; Crouse *et al*., 2001; Anzeveno and Green, 2002; Kirst *et al*., 2002b) (see Section 6.5.7). However, other approaches to macrolide modification are now possible. Sequencing the genes involved in spinosyn biosynthesis (Waldron *et al*., 2000, 2001; Madduri *et al*., 2001) has allowed the production of novel spinosyns through biotransformation and modification of the biosynthetic pathways. For example, a genetically engineered strain of *Saccharopolyspora erythraea* expressing the *spnP* glycosyltransferase gene was used to produce biotransformed spinosyns, wherein the β-D-forosamine moiety was replaced by α-L-mycarose at the C17 position (Gaisser *et al*., 2002). Alternatively, modifications to the basic tetracycle have been obtained via loading module swaps in the PKS, leading to a variety of novel substitutions at C21 and other positions (Burns *et al*., 2003; Martin, 2003). As one example, the ethyl group at C21 has been replaced with an *n*-propyl group (Martin, 2003), resulting in a unique spinosyn as active as spinosyn A (**Tables 1** and **3**).

6.5.2.4. Physical Properties of the Spinosyns

The spinosyns are high molecular weight (approximately 732 Da), relatively nonvolatile molecules (**Table 4**). As with the biological activity, small changes in structure can have far larger effects than might otherwise be expected. Although spinosyns A and D only differ by the presence of a methyl group at C6 (**Table 1**), this has a surprising effect on the physical properties, especially solvent solubilities. For example, spinosyn A is soluble in water at about 8.9 mg 100 ml^{-1}, while the water solubility of spinosyn D is only 0.05 mg 100 ml^{-1}. This pattern holds true for other solvents as well (**Table 4**).

6.5.3. Pharmacokinetics of Spinosad

6.5.3.1. Metabolism of the Spinosyns



6.5.3.1.1. Mammalian and avian spinosyn metabolism Studies of ^{14}C-spinosyns A and D metabolism in rats identified fecal excretion as the major route of elimination for both spinosyns A and D. In the fecal material, between 52% (males) and 28% (females) of the administered dose of spinosyn A was excreted in the feces as parent or metabolites within 0–24 h post-dosing. Of this material only 6.4% (males) and 5.4% (females) was spinosyn A (Domoradzki *et al*., 1996). For spinosyn D, between 67.7% (males) and 73.3% (females) of the applied dose was present in the feces, of which 34.5% (males) and 35.2% (females) was the parent spinosyn D (Domoradzki *et al*., 1996). Thus, for both spinosyns A and D a substantial amount of metabolism had taken place in the first 24 h following administration. The primary pathways for the spinosyns in rats involved loss of a methyl group on the forosamine nitrogen (*N*-demethylation), and/or loss of one of the *O*-methyl groups on the rhamnose (*O*-demethylation) (**Figure 4**), both followed by conjugation. Conjugation of the parent was also noted as an important pathway in rats (Domoradzki *et al*., 1996).

In lactating goats, following 3 days of dosing with either spinosyn A or D, eight metabolites of spinosyn A and five metabolites of spinosyn D were detected. As with rats, *N*-demethylation was an important metabolic route. In addition, hydroxylation of the macrolide ring was noted as a primary metabolic pathway (Rainey *et al*., 1996) (**Figure 4**).

In studies with poultry, *N*-demethylation of the forosamine nitrogen and *O*-demethylation of the rhamnose moiety were also found to be the two primary metabolic pathways (Magnussen *et al*., 1996). In the latter case, the 2′/4′-*O*-demethyl metabolites (i.e., spinosyns H and K, respectively, for spinosyn A metabolism) predominated over the 3′-*O*-demethyl metabolites. Another pathway, involving removal of the forosamine sugar to form the C17 PSA, was identified, but appears to be secondary to the *N*- and *O*-demethylation (Magnussen *et al*., 1996) (**Figure 4**).

As demonstrated by these three studies, spinosyns A and D are readily metabolized in vertebrate and avian systems. Furthermore, *N*-demethylation of the forosamine nitrogen is a metabolic route that predominates in all three species. *O*-Demethylation of the rhamnose sugar is also important in rats and poultry. These particular pathways are both consistent with oxidative metabolism via monooxygenases and/or the action of glutathione transferases. In the rat studies, glutathione conjugates were noted for *O*-demethylated metabolites as well as for the parent spinosyns (A and D). The presence of hydroxylated macrolide metabolites in the goat provides direct support for involvement of monooxygenases in spinosyn metabolism.

6.5.3.1.2. Spinosyn metabolism in insects Spinosyns A and D appear to have a number of potential sites for metabolism, including *N*-demethylation of the forosamine, *O*-demethylation of the rhamnose, epoxidation of the 5,6 or 13,14 double bonds, opening of the macrocyclic lactone, etc. As shown above (see Section 6.5.3.1.1), some of these potential metabolites have been observed. However, compared to more conventional insect control agents,

the spinosyns are very large, unusual, complex molecules, and metabolic enzyme systems do exhibit distinct substrate specificities. Studies of spinosyn A metabolism in tobacco budworm (*H. virescens*) larvae show spinosyn A to penetrate slowly, and that the primary, and apparently only, component that was detected (within the limits of the experiment) was the parent, spinosyn A (Sparks *et al.*, 1997, 2001) (**Figure 5**). Thus, until 24 h post treatment there appears to be little or no metabolism of spinosyn A in pest insects such as larvae of *H. virescens*. In contrast, these same larvae readily metabolize the quinazoline acaricide, fenazaquin (Sparks *et al.*, 1997) (**Figure 5**). Subsequent studies with *H. virescens* larvae that were highly resistant (ca. 1000-fold) (Bailey *et al.*, 1999) to spinosad, also failed to show significant levels of metabolism (Young *et al.*, 2000). These observations are in clear distinction to those observed for mammals (see Section 6.5.3.1.1).

The apparent lack of spinosyn A metabolism by pest insects is also supported by synergist studies with the monooxygenase inhibitor, piperonyl butoxide (PBO). PBO is able to synergize the biological activity of the pyrethroid permethrin in house flies, but not that of spinosyn A (Sparks *et al.*, 1997). Likewise no PBO-based synergism was noted for spinosyn A or spinosad activity in studies involving *H. virescens* larvae (Sparks *et al.*, 1997) or in spinosad resistant larvae of the diamondback moth (*Plutella xylostella*) (Zhao *et al.*, 2002). Thus, within the limits of the available data, many pest insects appear to have a limited capacity to metabolize some spinosyns.

6.5.3.2. Spinosyn Penetration into Insects

The observed biological activity of any toxicant is a function of two primary parameters: (1) inherent activity at the target site, and (2) concentration of the toxicant at the target site as a function of time. Compared to more conventional insect control agents such as the organophosphates, carbamates, and pyrethroids, the spinosyns are large, complex, relatively high molecular weight molecules. Although the spinosyns, such as spinosyn A, exhibit good activity via topical or contact application, better activity is observed by oral application or by injection (Sparks *et al.*, 1995, 1997, 1998), suggesting that penetration through the insect cuticle may be comparatively slow. In contrast, insecticides such as cypermethrin are equitoxic to lepidopterous larvae by either topical application or injection (Sparks *et al.*, 1997), suggesting relatively rapid penetration through the cuticle of pest insect larvae. A time course of penetration of permethrin or spinosyn A into the hemolymph of larvae of the cabbage looper (*Trichoplusia ni*) (Sparks *et al.*, 1997) showed the rate of penetration for spinosyn A to be much slower than that of the pyrethroid permethrin. Likewise, studies of initial penetration rates (2–4 h) for a variety of insect control agents showed that spinosyn A possessed one of the slowest rates of penetration. Most organophosphate and pyrethroid insect control agents have initial rates of penetration that are several-fold higher; in some cases by more than an order of magnitude (**Table 5**). Interestingly, one compound that is reported to have a similarly slow rate of penetration is abamectin, another large macrolide (**Table 5**). Thus, in light of the very good biological activity possessed by many of the spinosyns, their comparatively slow rate of penetration may be well compensated for by a limited capacity of many pest insects to metabolize them.

6.5.3.3. Insecticidal Concentration in the Cockroach

A key parameter in understanding the mode of action of biologically active compounds is the aqueous concentration that needs to be in contact with the receptors in the body to cause the biological effect of interest. For pharmaceuticals, the therapeutic concentration is defined as the aqueous concentration of the substance in the patient's blood plasma needed to obtain a desired therapeutic effect. Likewise, the insecticidal concentration can be defined as the concentration of an insecticide in the aqueous phase of an insect's hemolymph needed to obtain a desired insecticidal effect. Hemolymph is a complex tissue, composed of cells suspended in a complex solution of salts and organic molecules, including high concentrations of proteins. Whole hemolymph concentration, as is usually measured for insecticides, is in itself not interesting for the mode of

Figure 3 Potential biosynthesis of spinosyn A. PSA, pseudoaglycone. (Adapted, in part, from information in Kirst, H.A., Michel, K.H., Mynderse, J.S., Chio, E.H., Yao, R.C., *et al.*, **1992**. action because it can be much higher than the true aqueous concentration, due to partitioning into cell membranes and binding to hemolymph proteins. For most insecticides, it is not possible to measure hemolymph aqueous concentration directly, because of the difficulty of removing cells and proteins from whole hemolymph without also removing a portion of the hydrophobic insecticide from the aqueous phase. This problem can be circumvented by using an indirect method to estimate the insecticidal concentration, whereby the insecticide content of nerve cords isolated from poisoned, symptomatic insects is determined and compared with the content of nerve cords incubated with the insecticide in saline until a steady state has been reached.

In adult male American cockroaches (*Periplaneta americana*) poisoned with a threshold dose of spinosyn A, the nerve cord content was found to be 4.2 pmol. On the other hand, incubation of isolated nerve cords with 100 nM spinosyn A in saline gave a steady-state tissue content of 19.4 pmol. Assuming passive distribution of spinosyn A between the nerve cord and the aqueous medium *in vivo* and *in vitro* allows us to calculate by simple proportionality that a saline concentration of 21 nM would give the nerve cord content of 4.2 pmol, as observed at the threshold dose (Salgado *et al.*, 1998). Thus, it appears that 20 nM spinosyn A in the hemolymph should have an effect on the target receptors that is strong enough to cause symptoms (Table 6).

6.5.4. Mode of Action of Spinosyns

Because spinosad causes excitatory neurotoxic symptoms, a systematic investigation of the symptoms using neurophysiology was the most direct way to identify the target site. Although spinosad is

targeted commercially at Lepidoptera and thrips, spinosyns and spinosoids are inherently broad spectrum, showing activity against insects in the orders Coleoptera, Diptera, Homoptera, Hymenoptera, Isoptera, Orthoptera, Lepidoptera, Siphonaptera, and Thysanoptera, as well as mites (Thompson *et al.*, 1995). American cockroaches were used as the test insects for mode of action studies because of their large size, well-described neuroanatomy and neurophysiology, and distinctive spinosad poisoning symptoms. Spinosyn A was used in all mode of action studies because it is the major component of spinosad, and is similar in biological activity to spinosyn D but much more soluble.

6.5.4.1. Poisoning Symptoms

Symptoms of spinosyn A poisoining in three insect species were described in detail by Salgado (1998) and can in all cases be divided into three phases.

The earliest symptoms are due to prolonged involuntary muscle contractions that subtly alter the posture of the insect. This is evident in cockroaches and houseflies, where the first symptom is a lowering of the head and elevation of the tail, caused by involuntary straightening of the hindlegs. In the second phase of poisoning, the posture changes become so severe that the insects topple over and cannot right themselves, becoming prostrate. At this point, there are widespread fine tremors in all muscles, which sometimes can only be seen under a microscope. In hard-bodied insects, all appendages tremble constantly, and in soft-bodied insects such as caterpillars, the skin appears to crawl. In the last phase, the movements cease and the insects are paralyzed. The symptoms will be described in more detail for cockroaches, fruit flies, and tobacco budworm larvae.

The 24 h injection LD_{50} (median lethal dose) of spinosyn A was 0.74 (0.41–1.34) $\mu g\,g^{-1}$ for adult male *P. americana*. The first noticeable symptom was elevation of the body, due to depression of the coxae, extension of the legs, and flexion of the tarsae (**Figure 6b**). In this first poisoning phase, the cockroaches still walked around, and, if disturbed by touching, would resume a normal posture temporarily. These symptoms even persisted after the insect was decapitated (**Figure 6c**). As poisoning progressed to phase 2, the cockroaches became more uncoordinated and fell on their backs, as a result of asymmetric extension of the legs. The tarsae of the prostrate insects remained strongly flexed, and the insects showed tremors, which were not seen before prostration (**Figure 6d**). At the lowest effective dose, 0.625 $\mu g\,g^{-1}$, prostration occurred approximately 24 h after injection, whereas at 5 $\mu g\,g^{-1}$ it occurred within 4 h. The insects also showed other symptoms of excitation, such as wing beating and abdominal bloating resulting from their swallowing large amounts of air. The prostrate cockroaches eventually ceased trembling as they entered the third or quiescent poisoning phase, during which movement could still be elicited by a disturbance, but grew gradually weaker. The legs gradually relaxed as the insects became paralyzed, and no further movement could be elicited. No recovery was observed.

Adult male fruit flies, *D. melanogaster,* exposed to spinosyn A in sugar water, exhibited a characteristic set of sublethal symptoms. The 24 h LC_{50} (median lethal concentration) was 8.0 (5.7–12.1) ppm Initially, flies were able to remain upright and even walk around, but most had difficulty maintaining normal posture. When standing still, the tibiae slowly flexed and the tarsae extended, causing the legs to pull together and the body to rise. Approximately every 5 s, the fly compensated by spreading its legs into a normal stance, after which the process was repeated, with alternate slow pulling together, followed by rapid spreading, of the legs. While this effect occurred in nearly all flies at this concentration, some flies also held the wings abnormally. Normally, the wings are folded over the back, but in many poisoned flies they were either open straight out or folded down.

Heliothis virescens larvae prostrated by spinosyn A typically curled up due to abdominal flexion and lay on their sides, exhibiting widespread fine tremors. The true legs were extended and trembling, as were the mouthparts and even the surface of the soft cuticle. These excitatory effects were not obvious to the naked eye, but were easily seen with a stereomicroscope. Diuresis was also a common symptom of spinosyn A poisoning in *H. virescens*

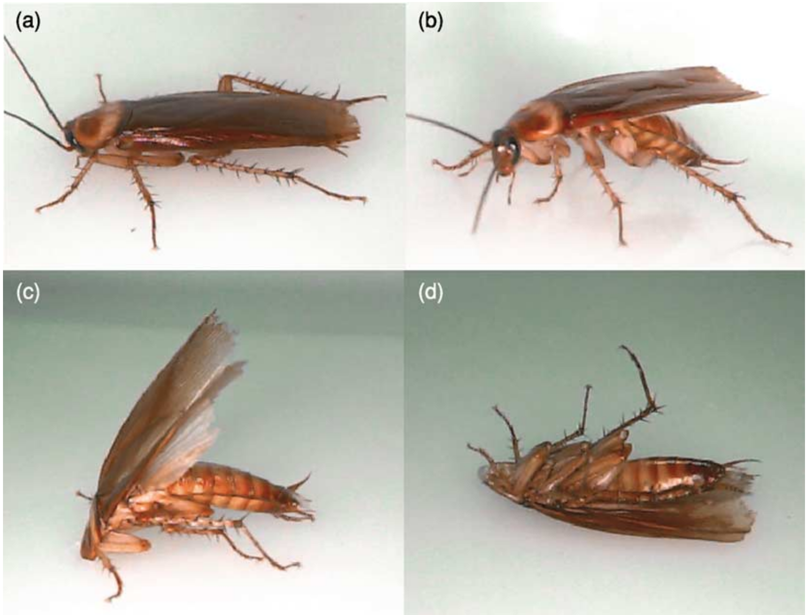

Figure 6 Typical symptoms shown by American cockroaches (*Periplaneta americana*) after injection with spinosyn A, in this case at 2 μg. (a) Control. (b) Depression of the legs elevates the body; note how all leg joints are extended. (c) The symptoms persist even after decapitation, and even worsen, as the whole body flexes. (d) Even after prostration, the tarsae remain strongly flexed, as seen in this decapitated insect. (Reprinted with permission from Salgado, V.L., **1998**. Studies on the mode of action of spinosad: insect symptoms and physiological correlates. *Pestic. Biochem. Physiol. 60*, 91–102; © Elsevier.)

larvae. The injection LD_{50} of spinosyn A against 50–70 mg *H. virescens* larvae was 0.23 (0.1–0.52) $\mu g\ g^{-1}$ (Salgado, 1998).

In summary, one of the first symptoms of spinosyn poisoning in all insects is leg extension, due to involuntary muscle contractions. Later in poisoning, all muscles appear to be affected.

6.5.4.2. Gross Electrophysiology

6.5.4.2.1. Spinosyns excite the central nervous system *in vivo* and *in vitro* Although many muscles are activated during spinosyn poisoning, tarsal flexion was an excellent model because it is one of the first symptoms to appear and persists throughout poisoning, even when the poisoned insect is decapitated and pinned on its back, allowing its physiological basis to be easily studied. This symptom is caused by contraction of the tarsal flexor muscle, located in the tibia (Snodgrass, 1952). The onset of spinosyn-A-induced tarsal flexion was accompanied by continual firing of the tarsal flexor muscle (**Figure 7a**). In control insects, the muscle was relaxed except for activity during sporadic movements (not shown). Cutting all contralateral nerve roots did not diminish flexion, and when all ipsilateral nerves except nerve 5, which innervates the tarsal flexor muscle, were cut, the tarsus still remained flexed, and the firing of the flexor muscle continued (**Figure 7b**). However, immediately upon severing nerve 5, the tarsus relaxed and the muscle recording became silent (not shown). Therefore, the smallest unit exhibiting the flexion was the leg and its ganglion attached through nerve 5, and it was concluded that spinosyn-induced tarsal flexion was caused by activation of the flexor motor neuron, driven by events occurring either within that neuron or elsewhere within that ganglion (Salgado, 1998).

Nerve recordings made from various nerves showed that central nervous system (CNS) and motor activity was generally increased in spinosyn A poisoned cockroaches, concomitant with appearance of excitatory symptoms and persisting even after paralysis. Alternatively, it could be demonstrated that the excitatory effects of spinosyn A were specifically on the CNS; there were no direct effects on axonal conduction, sensory receptor function, or neuromuscular function (Salgado, 1998).

The next step in analyzing the etiology of spinosyn-induced hyperactivity was to determine whether spinosyns could directly increase nerve activity when applied to isolated ganglia. **Figure 8** shows a ratemeter recording of the activity in a segmental nerve of an isolated larval housefly synganglion. In the control and before application of spinosyn A, the activity varied widely. Following treatment with 100 nM spinosyn A, the swings in activity became

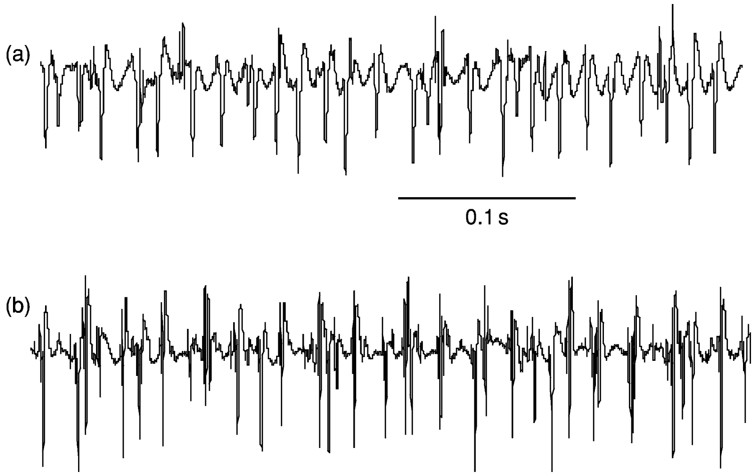

Figure 7 (a) Electromyogram showing continual firing of the metathoracic tarsal flexor muscle in a cockroach poisoned 4 h earlier by abdominal injection of 2.5 μg spinosyn A. (b) The activity persisted after all nerves to the metathoric ganglion, except ipsilateral nerve 5, were severed. (Reprinted with permission from Salgado, V.L., **1998**. Studies on the mode of action of spinosad: insect symptoms and physiological correlates. *Pestic. Biochem. Physiol. 60*, 91–102; © Elsevier.)

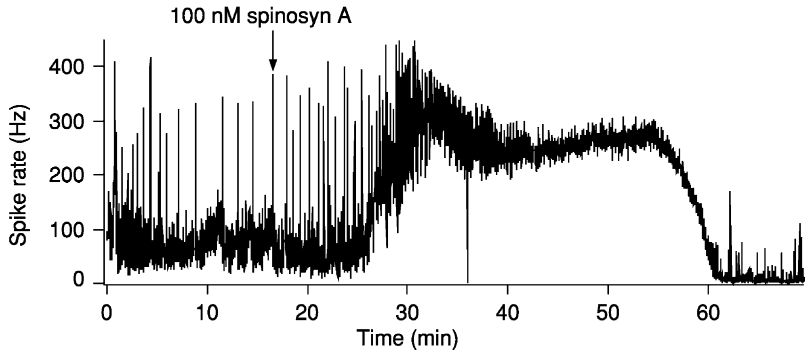

Figure 8 Spike rate recorded from a segmental nerve of an isolated housefly (*Musca domestica*) larval synganglion. Before spinosyn A, the activity varied mostly between 20 and 120 Hz, with occasional brief spikes to 400 Hz. After the addition of 100 nM spinosyn A, there was a delay of approximately 10 min, after which the activity increased greatly to a constant high level, with no dips below 200 Hz. After 25–30 min, the activity declined to below control levels. (Reprinted with permission from Salgado, V.L., **1998**. Studies on the mode of action of spinosad: insect symptoms and physiological correlates. *Pestic. Biochem. Physiol. 60*, 91–102; © Elsevier.)

much smaller and the activity stabilized at a high level, before eventually declining 20–30 min after the start of perfusion with spinosyn A. It was shown above that spinosyn A must attain an internal aqueous concentration near 20 nM in order to produce symptoms. This concentration applied in a saline bath was just sufficient to stimulate activity in isolated cockroach ganglia (**Table 6**). In other words, spinosyn A achieves a concentration in treated insects that is sufficient to cause the observed symptoms by direct actions on nerve ganglia. The ganglion from *Manduca sexta* is significantly more sensitive than the cockroach ganglion, giving a full response at 10 nM (Salgado *et al.,* 1998).

In summary, one of the first symptoms of spinosyn poisoning in all insects is leg extension, due to involuntary muscle contractions driven by activity in motor neurons, caused by a direct action of spinosyns within the ganglion. Later in poisoning, all muscles appear to be tonically activated. The elevated posture arises because, while opposing flexor and extensor muscles are both being activated, the stronger, weight-supporting, muscles overcome the weaker antagonists, so that each joint moves in the direction that elevates the body.

6.5.4.2.2. Mechanism of paralysis by spinosyns Spinosyn-poisoned insects eventually become paralyzed, but only after prolonged excitation, suggesting that paralysis results secondarily, from prolonged overexcitation of the nervous system. Interestingly, neural activity continues at high levels in paralyzed insects, indicating that paralysis is due to fatigue-related failure of the neuromuscular system. This

hypothesis was confirmed by showing that the maximal force exerted by the metathoracic femur in response to tetanic crural nerve stimulation faded more rapidly as poisoning progressed, and eventually disappeared concomitant with paralysis. The inhibitory neuromuscular synapses, which use γ-aminobutyric acid (GABA) as the neurotransmitter and are blocked after prostration with the GABA gated chloride channel blocker dieldrin, were shown to function normally in insects prostrated by spinosyn A (Salgado, 1998). In *in vitro* experiments on larval housefly muscle, spinosyn A at concentrations up to 1 μM had no effect on neuromuscular transmission, but at 5 μM and higher, the cell was slightly depolarized and the excitatory postsynaptic potential (EPSP) was enhanced. These concentrations are too high for these effects to be relevant during poisoning.

6.5.4.2.3. Spinosyns excite central neurons by inducing an inward, depolarizing, current Because spinosyns potently stimulate CNS activity (see Section 6.5.4.2.1), effects on neurons of the cockroach 6th abdominal ganglion were investigated *in situ* with intracellular microelectrodes. Dorsal unpaired median (DUM) neurons were chosen because they are spontaneously active and are the best-characterized neurons in the insect CNS, and known to contain many different receptors important for insecticide action, including nicotinic acetylcholine receptors (nAChRs) (Buckingham *et al.,* 1997), GABA (Le Corronc *et al.,* 2002) and inhibitory glutamate (Raymond *et al.,* 2000) receptors, and a variety of sodium, calcium, and potassium channels (Grolleau and Lapied, 2000). As reported previously (Dubreil *et al.,* 1994), DUM neurons were spontaneously activate and had random spontaneous unitary inhibitory postsynaptic potentials (IPSPs). Furthermore, stimulation of the connective evoked an IPSP in the DUM cell (Pitman and Kerkut, 1970; Dubreil *et al.,* 1994) (**Figure 9b**). At 200 nM, but not at 50 nM, spinosyn A depolarized DUM cells *in situ* (10 and 13 mV in two cells; compare the resting levels of the traces in **Figure 9b and c**) and increased the rate of spontaneous IPSPs considerably, but did not block the spontaneous or evoked IPSPs, even at concentrations as high as 1 μM ($n = 3$) (**Figure 9c**). It also increased the spontaneous firing rate, as can be seen by the two action potentials in this trace (the evoked IPSP abolished an action potential that was just starting). Picrotoxinin at 10 μM abolished the spontaneous and evoked IPSPs (**Figure 9d**), leading to further depolarization and excitation (note the increased action potential frequency). Thus, while spinosyn A did not appear to affect the inhibitory postsynaptic receptors in DUM neurons, or the ability to generate action potentials, it did have clear effects on the cells. While the increased spontaneous IPSP rates reflect changes occurring in presynaptic cells, the depolarization and increased firing rate appear to be due to a direct action of spinosyn A on the DUM cells themselves. It can be seen from the steady depolarization between action potentials (**Figure 9d**) that this firing is due to a continuous depolarizing stimulus flowing into the cell. This suggests that a spinosyn-induced inward current was responsible for the depolarization and increased firing rate. The depolarization was reversed by 10 μM methyllycaconitine (MLA), a selective nicotinic antagonist (**Figure 10**), indicating that it is mediated by nicotinic receptors. MLA also blocked the IPSP, consistent with the proposed multisynaptic pathway for this response, involving a nicotinic synapse (Dubreil *et al.,* 1994) (**Figure 10**).

6.5.4.2.4. Activation of nicotinic receptors by spinosyns generates a depolarizing inward current The intracellular recordings (**Figures 9 and 10**) indicated that spinosyn-A-induced an inward current in central neurons, probably mediated by nAChRs. This current was then directly investigated with voltage clamp experiments on isolated central neurons. The cells studied were a mixed population of neuronal somata, with diameters between 35 and 80 μm, isolated from the thoracic ganglia of the cockroach *P. americana* and studied with the single-electrode voltage clamp method (SEVC) as detailed by Salgado and Saar (2004). In ten cells tested, spinosyn A did indeed induce an inward current at concentrations between 50 nM and 1 μM. Furthermore, this current was completely blocked by 100 nM α-bungarotoxin (α-BGTX), a highly specific antagonist of nAChRs. Because the interaction of both α-BGTX and spinosyn A with the receptors was relatively slow, it was difficult to measure the dose response for block quantitatively. In the example in **Figure 11**, 3 nM α-BGTX blocked the spinosyn-A-induced current by approximately 75% before washout was begun, while 10 nM α-BGTX blocked the spinosyn-A-induced current by 85%, and 1000 nM blocked it completely. This sensitivity to α-BGTX is comparable to that of the nondesensitizing nAChR, which is blocked 78 ± 3% by 3 nM and 93 ± 1% by 10 nM α-BGTX (Salgado and Saar, 2004).

6.5.4.3. Nicotinic Receptors as the Spinosyn Target Site

6.5.4.3.1. Two subtypes of nicotinic receptors Two subtypes of α-BGTX-sensitive nicotinic receptors have been identified in insect neurons (van den

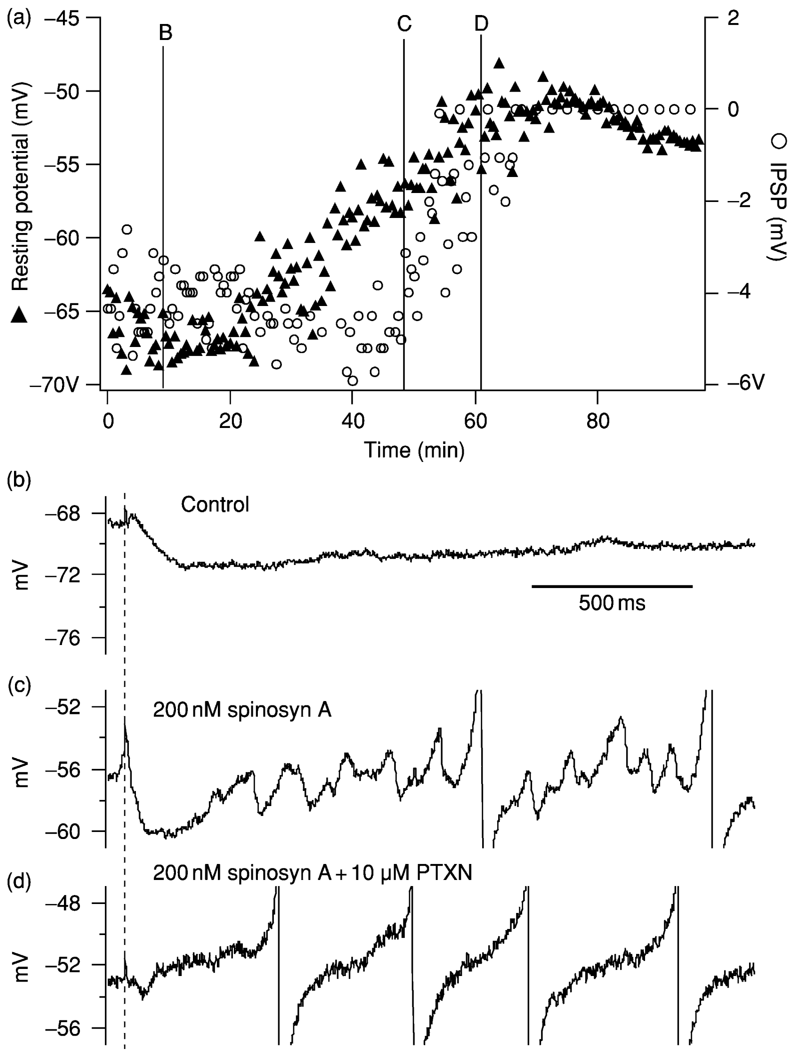

Figure 9 (a) Resting potential and inhibitory postsynaptic potential (IPSP) amplitude of a dorsal unpaired median (DUM) neuron in a cockroach terminal abdominal ganglion. (b–d) Sample recordings at the times indicated by the letters in panel A. The IPSP was evoked by connective stimulation at the vertical dashed line, 200 nM spinosyn A was added just after B, and 10 μM picrotoxinin (PTXN) was added just after point C. This example is representative of similar results obtained in three cells. The preparation for recording synaptic responses from DUM neurons is from Dubreil *et al.* (1994), with slight modifications. The terminal abdominal ganglion of adult male American cockroaches was removed with its associated peripheral nerves. The ganglion was desheathed, placed in an experimental chamber, and perfused with saline. Nerve XI and the anterior connectives were stimulated with suction electrodes, and compounds, dissolved in saline, were applied in the bath. Microelectrodes were filled with 3 M KOAc and had resistances between 110 and 150 MΩ (Salgado, unpublished data).

Beukel *et al.*, 1998; Nauen *et al.*, 2001). In American cockroaches, subtype nAChD receptors desensitize in the presence of agonists and are blocked by α-BGTX with a K_d of 21 nM, while subtype nAChN receptors are nondesensitizing and are blocked by α-BGTX with a K_d of 1.3 nM (Salgado and Saar, 2004). Both subtypes are blocked by MLA, with K_d values of 1 nM and 17 pM, respectively. Since nAChD receptors desensitize in the presence of agonists, they are antagonized during poisoning by nicotinic agonists such as the neonicotinoids (see **Chapter 5.3**), and this antagonism appears to cause the subacute symptoms of these compounds, such as feeding inhibition in aphids and inhibition of cleaning behavior in termites (Salgado and Saar, 2004). On the other hand, activation of nicotinic receptors by nicotinic agonists has long been known to cause excitatory symptoms (Schroeder and Flattum, 1984; Nauen *et al.*, 2001), which appear to be mediated by nAChN receptors.

6.5.4.3.2. Selective action of spinosyns on the nAChN subtype of nicotinic receptor Although almost all cockroach neurons studied contain both

nAChD and nAChN receptors, the two can be separated and studied independently using subtype-selective antagonists. nAChN receptors are extremely sensitive to MLA, with a K_d of 17 pM. Even though nAChD receptors are also very sensitive to MLA, their K_d of 1 nM permits selective block of only nAChN receptors with the inclusion of 100 pM MLA in the bath. Figure 12a shows the total ACh-evoked current in an isolated cockroach neuron and the pure nAChD current remaining after specific block of nAChN receptors by 100 pM MLA.

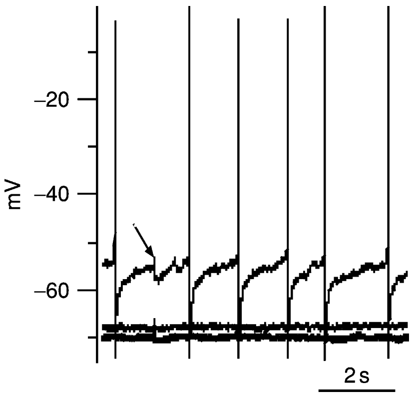

Figure 10 Reversal of spinosyn-A-induced depolarization by methyllycaconitine (MLA) in a DUM neuron. The lower trace is the control, with a resting potential near −70 mV. Spinosyn A at 1 μM depolarized the cell to −53 mV and induced firing. Addition of 10 μM MLA reversed the depolarization and stopped the firing (middle trace). Note that the small IPSP evoked by the stimulus (arrow) in the control became larger after the depolarization and was abolished by MLA. This example is representative of similar results obtained in two cells (Salgado, unpublished data).

On the other hand, selective block of nAChD receptors can be achieved by taking advantage of their property of desensitization. Desensitization is a property of the receptor itself, due to transition of activated receptors into a nonconducting state that binds agonists very tightly (Lena and Changeux, 1993). The desensitized state of the rat muscle nicotinic receptor, for example, has an affinity for agonists about 500-fold higher than that of the open state. The strong binding of agonists to the desensitized state can be used to specifically block the nAChD current (Figure 12b), where, in the presence of 100 nM imidacloprid (IMI), a potent nicotinic agonist (see **Chapter 5.3**), only the nAChN current remains functional, in a cell that has both receptor subtypes.

When nAChN receptors are blocked by the inclusion of 100 pM MLA in the bath, the effect of spinosyn A on nAChD receptors can be studied (Figure 12c). Spinosyn A blocked the nAChD receptors only very weakly, an average of only 23% at 10 μM (Salgado and Saar, 2004), and induced no inward current.

As mentioned above, the sensitivity of the spinosyn-A-induced nicotinic current to α-BGTX (IC_{50} (50% inhibitory concentration) of 1.8 nM measured by Salgado *et al.* (1997)) is very similar to that of nAChN receptors (IC_{50} of 1.2 nM measured by Salgado and Saar (2004), suggesting that spinosyn A activates nAChN receptors. Figure 12d shows the nAChN current, isolated with 100 nM IMI, in the presence of increasing concentrations of spinosyn A. As little as 1 nM spinosyn-A-induced a noticeable inward current and prolonged the action

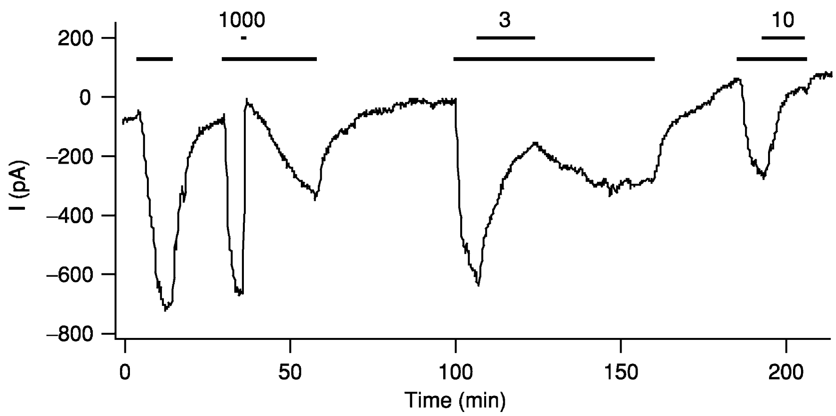

Figure 11 α-Bungarotoxin (BGTX) (thick bars, at concentrations indicated, in nM) block of the spinosyn A (thin bars, at 1 μM) induced inward current at −80 mV in an isolated voltage-clamped cockroach central neuron. The first application and washout of spinosyn A, between 0 and 35 min, reversibly induced a large inward (downward deflection) current. At the peak of the current evoked by the second application of spinosyn A, 1000 nM α-BGTX was applied, which rapidly blocked the current in the continued presence of spinosyn A; the inward current then slowly returned during washout of α-BGTX, but spinosyn A was also washed out, beginning at 60 min. The current evoked by the third application of spinosyn A, at 100 min, was blocked about 75% by 3 nM α-BGTX after about 15 min incubation, but the toxin was washed out before steady-state block was reached. The current evoked by the fourth spinosyn A application, though smaller, due to rundown, was blocked 85% by 10 nM α-BGTX (Salgado, unpublished data).

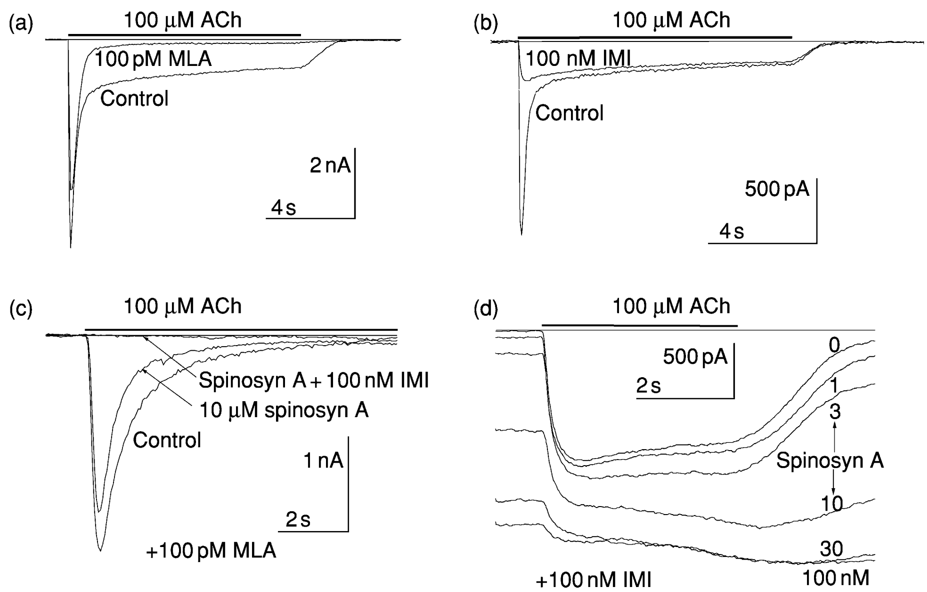

Figure 12 Pharmacological separation of cockroach nicotinic acetylcholine receptor (nAChR) subtypes and the action of spinosyn A on both subtypes. (a) Combined current in an isolated cockroach neuron and the pure nAChD current remaining after specific block of nAChN receptors by 100 pM MLA. (b) In the presence of 100 nM imidacloprid (IMI), only the nAChN current remains in a cell with both receptor subtypes. (c) When nAChN is blocked by the inclusion of 100 pM MLA in the bath, 10 μM spinosyn A slightly blocks the nAChD current. (d) nAChN current isolated with 100 nM IMI, alone and in the presence of increasing concentrations of spinosyn A (Salgado, unpublished data).

of ACh, and these effects increased dramatically with increasing concentrations of spinosyn A. Although the nAChN receptors do not desensitize, the control current drooped approximately 15% during the ACh pulse, possibly due to redistribution of ions near the membrane. At 3 nM spinosyn A, this droop was eliminated and at higher concentrations the current actually increased up to 10% during the ACh pulse, because of a synergistic interaction between spinosyn A and ACh on the nAChN receptor. This synergistic effect can also be seen from the fact that the current after the ACh pulses in the presence of spinosyn A decays much more slowly than in the control, an effect also noted by Salgado *et al.* (1997). The effect of spinosyn A on the nAChN receptors in **Figure 12d** was quantified by measuring the fraction of unmodified receptors remaining, taken as the amplitude of the rapid increase in current in the first second of ACh application as a fraction of the peak current in the control. For example, for the 10 nM spinosyn A treatment in **Figure 12d**, the result is 59% unmodified and for 100 nM it is 10%. The EC_{50} (concentration for 50% activation) for activation of nAChN receptors by spinosyn A, measured in the presence of 100 nM IMI to block nAChD receptors (**Figure 12d**) was 10 ± 1 nM ($n = 3$). Because of the synergistic interaction of spinosyns with competitive nicotinic agonists, the EC_{50} for activation of nAChN receptors was also measured in the absence of IMI, giving a value of 27 ± 4 nM ($n = 4$) (Salgado and Saar, 2004).

The synergistic interaction between spinosyn A and classical, competitive agonists acting at the ACh binding site shows that spinosyns are in fact allosteric agonists of nAChN. This is further supported by the fact that α-BGTX blocks the spinosyn-induced current noncompetitively and that spinosyn A does not displace binding of [^{3}H]α-BGTX (Salgado *et al.*, 1997). Under certain circumstances the synergism between spinosad and classical nicotinic agonists, such as neonicotinoids, is demonstrable in practice (Andersch *et al.*, 2003).

Note also in **Figure 12d** that the total current in the presence of 100 nM spinosyn A and 100 μM IMI is more than twice the total current evoked by ACh alone; spinosyn A is a more efficacious agonist than ACh and can therefore have very strong effects on cells that have a significant number of nAChN receptors. The sensitivity of any cell to the agonistic effects of spinosyns on nAChN receptors will be dependent on the number of those receptors and the input resistance of the cell, which together determine what proportion of the receptors need to be activated to significantly depolarize the cell and change its firing pattern. Symptoms arise in cockroaches at an internal aqueous concentration of 20 nM, at which 45% of nAChN receptors are

activated (Table 6). This represents the sensitivity of the most sensitive cells. This value appears relatively large, suggesting that cells have homeostatic mechanisms to compensate for a relatively large amount of inward current. In fact, DUM neurons first altered their firing pattern when the spinosyn A concentration reached 200 nM (Figure 9), at which 80% of nAChN receptors are activated. This may be related to the fact that DUM neurons fire spontaneously and have a relatively low input resistance.

6.5.4.3.3. Correlation of spinosyn biological activity with potency on nAChN receptors It has already been shown (Table 6) that symptoms appear when the internal aqueous concentration of spinosyn A reaches the range of 20 nM, which is also near the EC_{50} for activation of nAChN receptors, and is also in the range where significant nervous system stimulation is measurable. These results indicate that activation of nAChN receptors can account for the insecticidal activity of spinosyn A.

Potency in activating nAChN receptors was determined for 15 spinosyns and spinosoids, and the data are shown in Table 7 and plotted in Figure 13. There is a clear relation between activity on cockroach nicotinic receptors and insecticidal activity against first instar *H. virescens* larvae. These results provide further support for the importance of nAChR activation in spinosyn poisoning.

Table 7 Spinosyns and spinosoids tested for nicotinic activity. Each cell was calibrated with 100 nM spinosyn A and the potency of the test compound was determined by increasing the concentration gradually to bracket the magnitude of the response to 100 nM spinosyn A. The potency of the test compound relative to spinosyn A was determined by dividing 100 nM by the interpolated equi-effective concentration of the test compound. At least two determinations were made for each compound. The data are plotted in Figure 13

Number	*Spinosyn or spinosoid*	*Relative nicotinic potency*	*Relative* Heliothis *activity*

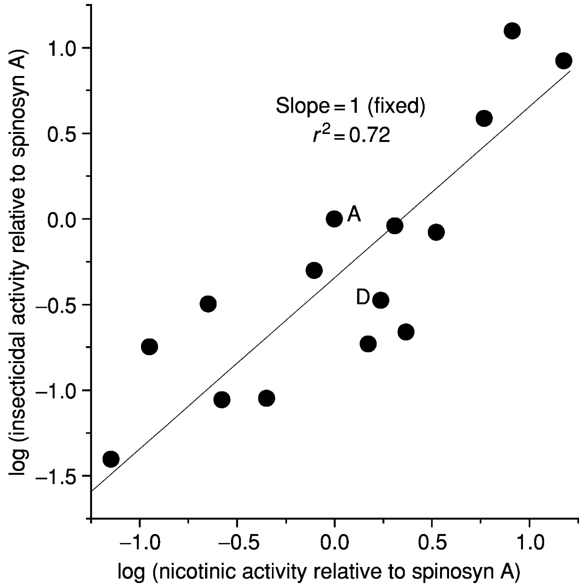

Figure 13 Relationship between relative insecticidal activity against first instar *Heliothis virescens* larvae in a drench assay and relative potency against nAChN receptors, for 15 spinosyns and spinosoids that were tested and had measurable activity in both assays. The regression line had a slope of 0.91, and $r^2 = 0.72$. The data and structural information for the spinosyns included in this figure are shown in Table 7. (Adapted from Salgado, V.L., Watson, G.B., Sheets, S.S., 1997. Studies on the mode of action of spinosad, the active ingredient in Tracer® insect control. Proc. 1996 Beltwide Cotton Production Conf., pp. 1082–1086.)

6.5.4.4. Effects of Spinosyns on GABA Receptors in Small Diameter Neurons of Cockroach

Watson (2001), using the whole-cell patch clamp method, found that in cockroach neurons with a diameter less than 20 μm, the GABA-activated chloride current was completely and irreversibly antagonized by as little as 5 nM spinosyn A (Figure 14), whereas GABA-activated chloride currents in cells larger than 25 μm were not affected. Over the same concentration range, a picrotoxinin-sensitive chloride current was activated by spinosyn A. The chloride current activated by spinosyn A is small in relation to the GABA response, an average of 124 pA in cells with GABA-activated chloride currents generally exceeding 2 nA, but because of the occurrence of GABA receptor antagonism and chloride current activation in the same concentration range, both of these effects might be due to a low efficacy partial agonist action of spinosyn A on a subtype of GABA receptor that appears to be found specifically in small neurons. This would presumably be an allosteric effect, due to binding of spinosyns at a modulatory site analogous to that for spinosyns on nicotinic receptors or avermectins

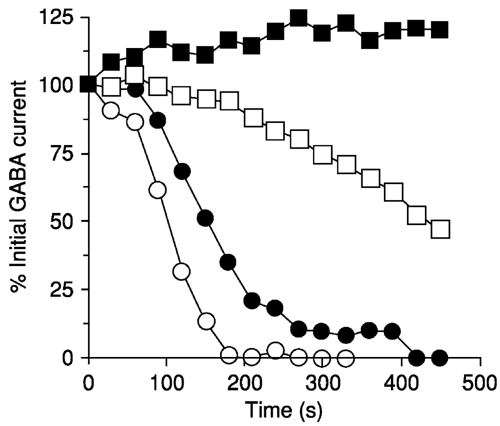

Figure 14 Representative data from individual neurons, showing loss of γ-aminobutyric acid (GABA) currents after the application of increasing concentrations of spinosyn A. With ATP in the recording electrode, responses to 20 mM GABA were fairly constant over time (filled squares). When spinosyn A was added to the perfusing medium at 1 nM (open squares), 5 nM (filled circles), and 100 nM (open circles), responses to GABA diminished over time. (Reprinted with permission from Watson, G.B., **2001**. Actions of insecticidal spinosyns on γ-aminobutyric acid responses from small-diameter cockroach neurons. *Pestic. Biochem. Physiol.* *71*, 20–28; © Elsevier.)

on glutamate and GABA gated chloride channels. Spinosyns did not antagonize the binding of [^{3}H]ivermectin to membranes prepared from several insect species, including cockroach (N. Orr, unpublished data). Although [^{3}H]ivermectin appears to bind to both GABA and GluCl receptors (Ludmerer *et al.*, 2002), it is not known how much of this binding is to the spinosyn-sensitive GABA receptor subtype present in small neurons. That component may be so small as to be undetectable in binding studies, but could nevertheless be very important physiologically.

The observed effect on GABA receptors in small neurons would be expected to have significant effects on the function of affected inhibitory synapses in poisoned insects, but it is not yet clear what the functions of these synapses are or what effect their disruption by spinosyns has on the insect. Since the activated current is relatively small, the overriding effect may be loss of inhibition caused by the loss of GABA receptor function. However, it cannot be excluded that the induced chloride current induces inhibition in some neurons. The excitatory symptoms first become significant in cockroaches at internal aqueous concentrations in the range of 20 nM, whereas block of the GABA receptors in small neurons is strong, if not complete, at 1 nM, and quite rapid and complete at 5 nM (**Figure 14**). While the activation of nicotinic receptors requires a somewhat higher spinosyn A concentration than the effects on GABA receptors in small neurons, its concentration dependence is such that it can account for the excitatory symptoms. Inhibition of GABA receptors in small neurons may act synergistically with nicotinic receptor activation to cause the excitatory symptoms.

In summary, spinosyns cause excitatory symptoms in insects by stimulating activity in the CNS. Activation of nondesensitizing nAChRs by an allosteric mechanism appears to be the primary mechanism by which spinosyns stimulate the neuronal activity, but it has also been shown that spinosyns potently antagonize GABA responses of small neurons, and this could also play a significant role in spinosyn poisoning. Both of these mechanisms are unique among insect control agents.

6.5.5. Biological Properties of the Spinosyns

6.5.5.1. Biological Activity and Spectrum of the Spinosyns

6.5.5.1.1. Pest insects The spinosyns are active against a broad range of insect pests, including many pest species among the Thysanoptera, Coleoptera, Isoptera, Hymenoptera, and Siphonaptera. However, for the spinosyns, the main focus for the activity is centered on the Lepidoptera and to a lesser degree the Diptera (Thompson *et al.*, 1995; Bret *et al.*, 1997; DeAmicis *et al.*, 1997; Sparks *et al.*, 1999; Kirst *et al.*, 2002a). The spinosyns are active against a wide variety of lepidopteran pest species including tobacco budworm (*Heliothis virescens*), cotton bollworm (*Helicoverpa zea*), diamondback moth (*Plutella xylostella*), fall armyworm (*Spodoptera frugiperda*), beet armyworm (*S. exigua*), cabbage looper (*Trichoplusia ni*), American bollworm (*Heliothis armigera*), rice stemborer (*Chilo suppressalis*), and many others (Thompson *et al.*, 1995; Bret *et al.*, 1997). This broad spectrum of pest insect activity is coupled with a high level of potency. Spinosyn A, the most abundant factor produced by *S. spinosa*, is very active against pest lepidopterans, with LC_{50} values in the same range as some pyrethroid insecticides, such as permethrin, cypermethrin, or λ-cyhalothrin (**Table 8**).

6.5.5.1.1.1. Structure–activity relationships of spinosyns – Lepidoptera Among the spinosyns produced by *S. spinosa*, spinosyn A is the most active against pest lepidopterans such as *H. virescens* (**Table 2**). Interestingly, spinosyn A is also the most abundant factor produced in the wild-type strains of *S. spinosa*. Other spinosyns, such as B and C (the

4″-*N*-demethyl and 4″-*N*,*N*-didemethyl derivatives of spinosyn A, respectively) (Table 2), are nearly as active as spinosyn A against *H. virescens*, as is the second most abundant factor, the 6-methyl analog, spinosyn D. Loss of a methyl group at the 2′-, 3′-, or 4′-position of the rhamnose moiety reduces lepidopteran efficacy by about an order of magnitude, as measured by activity against *H. virescens* larvae (spinosyns H, J, K, respectively) (Table 2). A comparable loss in activity is also associated with loss of a methyl group at C16 or a reduction in alkyl size (ethyl to methyl) at C21 (spinosyns F and E, respectively) (Table 2). Interestingly, an increase in alkyl size at C21 (ethyl to *n*-propyl) results in a slight improvement in activity towards *H. virescens* larvae (Table 3), while a further alkyl extension at C21 (2-*n*-butenyl) is about as active as spinosyn A (C21 = ethyl). Among the spinosyns arising from mutant strains (2′, 3′, or 4′-demethyl rhamnose derivatives) (Table 2), virtually all were far less active than spinosyn A. The one notable exception to this is spinosyn Q (LC_{50} 0.5 ppm) which is close in activity to spinosyn A.

6.5.5.1.1.2. Structure–activity relationships of spinosyns – Diptera In general, the pattern of activity for the different spinosyns towards adult stable flies is similar to that observed for the Lepidoptera (Kirst *et al*., 2002a). For example, spinosyns A–D and Q are nearly equitoxic to the adult stable fly (*Stomoxys calcitrans*), while the C16 demethyl analog (spinosyn F) is less active, as is spinosyn K (Table 2). However, unlike with *H. virescens* larvae, spinosyns E, H, and J are as active as spinosyn A (Table 2). The difference for spinosyn J is especially interesting since it is at least 100-fold less active than spinosyn A against larvae of *H. virescens*. Thus, there may be some significant differences in the spinosyn target site in adult stable flies, in the metabolism/conjugation of spinosyn J, or both, compared to larvae of *H. virescens*. Larval blowfly (*Calliphora vicina*) activity of the tested spinosyns was even more like lepidopteran activity than *S. calcitrans* activity (Kirst *et al*., 2002a). As in *H. virescens* larvae, spinosyns A–D are as toxic as spinosyn A, while spinosyns E and F, and the 2′, 3′, or 4′-demethyl analogs (spinosyn H, J, and K, respectively) are less active than spinosyn A. However, unlike in larvae of *H. virescens*, spinosyn J still displayed a reasonable level of activity towards larvae of *C. vicina* (Table 2).

6.5.5.1.1.3. Structure–activity relationships of spinosyns – Homoptera Unlike members of the Lepidoptera and Diptera, homopterans such as aphids are not very susceptible to the spinosyns (DeAmicis *et al*., 1997; Sparks *et al*., 1999; Crouse *et al*., 2001). With the exception of spinosyns B, K, and O, the spinosyns of *S. spinosa* for which data are currently available are not very active against cotton aphid (*Aphis gossypii*) (Table 2). Spinosyn activity against the aster leafhopper (*Macrosteles quadrilineatus*) reflects a similar pattern in that spinosyn K is again the most active of the spinosyns tested, although comparatively, spinosyns A and B are also active. Interestingly, other 4′-*O*-demethyl spinosyns such as spinosyn O and the 2′,4′-di-*O*-demethyl spinosyns U and V are also quite active against the leafhoppers, relative to spinosyn A (Table 2).

6.5.5.1.1.4. Structure–activity relationships of spinosyns – Acarina The spinosyns are also active against tetranychid mite species such as the two-spotted spider mite (*Tetranychus urticae*) (Sparks *et al*., 1999; Crouse *et al*., 2001). As observed with some of the homopteran species, spinosyns K and O are among the most active of the natural spinosyns from *S. spinosa*, while spinosyns H and Q are comparatively weaker than spinosyn A (Table 3). Likewise, spinosyn B is also relatively active. As noted previously, there is only a weak correlation between activity towards neonate *H. virescens* larvae versus spinosyn activity towards *T. urticae* (Sparks *et al*., 1999). While improvements in mite activity are possible, the physical properties affecting residuality and translaminar characteristics are such that the spinosyns are typically not well suited for mite control compared to available commercial standards (Crouse *et al*., 2001).

6.5.5.1.2. Nontarget organisms

6.5.5.1.2.1. Beneficial insects The spinosyns, exemplified by spinosad, are highly efficacious against a variety of pest insect species, yet relatively weak against towards a variety of beneficial insect species, especially predatory insects. A detailed summary of studies involving the effects of spinosad on a wide variety of beneficial insects has recently been published (Williams *et al*., 2003). Spinosyns such as spinosad typically have little effect on predatory insects and mites (Williams *et al*., 2003). Where particular laboratory bioassays have shown some spinosad toxicity to predators (e.g., *Orius insidiosus*), corresponding greenhouse and field tests have generally shown spinosad to have little effect (Studebaker and Kring, 2003), principally due to the rapid environmental degradation of spinosad (Saunders and Bret, 1997; Crouse *et al*., 2001; Williams *et al*., 2003). Based on data in Williams *et al*. (2003), in more than 88% of the greenhouse/field assays

involving predatory insects, the effects of spinosad on the predators fall into the harmless to slightly harmful categories, with the bulk (79%) in the harmless category.

Initial studies with spinosad suggested that there was some activity against hymenopterous parasitoids (*Encarsia formosa*) and honeybees (*Apis mellifera*), but that these pests were much less sensitive to spinosad compared to more conventional insect control agents such as the pyrethroids (e.g., cypermethrin) (Thompson *et al*., 1995, 2000). Subsequent studies, as recently reviewed by Williams *et al.* (2003), show hymenopterous parasitoids to have varying levels of susceptibility to spinosad, with many, unlike predaceous insects, tending to be relatively sensitive. While not all parasitoids are susceptible to spinosad (Elzen *et al*., 2000; Papa *et al*., 2002; Hill and Foster, 2003), studies with a wide variety of parasitoids show spinosad to be toxic to many of them, especially when applied directly to the parasite (Williams *et al*., 2003). However, unlike most of the lepidopteran and dipteran pest insect larvae targeted for control by spinosad, parasitoids are typically highly mobile. As such if they are able to escape the initial, direct contact with wet residues, these same parasitoids may not be highly impacted by the dried residues, especially after a few days (e.g., Tillman and Mulrooney, 2000). As noted above, spinosad is rapidly degraded in the environment (Sanders and Bret, 1997; Crouse *et al*., 2001). This rapid degradation contributes to observations in greenhouse and field studies that parasitoid populations, even those that are relatively sensitive to spinosad, can recover in a short period of time (1–2 weeks) (Williams *et al*., 2003).

Thus, as with all insect control agents, the use and efficacy of spinosad should be based on a variety of factors, including the presence and role of any beneficial insects. Compared to many of the organophosphate and pyrethroid insect control agents available for pest insect control, spinosad, as well as other recently introduced insect control agents (Sparks, 2004), have a reduced overall potential to adversely impact beneficial insects in the field.

6.5.5.1.2.2. Mammalian toxicology and ecotoxicology Among the critical attributes for any new insect control agent is the need to provide a high level of comparative safety to nontarget species and the environment.

The highly desirable trend with new insect control agents has been to increase efficacy towards target pest species while attempting to reduce the relative toxicity towards mammals and other nontarget species. Among the general populace, natural products are often viewed as inherently safer or "greener" than synthetic organic compounds, a view that ignores or is ignorant of the fact that many natural products are highly toxic to mammals and/or nontarget species (Thompson and Sparks, 2002). However, the spinosyns, in the form of spinosad, do indeed couple excellent levels of efficacy against pest insect species with a highly desirable environmental/toxicological profile.

Data for spinosad, as well as several new insect control agents, shows that toxicity to mammalian, avian, and aquatic species is relatively low when compared with many older and currently used insect control agents (**Table 8**). The relative selectivity of an insect control agent can be quantified (therapeutic index) by comparing the activity of a compound on a target insect pest with the activity towards a nontarget species. One such therapeutic index applied to insect versus mammalian activity is the vertebrate selectivity ratio (VSR) defined by Hollingworth (1976):

$$\mathrm{VSR} = \frac{\text{Acute rat oral LD}_{50}\text{ in mg kg}^{-1}}{\text{Insect LD}_{50}\text{ in }\mu\text{g g}^{-1}} \qquad [1]$$

The VSR for spinosad is among the most favorable in a set of now classic, current and newer insect control agents, when comparing *H. virescens* larvae topical toxicity and rat oral toxicity (Sparks *et al*., 1999; Thompson and Sparks, 2002) (**Table 8**). Thus, the superb mammalian toxicity profile observed for spinosad is further enhanced by the high level of efficacy towards the target insect pests, thereby contributing to spinosad's very favorable toxicology

profile. Additionally, tests conducted for EPA registration showed spinosad to neither leach nor persist in the environment. These factors all contributed to the EPA's registration of spinosad as a reduced risk pesticide in early 1997 (Thompson *et al*., 2000; Thompson and Sparks, 2002), and the bestowing of the Presidential Green Chemistry Award in 1999.

6.5.6. Resistance Mechanisms and Resistance Management

6.5.6.1. Cross-Resistance

Many of the primary insect pests in major markets have a history of developing resistance to insect control agents. Thus, efficacy against insecticide resistant pest insects and the potential for the development of resistance are increasingly important considerations in the development decision for any new insect control agent. Early in the development process, spinosad was examined for efficacy against a variety of insecticide resistant strains of pest lepidopterans, such as larvae of *H. virescens* and *P. xylostella* (Sparks *et al*., 1995). *Heliothis virescens* larvae collected from a number of locations in the mid-southern USA were subjected to discriminating dose assays for a variety of insecticides. Relative to the susceptible strains, larvae collected from almost all of these locations were poorly controlled by cypermethrin (pyrethroid) or profenophos (organophosphate). In contrast, spinosad provided very good to excellent control of all of the strains tested (Sparks *et al*., 1995), demonstrating its utility against insecticide-resistant strains possessing what was likely a mixture of resistance mechanisms (based on the diverse nature of the other insect control agents). Likewise, studies with laboratory strains of *P. xylostella* selected for high levels of resistance to pyrethroid, avermectin, or acylurea insecticides and known to possess enhanced glutathione transferase and/or monooxygenase activity (Chih-Ning Sun, personal communication), showed no appreciable levels of cross-resistance to spinosad (Sparks *et al*., 1995) (**Table 9**). One subsequent study with field-selected strains of *P. xylostella* resistant to the pyrethroid permethrin, has shown a low level of, but broad, cross-resistance to several insect control agents including spinosad and the avermectin emamectin benzoate (Shelton *et al*., 2000) (**Table 9**). However, virtually all other studies involving a variety of insecticide resistant species and strains have shown no cross-resistance to spinosad (**Table 9**). For example, a multiresistant strain of housefly (*Musca domestica*) that was highly resistant (1800-fold and 4200-fold) to the pyrethroids permethrin, and cypermethrin, respectively, exhibited no cross-resistance to spinosad (Liu and Yue, 2000) (**Table 9**). Spinosad was highly effective against a number of strains that were highly resistant to other insect control agents including abamectin (decreased penetration and altered target site), cyclodienes (*rdl*), pyrethroids (monooxygenases, knockdown resistance, and reduced penetration), and organophosphates (altered acetylcholinesterase) (Scott, 1998). Only with the multiresistant LPR strain of housefly was any cross-resistance noted, and that was only at a very low level (Scott, 1998). Taken in total, these data are most consistent with the presence of a unique mode of action for the spinosyns as well as what may be an apparent limited susceptibility of the spinosyn structure to insect metabolic systems.

6.5.6.2. Resistance Mechanisms

While almost all insecticide-resistant strains of pest insects have exhibited little or no cross-resistance to the spinosyns/spinosad, it is nearly axiomatic that if sufficient pressure is put on an insect population, resistance will be developed to any insect control agent, and the spinosyns/spinosad are certainly no exception. This has indeed been borne out in that there are now a few examples of spinosad resistance being developed in the laboratory and in the field.

Resistance to spinosad has been selected for in the laboratory. Bailey *et al.* (1999) used a topical selection protocol to generate a high level of spinosad resistance (toxicity ratio, TR = 1068-fold, topical assay) in larvae of *H. virescens* after 14 generations of selection using methods that favored the development of resistance (NC spinosad-R) (Young *et al*., 2001, 2003). Likewise, a spinosad resistant strain (NYSPINR) of *M. domestica* (TR = >150) was selected in the laboratory starting from a composite of field strains (Shono and Scott, 2003). From this multiresistant NYSPINR strain, a further spinosad resistant strain (*rspin*) was developed that was specifically resistant to only spinosad and also incorporated a number of recessive mutant markers (Shono and Scott, 2003). For spinosad resistant strains of both *H. virescens* (NC-spinosad-R) and housefly (*rspin*), cross-resistance to other insect control agents such as emamectin benzoate, indoxacarb, acetamiprid, abamectin, etc. was negligible (Young *et al*., 2001; Shono and Scott, 2003) (**Table 9**). Both studies also showed spinosad resistance to be linked to a single, non sex-linked, recessive gene (Shono and Scott, 2003; Wyss *et al*., 2003). Studies with the NYSPINR housefly strain also showed no synergism of spinosad activity with piperonyl butoxide, *S,S,S*-tributylphosphorothioate (DEF), or diethyl maleate (DEM), suggesting that metabolism was not likely to be the

basis for the observed resistance. In the case of the NC-spinosad-R *H. virescens* larvae, studies also showed that the resistance to spinosad did not appear to be associated with enhanced metabolism, decreased penetration, or excretion (Young *et al.*, 2000, 2001). At low concentrations, a decreased neural sensitivity was observed in the resistant strain (Young *et al.*, 2001). Thus, available data for both these spinosad resistant strains is most consistent with an altered target site resistance mechanism.

In addition to the laboratory selection studies, there are now a couple of studies indicating the presence of resistance to spinosad in field-collected insects. Surveys of beet armyworm (*Spodoptera exigua*) populations from the US and Thailand showed that there was a wide range in the biological response to spinosad when compared to a US Department of Agriculture (USDA) susceptible reference colony (Moulton *et al.*, 1999, 2000). Compared to the USDA larvae, toxicity ratios for an Arizona strain ranged from 14-fold to 20-fold, depending on assay method, while those of the Thailand strain ranged from 58-fold to 85-fold. Interestingly, the F_1 hybrids from the Thailand colony possessed toxicity ratios of 22-fold compared to the USDA strain, suggesting that the reduced susceptibility was incompletely dominant (Moulton *et al.*, 2000). Subsequent studies with the Thailand strain showed that susceptibility was returning after some time in laboratory culture (toxicity ratio declined to 15-fold) and that synergists (Piperonyl butoxide, DEF, and DEM) did not alter spinosad activity (Moulton *et al.*, 1999).

In mid-1998, spinosad was registered in Hawaii, for use on crucifers, for the control of *P. xylostella* larvae that had become resistant to all other then available insect control agents (Zhao *et al.*, 2002). Unfortunately, resistance management strategies incorporated into the spinosad label by the manufacturer did not foresee the particular cultural practices used in Hawaii. In many cases, the practices then in use resulted in nearly exclusive, almost continuous, year-round, weekly applications of spinosad to sequential crop plantings involving the same *P. xylostella* population, a situation that went on for more than 2 years. In 2000, field failures were observed with spinosad in Hawaii. Subsequent laboratory testing of the *P. xylostella* populations around the growing regions of the Hawaiian Islands demonstrated the presence of high levels of resistance to spinosad in several locations (Zhao *et al.*, 2002). Further laboratory selection, for nine generations, of one of the most resistant colonies (Pearl City, Oahu) with spinosad, increased resistance towards spinosad to an even larger degree (Zhao *et al.*, 2002). As noted above for the laboratory-selected spinosad-resistant strains of *H. virescens* and *M. domestica*, resistance to spinosad in this spinosad-selected strain of *P. xylostella* was also an autosomal, incompletely recessive trait (Zhao *et al.*, 2002), which has led to the rapid dissipation of resistance. Likewise, the synergists piperonyl butoxide and DEF did not alter the level of resistance to spinosad, and there was no cross-resistance to either emamectin benzoate or indoxacarb. While these data are of a limited nature, like those above, they are most consistent with an altered target site as the resistance mechanism.

6.5.6.3. Resistance Management

The development of any new insect control agent is a very expensive proposition. For a company to derive full value, a new molecule must remain in the marketplace for many years. Thus, the development of resistance has become an increasingly important consideration in the development of any new insect control agent. In light of spinosad's uniqueness, as well as the expense and effort that led to its development, insecticide resistance management (IRM) was a consideration at an early stage in the development of spinosad, (Thompson *et al.*, 2000). The goal of this effort was to increase the likelihood of spinosad's long-term efficacy and utility in the marketplace. One aspect of the IRM program was the incorporation of use patterns on the product label that reduced the likelihood of selecting back-to-back generations of insect pests. The IRM recommendation from the manufacturer included limiting use to three or fewer applications within a 30-day period, followed by another 30-day period during which spinosad was not to be used (Zhao *et al.*, 2002). For most lepidopterous pests, this spinosad-free period would allow at least one complete generation that had not been selected. A total of only six applications was allowed per crop (Zhao *et al.*, 2002). Another aspect of the spinosad IRM plan was implementation of a program to monitor the susceptibility of key insect pests.

As demonstrated repeatedly over the past 50 years, given time and very heavy selection pressure, resistance can develop to any insect control agent (Sparks *et al.*, 1993; Clark and Yamaguchi, 2002). Likewise, as demonstrated by the development of spinosad resistance in *P. xylostella* in Hawaii, not every use pattern or scenario can be foreseen. The practice of having multiple "crops" at different stages in adjacent fields effectively negated IRM recommendations for spinosad. However, the monitoring program that was in place was able to quickly provide needed susceptibility data for a number of sites in the Hawaiian Islands. While the initial data showed most sites to be free of problems, several

sites were also shown to exhibit significant levels of resistance to spinosad that increased with time and were associated with failures to control *P. xylostella* larvae in the field (Zhao *et al.*, 2002). As a response to these developments, a regional IRM program was implemented (Zhao *et al.*, 2002; Mau and Gusukuma-Minuto, 2004). Spinosad was voluntarily withdrawn from use where field failures had occurred and two newly registered products, emamectin benzoate and indoxacarb, were put into a rotation scheme (Mau and Gusukuma-Minuto, 2004). Following its withdrawal from use, susceptibility to spinosad increased rapidly such that for some of the locations (Maui and Hawaii) the thresholds for spinosad reintroduction were met within 6-8 months, setting the stage for spinosad's reintroduction in early 2002 (Mau and Gusukuma-Minuto, 2004). By the fall of 2002, resistance to spinosad had also fallen below the threshold in the remaining region (Oahu) such that it was reintroduced in early 2003 (Mau, personal communication). With its reintroduction, spinosad has become part of an IRM rotation scheme that also includes emamectin benzoate and indoxacarb (Mau, personal communication). Given the selection pressure that was placed on spinosad in several of the locations in Hawaii, it is not clear how long this rotation scheme will remain effective in the control of a pest that has developed resistance to virtually all insecticides previously used. Nevertheless, this experience with spinosad in Hawaii has demonstrated that IRM can indeed help extend, if not preserve, the life of an insect control agent.

6.5.7. Spinosyns and Spinosoid Structure–Activity Relationships

Exploration of the spinosyns included continued isolation and identification of new spinosyns (naturally occurring analogs of spinosyn A). This effort

ultimately led to the isolation more than 20 new spinosyns from *S. spinosa* (see Section 6.5.2.1), and an expanding number from *S. pogona* (Hahn *et al.*, 2002; Lewer *et al.*, 2003). At the same time, running in parallel with the spinosyn isolation program, was a long-standing effort aimed at the preparation of semisynthetic derivatives/analogs of the spinosyns, termed spinosoids. In light of the excellent activity against lepidopterans and the desire for greater utility, the spinosoid synthesis program had two goals. The first was to increase activity against lepidopterans, typically using *H. virescens* larvae as an indicator species. The second goal was, if possible, to expand the spectrum of this unique chemistry. To date, the total number of spinosyns and spinosoids resulting from this long-standing and continuing effort easily exceeds 1000 molecules, the vast majority being spinosoids.

Chemistry around the spinosyns has been focused on modifications to various functionalities in the spinosyn structure, which has been both limited by and facilitated by the novel chemical nature of these molecules. These modifications can loosely be grouped into:

- modifications of the tetracycle,
- modification/replacement of the forosamine sugar, and
- modification/replacement of the tri-*O*-methyl rhamnose sugar.

Due to limited quantities of starting material, initial modifications to the spinosyn structure were limited to relatively simple or straightforward modifications, most often associated with a reduced level of activity. Later modifications did ultimately succeed in devising spinosoids that were more active than the naturally occurring spinosyns (Sparks *et al.*, 2000a, 2001; Crouse *et al.*, 2001).

6.5.7.1. Modifications of the Tetracycle

The tetracycle of spinosad is a rather rigid structure, the shape of which is influenced, in part, by the conjugated 13,14 double bond. Hydration of the 13,14 double bond (compounds 71 and 72) alters the three-dimensional shape of the tetracycle, which is associated with a reduction in activity (Crouse and Sparks, 1998; Crouse *et al.*, 1999) (**Table 3**). The 13,14-α-dihydro (compound 71) results in less of a conformational change and hence less of a distortion than the corresponding 13,14-β-dihydro (compound 72), which is reflected in the better activity of the α-analog (**Table 3**). Not surprisingly, reduction of both the 5,6 and 13,14 double bonds (compounds 69 and 70) reduces activity against *H. virescens* larvae (Crouse *et al.*, 1999) and is neutral to negative for stable flies (Kirst *et al.*, 2002a) and mites (**Table 3**). In contrast, a reduction of only the 5,6 double bond (compound 70) has little effect on the three-dimensional shape or on activity towards *H. virescens* larvae, but reduces activity to stable flies, and is associated with an increase in activity against aphids and mites (Crouse *et al.*, 2001) (**Table 3**). Likewise, the 5,6-β-epoxy analog of spinosyn A is about as active against *H. virescens* larvae as spinosyn A, while the 5,6-α-epoxy analog (compound 74) is much less active (**Table 3**). Both 5,6-epoxides are slightly less effective against stable fly adults compared to spinosyn A, while the 5,6-β-epoxy analog is, just like the 5,6-dihydro derivative (compound 74), more active against mites (**Table 3**). Thus, for larvae of *H. virescens* and stable fly adults, alteration of the 5,6 double bond provides no improvement in activity, while some interesting increases in activity are noted for *T. urticae* (**Table 3**). In general, for *H. virescens* larvae, any modification to the internal structure of the tetracycle reduces activity (Crouse *et al.*, 1999), with the exception of the addition of extra unsaturation at the 7–11-position of spinosyn D (compound 73), which is about as active as spinosyn A (**Table 3**). Many other synthetic modifications have been made to the tetracycle (Crouse and Sparks, 1998; Crouse *et al.*, 1999) but none has provided a significant overall improvement in biological activity.

Where chemical synthesis has been unable to thus far succeed, mother nature, and the genetic manipulation thereof, have been able, in part, to fill the gap. Extension of the alkyl group at C21 to *n*-propyl (compound 30), produced through alteration of polyketidesyntase (PKS) modules (Burns *et al.*, 2003), provides a slight improvement in activity over spinosyn A against *H. virescens* larvae and aphids (**Table 3**). Further extension of the C21 position to 21-butenyl (compound 31), the primary factor produced by *S. pogona* (Lewer *et al.*, 2003), provides activity against *H. virescens* equivalent to spinosyn A. However, for *Aphis gossypii*, activity is further improved over C21-*n*-propyl (compound 30) (**Table 3**). Unfortunately, as with the other modifications that have improved intrinsic aphid and mite activity, the physical properties of the spinosyns thus far discovered generally preclude the effective plant mobility and residuality necessary for effective control of aphids or mites in the field (Crouse *et al.*, 2001).

6.5.7.2. Modification or Replacement of the Forosamine Sugar

As described above (see Section 6.5.7.1) for the spinosyns, removal of a methyl group from the forosamine nitrogen tends to be a fairly neutral

modification, resulting in a slight decrease (spinosyns A to B, spinosyns H to R, spinosyn L to N) or a modest increase in activity (spinosyn J to M). An increase in alkyl size for one of the positions on the forosamine nitrogen (i.e., ethyl and *n*-propyl; compounds 64 and 65) has little effect on *H. virescens* activity, while further increases in bulk greatly reduce activity (compounds 66 and 67). In contrast, *T. urticae* activity is only increased by these same modifications as is, to a lesser degree, activity against *A. gossypii* (Table 3). Replacement of the forosamine *N,N*-dimethylamine moiety with a hydroxyl (compound 68), reduces activity against *H. virescens* larvae while, apparently (response can be variable), increasing aphid activity (Table 3). Loss of the entire forosamine moiety results in major loss of activity (Sparks *et al.,* 1999) (Table 2) with only a small improvement noted by replacement with an acetate (C17-acetate, compound 79) group. Substitution of the forosamine with *N,N*-dimethylaminoacyl esters (compounds 80–82) only partially restores activity (Kirst *et al.,* 2002b) (Table 3). *N*-methylamino piperazinyl-acetate (compound 83) or *N,N*-dimethylamino-piperidinylacetate esters (compound 84) at C17 go further towards restoring activity against *H. virescens* and *Stomoxys calcitrans*, but still fall far short of the activity observed with forosamine (spinosyn, compound 1) (Kirst *et al.,* 2002b) (Table 3). A similar trend is observed with *S. calcitrans* (stable fly). Thus, for the lepidopterans, the above modifications to the forosamine do not lead to improvements in activity. In contrast, both aphid and mite activity were improved by replacement of the forosamine *N*-methyl groups with larger alkyl groups (compounds 64–67).

6.5.7.3. Modification or Replacement of the Tri-*O*-Methyl-Rhamnose Sugar

While many of the early synthetic modifications to the spinosyn structure were insecticidal, all of the early spinosoids were typified by a somewhat reduced or most often an almost total lack of *H. virescens* activity compared to spinosyn A. However, an exception was found in the form of the desmethoxy (2′-H or 3′-H) analogs of spinosyns H/Q and J, respectively (compounds 35, 36 and 43) (Table 3). These “desmethoxy” analogs were found to be as active against *H. virescens* larvae or slightly more so, than spinosyn A (Creemer *et al.,* 2000; Kirst *et al.,* 2002b) (Table 2). These modifications constituted the first clear indication that spinosoids at least matching the activity of the most active of the natural spinosyns (i.e., spinosyn A) were possible.

Concurrent with the synthetic efforts, several computer-aided modeling and design (CAMD) approaches were examined in an attempt to identify potential synthetic directions for improved analogs. Included among the computer modeling approaches initially used were comparative molecular field analysis (CoMFA) and Hansch-style quantitative structure–activity relationships (QSAR) (Crouse and Sparks, 1998). However, the large molecular size and complex structure rendered the available computing power insufficient to the task for these more conventional methodologies and generally made QSAR difficult. However, where conventional CAMD techniques were not successful, the application of artificial neural networks to spinosyn QSAR (Sparks *et al.,* 2000a) identified new directions that led to, as one example, new modified-rhamnose spinosoids. These latter compounds were in many cases far more active than spinosyn A against pest lepidopterans (Crouse and Sparks, 1998; Sparks *et al.,* 2000a, 2001; Anzeveno and Green, 2002).

As shown by the activity of the 2′, 3′, 4′-demethyl analogs from the mutant strains, *O*-demethylation generally leads to less active compounds compared to spinosyn A (Table 2). Loss of the rhamnose also leads to a large reduction in activity (Table 2). The first spinosoids possessing any kind of improvement in lepidopteran activity over spinosyn A were (as noted above) the des-methoxy (2′-H (compounds 35 and 36), or 3′-H (compound 43) analogs of spinosyns H/Q and J, respectively (Table 3). For the 2′-substituted spinosoids, the 2′-des-methoxy analog (compound 35) along with the 2′-*O*-ethyl (compound 37) and 2′-*O*-*n*-propyl (compound 39) represent the most active of the 2′-substitution-based analogs, which are as active or very slightly more so than spinosyn A. Likewise, modifications of the 4′-position of the rhamnose (e.g., compound 60) results in no real activity improvement over spinosyn A, with the exception of the 4′-des-methyoxy analog (compound 59), which generally remains equivalent or nearly so, to spinosyn K (4′-O-demethyl, compound 23) (Table 3). Thus, in general, modifications to the 2′- or 4′-positions do little to improve activity compared to spinosyn A.

Unlike the 2′- and 4′-positions (e.g., compounds 37 and 60), a genuine improvement in *H. virescens* activity was found to be associated with an increased size of the alkoxy groups on the rhamnose at the 3′-position (compounds 46–52) (Sparks *et al.,* 2000a). At the 3′-position, the activity optimum is between two to three carbons. Further increases in bulk or length resulted in a loss of activity (Sparks *et al.,* 2000a, 2001; Crouse *et al.,* 2001). The introduction of unsaturation into these short alkyl chains (e.g., compounds 47, 53, 54) was generally neutral in effect, while branching was detrimental (compounds

49 and 50) (Table 3). The 3′-O-vinyl analog (compound 47) could represent a very active configuration, but stability issues resulted in erratic results (Crouse *et al.*, 2001). Other modifications to the alkyl chains (halogenation, introduction of another oxygen, etc.) were generally not as effective as the simple alkyl chains (compounds 55 and 57) (Crouse *et al.*, 2001) (Table 3). While the optimum in 3′-O-alkyl chain length for lepidopterous larvae such as *H. virescens* (Crouse *et al.*, 2001), beet armyworm (*Spodoptera exigua*) and cabbage looper (*Trichoplusia ni*) (data not shown) is between two and three carbons (e.g., compounds 46, 48, 53 and 54), the optimum for aphids such as *A. gossypii* extends to four carbons (compound 51) (Crouse *et al.*, 2001) (Table 3). Unlike either aphids or lepidopterans, the longer chain 3′-O-alkyl groups (C2–C4) (compounds 46, 48, and 51, respectively) were essentially equivalent in activity for *T. urticae* (Table 3) and were only modestly more active than spinosyn A.

Interestingly, the 2′,3′,4′-tri-O-ethyl analog (compound 62) is essentially as potent against *H. virescens* larvae, *A. gossypii*, and *T. urticae* as the 3′-O-ethyl derivative (compound 46) (Table 3), further supporting the importance of the 3′-position of the rhamnose to insecticidal activity.

In addition to modifications to the tri-O-methylrhamnose moiety, the effects of rhamnose replacement with other sugar and nonsugar moieties were also investigated (Anzeveno and Green, 2002). These studies demonstrated that very little change around the rhamnose moiety is tolerated. Replacement sugars such as D-rhamnose, the β-anomeric rhamnose, furanose, and forosaminyl analogs (not shown) were much less active or inactive against *H. virescens* larvae and *T. urticae* (Anzeveno and Green, 2002). In contrast, removal of the methyl group at the 6′-position (L-lyxose analog, compound 85) had little effect on activity relative to spinosyn A, while addition of hydroxy to the 6′-methyl group (L-mannose, compound 86) provided a very significant improvement in activity over spinosyn A (Anzeveno and Green, 2002), nearly equaling that of the 3′-O-ethyl analog (compound 46). Replacement of the tri-O-methylrhamnose with nonsugar moieties such as simple alkyl groups or methoxy-substituted benzoyl groups (compounds not shown) all were found to be inactive (Anzeveno and Green, 2002).

6.5.7.4. Quantitative Structure–Activity Relationships and the Spinosyns

The above examples (see Sections 6.5.7.1–6.5.7.3) clearly demonstrate that very significant improvements in activity of the spinosyns are possible, both in terms of potency towards a particular pest or group of insect pests and greater spectrum. These improvements, especially those involving rhamnose ring modifications, were facilitated through the application of both classical and less conventional CAMD techniques early in the project. The QSAR analysis of the spinosyns conducted using artificial neural networks directly led to the identification and synthesis of far more potent spinosoids than had been seen up to that time (Sparks *et al.*, 2000a, 2001; Anzeveno and Green, 2002). The analysis identified several potential modifications to improve activity, including the lengthened alkyl groups on the rhamnose, and also pinpointed the 3′-position as the most important for activity (Sparks *et al.*, 2000a, 2001). While the neural net-based QSAR was able to identify useful targets for synthesis, understanding the physicochemical basis for the improved activity is not a question easily addressed with neural nets (Sparks *et al.*, 2001). Thus, more classical approaches have also been employed. Hansch-style multiple regression analysis (Kubinyi, 1993) of the spinosyns and spinosoids was able to establish some relationships between insecticidal activity against *H. virescens* larvae and several physicochemical parameters.

Among the spinosyns, the biological response of *H. virescens* larvae was best described by the three whole-molecule parameters, CLogP, Mopac dipole (dipole moment of the whole spinosyn molecule), and HOMO (highest occupied molecular orbital) (Sparks *et al.*, 2000b):

$$\begin{aligned}\text{Log } Hv\, \text{LC}_{50} &= -2.18\ \text{CLogP} + 0.61\ \text{Mopac dipole} \\ &\quad + 2.89\ \text{HOMO} + 33.74 \\ r^2 &= 0.824, \quad s = 0.372, \quad F = < 0.0001, \\ q^2 &= 0.724, \quad n = 18 \end{aligned} \qquad [2]$$

For a larger set of spinosyns and spinosoids, these same parameters (eqn [3]) were also able to explain much of the observed insecticidal activity towards *H. virescens* larvae (Sparks *et al.*, 2001). The addition of the squared term for CLogP (eqn [3]) also reflects the presence of an optimum of between two and three carbons at the rhamnose 3′-position, that is observed for *H. virescens* larval activity (Sparks *et al.*, 2001) (Table 3):

$$\begin{aligned}\text{Log } Hv\, \text{LC}_{50} &= -6.62\ \text{CLogP} + 0.67\ \text{CLogP}^2 \\ &\quad + 0.59\ \text{Mopac dipole} \\ &\quad + 3.09\ \text{HOMO} + 43.05 \\ r^2 &= 0.816, \quad s = 0.475, \quad F = < 0.0001, \\ q^2 &= 0.706, \quad n = 34 \end{aligned} \qquad [3]$$

For the spinosyns and spinosoids, HOMO appears to be directly influenced by substitution on the forosamine nitrogen (Sparks *et al.*, 2000b) suggesting that the primary drivers for activity are CLogP and Mopac dipole moment. In turn, Mopac dipole moment appears rather well correlated with the substitution pattern on the rhamnose moiety, and secondarily by substitution on the forosamine nitrogen (Sparks *et al.*, 2001). As implied by the above equations, the most active spinosyns and spinosoids tend to have smaller values for Mopac dipole moment and larger values (up to a point) for CLogP (Sparks *et al.*, 2001). Thus, these relationships provide a useful basis for understanding spinosyn and spinosoid activity not only against lepidopteran insect pests but also for other pest insects, including aphids and leafhoppers (Dintenfass *et al.*, 2001). CAMD and QSAR continue to play an important role in the investigation and exploitation of the spinosyn family of chemistry.

6.5.8. Conclusion

The natural spinosyns produced by select members of the genus *Saccharopolyspora*, and their semisynthetic derivatives, known as spinosoids, constitute a new and unique class of insect control agents. The spinosyns possess a novel mode of action, a very favorable toxicological profile coupled with high insecticidal efficacy against a broad range of pest insects, with commercial use focused on the Lepidoptera and, to a lesser degree, the Diptera. The commercial fermentation-derived product, spinosad, is a naturally occurring mixture of spinosyns A and D, which also happen to be the most insecticidally active of the natural spinosyns produced by *S. spinosa*. While possessing good contact activity, the spinosyns are most often more active orally, in part due to the slow cuticular penetration of the spinosyns compared to many insect control agents. Although spinosyns A and D are readily metabolized in vertebrate and avian systems, metabolism in insects is limited, compensating in part for slow penetration into insects. The spinosyns cause excitatory symptoms in insects by stimulating activity in the CNS. Activation of nondesensitizing nicotinic acetylcholine receptors by an allosteric mechanism appears to be the primary mechanism by which spinosyns stimulate neuronal activity, but antagonism of an as-yet-unidentified subtype of GABA receptor may also play a significant role in spinosyn poisoning. Through an extensive program of strain selection, genetic manipulation of the biosynthetic pathways and chemical synthesis, the effects of many modifications to the forosamine and rhamnose moieties as well as to the core tetracycle have been investigated. This experience, with guidance from classical modeling approaches as well as the application of QSAR methodologies utilizing artificial intelligence, has led to the synthesis of spinosoids with biological activity far exceeding that of spinosyn A. Because of its unique mode of action and limited susceptibility to metabolism in insects, pest insects resistant to other insecticides would typically not show cross-resistance to spinosad. However, as expected for any insect control agent put under heavy selection pressure, resistance to spinosad has been developed in the laboratory and has also recently appeared in the field. Available information suggests that resistance to spinosad is most likely target-site based, reinforcing the importance of the IRM recommendations developed by the manufacturer at the time of its launch that spinosad be used in rotation with products with other modes of action to ensure the long-term utility of this novel chemistry.

Acknowledgments

The authors would like to thank their many colleagues from Eli Lilly and Co., and Dow AgroSciences (DAS) who have contributed to our knowledge of the spinosyns. Special thanks are due to Mr. Jerry Watson (DAS), Dr Nailah Orr (DAS), Dr Gary Thompson (DAS), Dr Mark Hertlein (DAS), Dr Gary Crouse (DAS), Dr Paul Lewer (DAS), and Dr Ron Mau (University of Hawaii) for their many helpful discussions during the writing of this chapter.

6.6 *Bacillus thuringiensis*: Mechanisms and Use

A Bravo and M Soberón, Instituto de Biotechnología, Cuernavaca Morelos, Mexico
S S Gill, University of California, Riverside, CA, USA

6.6.1. General Characteristics

Bacillus thuringiensis is a member of the *Bacillus cereus* group that also includes *B. cereus*, *B. anthracis*, and *B. mycoides* (Helgason *et al.*, 2000). The feature that distinguishes *B. thuringiensis* from the other members of the *B. cereus* group is its entomopathogenic properties. This bacterial species produces insecticidal proteins (δ-endotoxins) during sporulation phase as parasporal inclusions, which predominantly comprise one or more proteins, called Cry and Cyt toxins. These protein toxins are highly selective to their target insect, are innocuous to humans, vertebrates, and plants, and are completely biodegradable. Therefore, *B. thuringiensis* is a viable alternative for the control of insect pests in agriculture and disease vectors of importance in human public health.

Numerous *B. thuringiensis* strains have been isolated that show activity towards lepidopteran, dipteran, or coleopteran insects (Schnepf *et al.*, 1998). In recent years *B. thuringiensis* strains active against Hymenoptera, Homoptera, Orthoptera, and Mallophaga insect orders and to other noninsect organisms like nematodes, mites, and protozoa have been isolated (Crickmore *et al.*, 1998; Wei *et al.*, 2003). The entomopathogenic activity of *B. thuringiensis* is mainly due to Cry toxins. One feature that distinguishes these Cry proteins is their high selectivity for their target insect. More than 200 different *cry* genes have been isolated, and this constitutes an important arsenal for the control of a wide variety of insect pests. In this chapter we will summarize the present knowledge of the pathogenic properties of *B. thuringiensis*,

the mode of action of Cry toxins, and their application in agriculture and disease-vector control.

6.6.2. Virulence Factors and the PlcR Regulon

The *B. cereus* group is characterized by its pathogenic capabilities to a diverse group of organism, such as mammals in the case of *B. anthracis* and *B. cereus,* and insects in the case of *B. thuringiensis*. The pathological characteristics of the different members of the *B. cereus* group are mainly due to the presence of specific toxin genes that for the most part encoded by large, self-transmissible extrachromosomal plasmids (Schnepf *et al*., 1998). However, other chromosomal encoded virulence factors contribute to the pathogenic effects of different members of the *B. cereus* group (Dubois and Dean, 1995; Lereclus *et al*., 1996; Agaisse *et al*., 1999; Guttman and Ellar, 2000). In the case of *B. thuringiensis*, it has been known for some time that the spores synergize the effects of Cry proteins (Dubois and Dean, 1995). This synergistic effect was shown to be due to the production of several virulence factors, such as α-exotoxins, β-exotoxins, chitinases, phospholipases, and enterotoxins (Lereclus *et al*., 1996; Agaisse *et al*., 1999; Guttman and Ellar, 2000).

Mutation of genes encoding some of these virulence factors showed that they contribute to the pathogenicity of *B. thuringiensis* to insects (Lereclus *et al*., 1996; Fedhila *et al*., 2002). In the case of phosphatidylinositol specific phospholipase C (PI-PLC), disruption of the structural gene *plcA* diminished the synergistic effects of spores indicating that at least this virulence factor was necessary for an efficient virulence of the bacterium (Lereclus *et al*., 1996). This is also the case for the *inhA*2 gene that codes for a zinc-requiring metalloprotease (Fedhila *et al*., 2002). Characterization of the mechanism controlling *plcA* gene expression led to the discovery of a pleiotropic transcriptional regulator, PlcR. Mutations in the *plcR* gene abolished *plcA* gene expression and the virulence of the bacterium (Lereclus *et al*., 1996; Agaisse *et al*., 1999). A genetic screening of PlcR regulated genes identified several extra cellular virulence factors including a secreted RNase, an S-layer protein, phospholipase C, and enterotoxins, indicating that the PlcR regulon includes a diverse set of virulence factors (Agaisse *et al*., 1999). Also, the *inhA*2 gene was shown to be under the control of PlcR (Fedhila *et al*., 2003). A proteome analysis of secreted proteins from *B. cereus* strain ATCC 14579 showed that disruption of the *plcR* gene reduced the levels at least 56 exported proteins (Gohar *et al*., 2002). Alignment of the promoter regions of the PlcR regulated genes identified a 20-nucleotide palindromic sequence ("PlcR box") that is required for PlcR activation (Agaisse *et al*., 1999). Although, several PlcR regulated genes are also present in *B. cereus* and *B. anthracis* (Guttman and Ellar, 2000), only the *B. cereus* PlcR protein is functionally equivalent to that of *B. thuringiensis*, since the *B. anthracis plcR* gene is disrupted by a transposon-like sequence indicating that production of virulence factors in *B. anthracis* is blocked or may be different from that of *B. thuringiensis* and *B. cereus* (Agaisse *et al*., 1999). In fact, expression of a functional PlcR in *B. anthracis* leads to the activation of a large set of genes encoding enzymes and toxins that have protease, phospholipase, and hemolysis activities (Mignot *et al*., 2001).

PlcR regulated genes are expressed at the end of the vegetative growth phase during the stationary phase of growth (Lereclus *et al*., 1996). PlcR expression is negatively regulated by the sporulation key factor Spo0A, indicating that this gene is only temporally expressed in vegetative cells before the onset of sporulation (Lereclus *et al*., 1996). The PlcR protein senses cell density and is, therefore, part of a quorum sensing mechanism (Slamti and Lereclus, 2002). The *papR* gene, which encodes a 48 amino acid peptide and is located downstream of the *plcR* gene, is activated by PlcR and the gene product is secreted. Outside the cell, PapR is degraded by extra cellular proteases and the C-terminus end pentapeptide is internalized to the bacterium cytoplasm by the oligopeptide permease Opp (Slamti and Lereclus, 2002). Inside the cell, the pentapeptide binds PlcR activating the capacity of PlcR to bind to the PlcR box sequence. This binding then induces the activation of PlcR specific gene expression (Slamti and Lereclus, 2002). It was also shown that the PlcR activating peptide is strain specific for the activation of the PlcR regulon. Single amino acid changes on the activating PapR peptide were enough for strain-specific induction of the PlcR regulon (Slamti and Lereclus, 2002). These results suggest that quorum sensing of related *B. thuringiensis* strains is restricted by the sequence homology of the C-terminal pentapeptide of PapR. **Figure 1** shows the PlcR regulon network including the gene targets and the regulation of PlcR activation by PapR protein.

6.6.3. Insecticidal Toxins

6.6.3.1. Classification and Nomenclature

The major determinants of *B. thuringiensis* insecticidal properties are the δ-endotoxins (Schnepf *et al*., 1998). These endotoxins form two multigenic families, *cry* and *cyt*. Cry proteins are specifically toxic to orders of insects, Lepidoptera, Coleoptera,

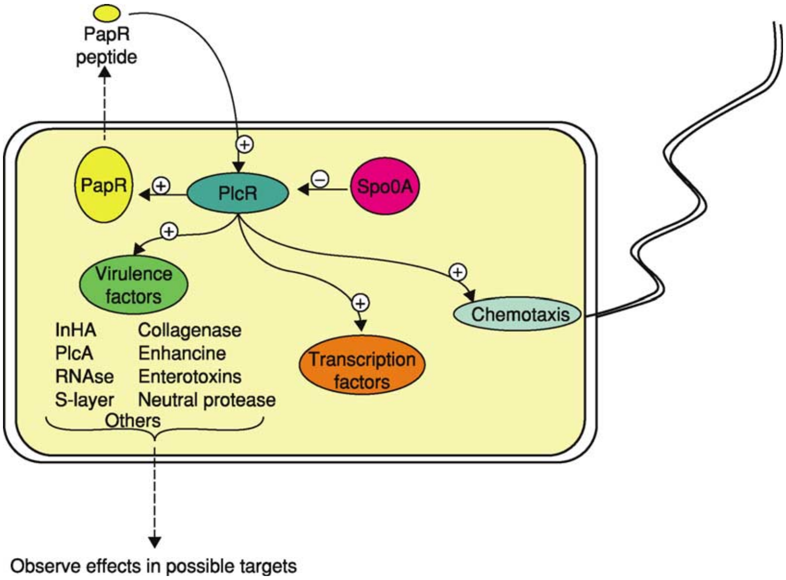

Figure 1 The PlcR regulon in *Bacillus thuringiensis*. Positive (+) and negative (−) regulation in the PlcR regulon are shown.

Hymenoptera, and Diptera. In contrast, Cyt toxins are mostly found in *B. thuringiensis* strains active against Diptera, although a few exceptions of coleopteran active strains containing Cyt proteins have been documented (Guerchicoff *et al*., 2001). Besides these crystals proteins, some *B. thuringiensis* and *B. cereus* strains produce a third group of insecticidal proteins called vegetative insecticidal proteins (Vip proteins) (Estruch *et al*., 1996). In contrast to crystal proteins, the Vip proteins are synthesized during the vegetative growth phase of the bacterium and secreted into the medium without forming crystal inclusions.

The Cry proteins comprise 40 subgroups with more than 200 members. The definition of Cry proteins is rather broad: a parasporal inclusion protein from *B. thuringiensis* that exhibits toxic effect to a target organism, or any protein that has obvious sequence similarity to a known Cry protein (Crickmore *et al*., 1998). This definition includes the Cyt toxins although the mnemonic Cyt is given for Cry proteins that are structurally related to Cyt toxins (Crickmore *et al*., 1998, 2002). The nomenclature of Cry and Cyt proteins is based on primary sequence identity among the different protein sequences. Crystal proteins receive the mnemonic Cry or Cyt and four hierarchical ranks consisting of numbers, capital letters, lowercase letters, and numbers (e.g., Cry1Ab1). The ranks are given depending on the sequence identity shared with other Cry or Cyt proteins. A different number (first rank) is given to a protein if it shares less than 45% identity with all the others Cry proteins (Cry1, Cry2, etc.). The capital letter (second rank) is given if the protein shares less than 78% but more than 45% identity with a particular group of Cry proteins (e.g., Cry1A, Cry1B, etc.). The third rank, a lowercase letter, is given to distinguish proteins that share more than 78% but less than 95% identity with other Cry proteins (e.g., Cry1Aa, Cry1Ab, etc.). Finally a number is given to distinguish proteins that share more than 95% identity, but which are not identical and should be considered variants of the same protein (Crickmore *et al*., 1998, 2002). Although this system does not take into account the insect selectivity of Cry toxins, some subgroups of Cry toxins show toxicity against a particular genus of insects. Thus Cry1 proteins are active principally against lepidopteran insects, while the Cry3 proteins are toxic towards coleopterans. In the case of dipteran-active toxins, a surprisingly high number of different subgroups are active. For example, Cry proteins that share low sequence similarity (e.g., Cry1C, Cry2Aa, Cry4, Cry11, etc.) are active against mosquitoes.

Bacillus thuringiensis strains produce different proteins that are not related phylogenetically and all these subfamilies comprise the Cry family. Among these are: the three-domain Cry family; the larger group of Cry proteins (formed by 30 different Cry subgroups); the binary-like toxins (Cry35 and Cry36); and Mtx-like toxins (Cry15, Cry23, Cry33, Cry38, and Cry40), which are related to toxins produced by *B. sphaericus* (Crickmore *et al*., 1998, 2002). The Cry35 requires the Cry34 toxin to induce the lethal effects against *Diabrotica virgifera*

(Ellis *et al.*, 2002). The Cry34 is not related to other toxins but as mentioned above is the binary partner of Cry35. Similarly the coleopteran specific Cry23A toxin functions effectively only in the presence of the Cry37 protein (Donovan *et al.*, 2000). The sequence of Cry37 is not related to other proteins in the database but showed some similarities with Cry22 (Baum and Light Mettus, 2000) and Cry6, which are coleopteran specific (Thompson *et al.*, 2001) and also nematode specific toxins (Wei *et al.*, 2003).

The members of the three-domain family are globular molecules containing three distinct domains connected by single linkers. The alignment of their protein sequences revealed the presence of five conserved sequence blocks, although, some blocks are absent in some subgroups of the three-domain family. One particular feature of the members of this family is the presence of protoxins with two different lengths. One large group of protoxins is approximately twice as long as the majority of the toxins (130 or 70 kDa). The C-terminal extension found in the longer protoxins is dispensable for toxicity but is believed to play a role in the formation of the crystal inclusion bodies within the bacterium (de Maagd *et al.*, 2001).

Cyt toxins comprise two highly related gene families (*cyt1* and *cyt2*) (Crickmore *et al.*, 1998, 2002). Analysis of amino acid sequences shows that the different Cyt versions show a high degree of conservation in predicted α-helices and β-sheets (Guerchicoff *et al.*, 2001). Cyt toxins are also synthesized as protoxins and small portions of the N-terminus and C-terminus are removed to activate the toxin (Li *et al.*, 1996). Cyt proteins are almost exclusively found in dipteran active strains, although a few exceptions have been found as the presence of Cyt in coleopteran specific strains (Guerchicoff *et al.*, 2001). Cyt toxins synergize the toxic effect of some Cry proteins against different targets and also that of the *B. sphaericus* binary toxin (Wu *et al.*, 1994; Sayyed *et al.*, 2001; Wirth *et al.*, 2001). In the case of the three-domain Cry and Cyt proteins it is widely accepted that the primary action of these toxins is the formation of lytic pores in the midgut cells of susceptible insects. **Figure 2** shows the phylogenetic dendogram of Cry and Cyt toxins (Crickmore *et al.*, 2002).

Finally, Vip proteins comprise three families with seven members. The *vip1* and *vip2* genes are located in a single operon, and the proteins encoded by these genes constitute a binary toxin since both are necessary for toxicity against coleopteran larvae. The Vip1 and Vip2 proteins are 100 and 52 kDa in size, respectively (Warren, 1997). The mechanism of action of these proteins has not been clearly described. Nevertheless, the three-dimensional structure of Vip2 protein indicates that it may have ADP-ribosylating activity (Craig *et al.*, 1999). The Vip3 protein (88 kDa) is toxic to several lepidopteran larvae (Estruch *et al.*, 1996). A preliminary mode of action of Vip3 has been recently described. This protein is proteolytically activated by proteases present in the midgut juice extract or by trypsin to a 62 kDa resistant fragment, which binds two proteins of 80 and 100 kDa located in the apical membrane of the lepidopteran midgut cells. Vip3A also forms ionic pores that are voltage independent and cation selective characterized by long open times (Lee *et al.*, 2003).

6.6.3.2. Structure of Toxins

The crystal structures of the trypsin activated toxin Cry1Aa (lepidopteran specific), Cry3A and Cry3B (coleopteran specific), and Cry2Aa (dipteran–lepidopteran specific) protoxin have been solved (Li *et al.*, 1991; Grouchulski *et al.*, 1995; Galistki *et al.*, 2001; Morse *et al.*, 2001). Although the sequence similarity between these toxins is very low (20% and 17% identity of Cry2Aa with Cry3Aa and Cry1Aa, respectively) the overall structural topology of these proteins is very similar. **Figure 3** shows the three-dimensional structure of Cry1A, Cry3Aa toxins, and Cry2Aa protoxin (Morse *et al.*, 2001). The structure is composed of three structural domains. Domain I is a seven α-helix bundle in which a central helix α-5 is surrounded by six outer helices. This domain has been implicated in the membrane ion channel formation. The six α-helices are amphipathic and are long enough to span the 30-Å thick hydrophobic region of a membrane bilayer. Cry2Aa protoxin has an extra 49 amino acid region forming two extra α-helices in the N-terminal end that are cleaved out after proteolytic activation of the toxin (Morse *et al.*, 2001) (**Figure 3**). Domain II consist of three antiparallel β-sheets packed around a hydrophobic core in a "β-prism." This domain represents the most divergent part in structure among Cry toxin molecules (de Maagd *et al.*, 2001) and has been described as the selectivity-determining domain. Finally, domain III is a β-sandwich of two antiparallel β-sheets. Several lines of evidence indicate that domain III is implicated in insect selectivity and therefore involved in receptor binding. However, additional roles for this domain, such as in pore formation, have been suggested (Schwartz *et al.*, 1997c; de Maagd *et al.*, 2001).

Figure 4 shows the analysis of structural similarities of the three domains of Cry toxins with other proteins. This analysis revealed interesting features

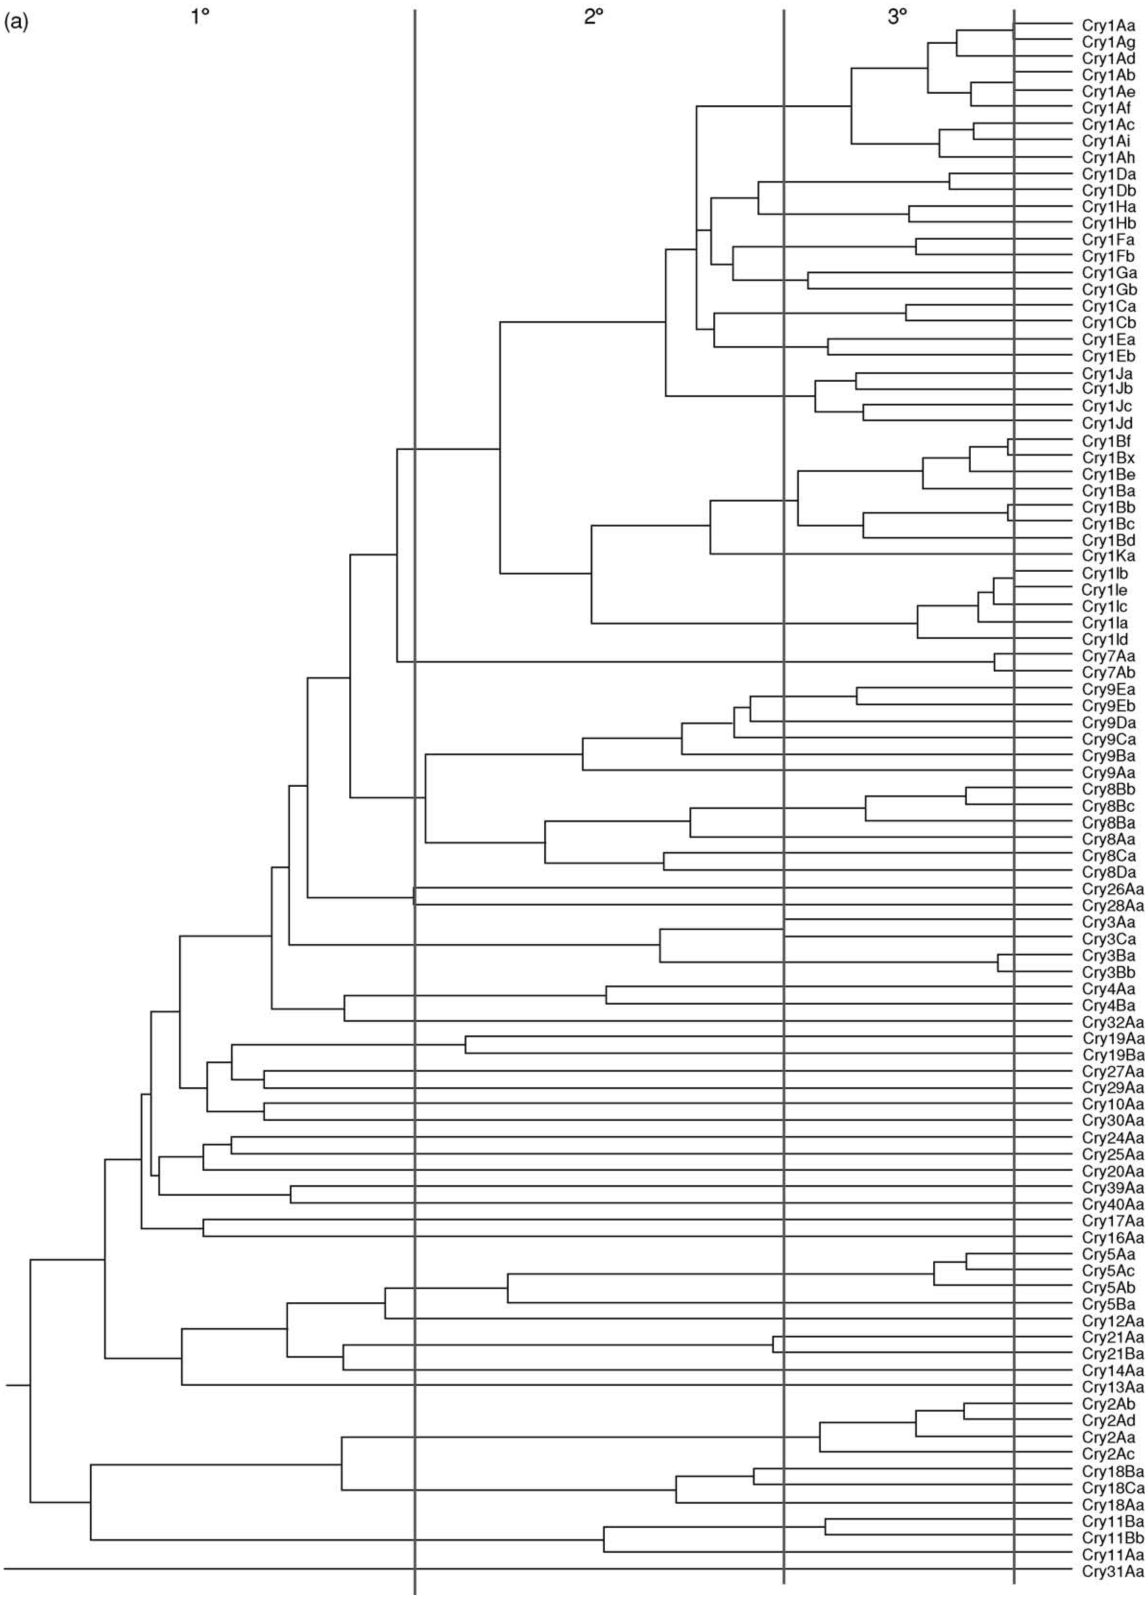

Figure 2 Continued

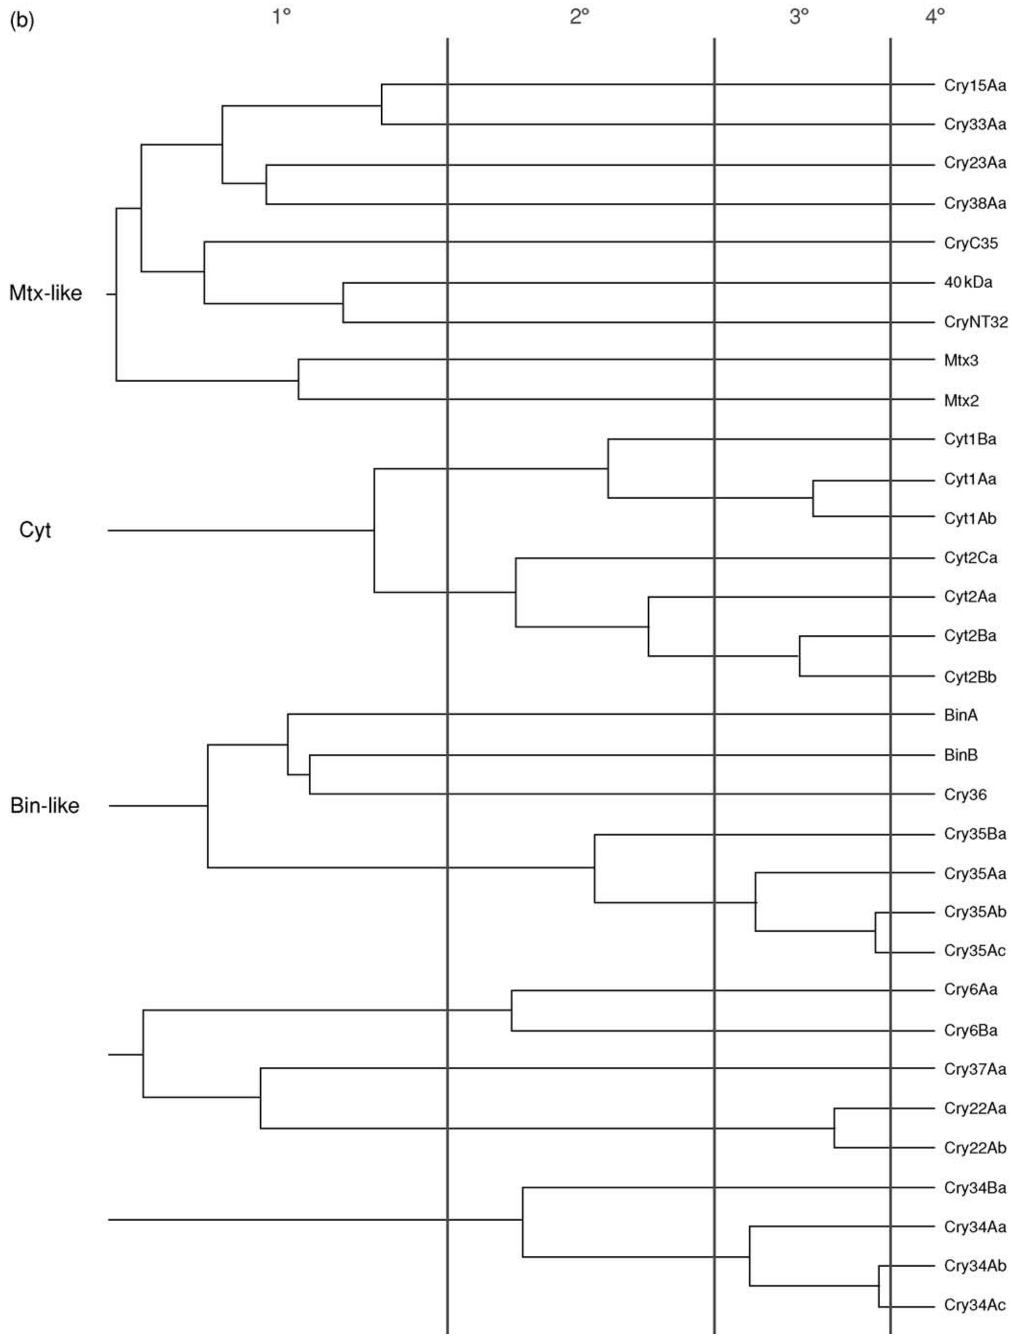

Figure 2 Dendograms of *cry* gene sequences. (a) The three domain sequences; (b) other *cry* gene sequences. Update and dendogram analysis can be found at http://www.biols.susx.ac.uk.

that could give hints on the possible role of these domains in the mode of action of Cry proteins. Domain I shares structural similarities with other pore forming toxins like colicin Ia and N (Protein Data Bank (PDB) codes: 1cii, 1a87), hemolysin E (1qoy), and diphtheria toxin (1ddt). This similarity suggests the role of this domain is in pore formation. In the case of domain II, structural similarities with several carbohydrate binding proteins like vitelline (1vmo), lectin jacalin (1jac), and lectin Mpa (1jot) supports the conclusion that this domain is involved in binding. Also for domain III, carbohydrate binding proteins with similar structures were identified as the cellulose binding domain of 1,4-β-glucanase CenC (1ulo), galactose oxidase (1gof), sialidase (1eut), β-glucuronidase (1bgh), the carbohydrate binding domain of xylanase U (1gmm), and β-galactosidase (1bgl). These results suggest

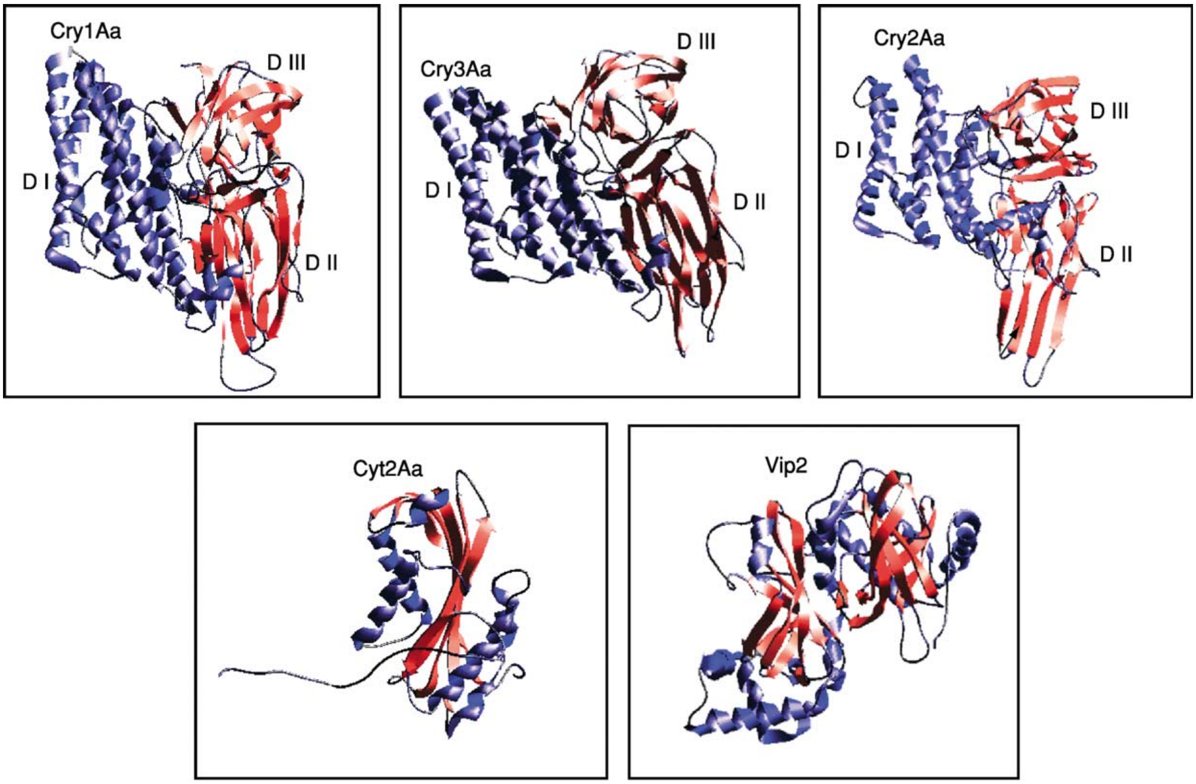

Figure 3 Three-dimensional structures of insecticidal toxins produced by *Bacillus thuringiensis*. D I, II, III, domains I, II, and III.

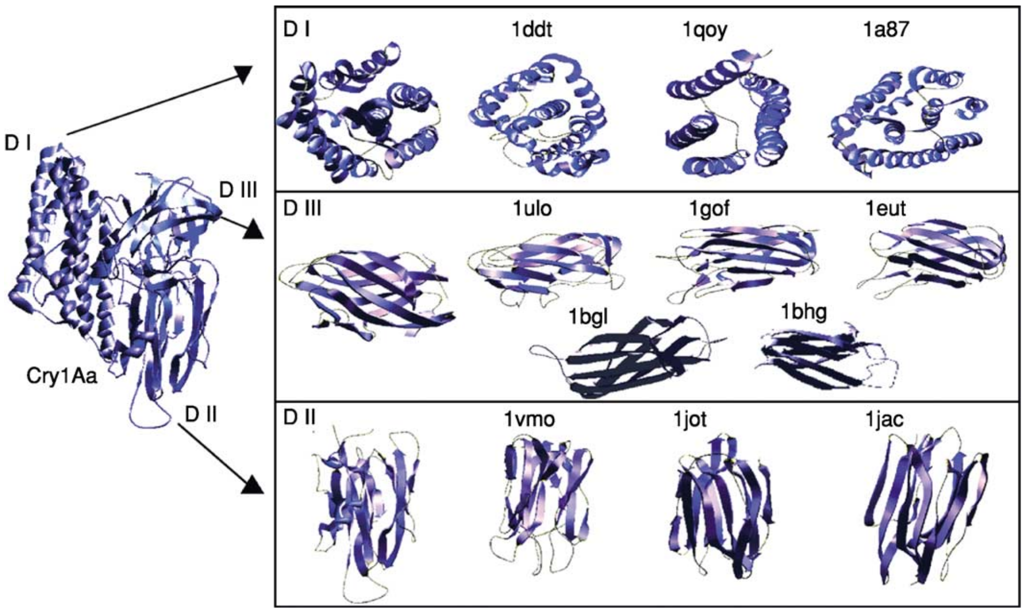

Figure 4 Proteins with structural similarity to the three domains of Cry toxins.

that carbohydrate moieties could have an important role in the mode of action of these three-domain Cry toxins, specifically in the recognition interaction of the toxin and its membrane receptors. As will be discussed later, the involvement of carbohydrate moieties in the mode of action of some Cry toxins has been demonstrated since different glycosylated proteins (aminopeptidase-N, a cadherin-like protein, and a glycoconjugate) have been identified as Cry toxin receptors in lepidopteran larvae.

Figure 3 also shows the ribbon representation of the three dimensional structure of Cyt2Aa toxin (Li *et al*., 1996). Cyt2Aa has single domain of α/β architecture comprising two outer layers of α-helical hairpins wrapped around a β-sheet. The Cyt2Aa protoxin is organized as a dimer, and proteolytic activation releases the active Cyt2Aa toxin monomer (Li *et al*., 1996; Gazit *et al*., 1997). Based on the length of the secondary structures it was proposed that the inner core of β-sheets (β-5, β-6, β-7, and β-3) could span the cell membrane (Gazit *et al*., 1997). However, analysis of membrane insertion capabilities of synthetic peptides corresponding to the different secondary structural elements suggested that α-helices A and C, rather than the β-sheets, could be the elements responsible for membrane interaction (Gazit *et al*., 1997).

Vip2A and Vip1A were isolated and characterized from a *B. cereus* strain (Warren, 1997). As mentioned above the structural genes *vip2* and *vip1* form an operon, and both Vip1 and Vip2 proteins constitute a binary toxin since both proteins are required for toxicity. Figure 3 shows the three-dimensional structure of Vip2 protein. Vip2 is a mixed α/β protein and is divided into two domains. The domains are structurally homologous although they share low amino acid identity. The overall fold of each domain resembles the catalytic domains of classical A-B toxins that have two components, a binding component (Vip1 presumably) and a catalytic ADP-ribosylating component (Vip2) (Warren, 1997). The cellular target of Vip2 is still unknown.

6.6.3.3. Evolution of Three-Domain Toxins

The increasing number of Cry toxins and the wide variety of target organisms that these proteins have puts forward the question of how evolution of this protein family created such a diverse arsenal of toxins. It has been proposed that toxins coevolved with their target insects (de Maagd *et al*., 2001). However, there are no studies that correlate the geographical distribution and Cry protein content of *B. thuringiensis* strains and the distribution of their target insect species in nature. In one particular study, a *B. thuringiensis* strain collection obtained from different climate regions of Mexico revealed that putative novel *cry* genes were more frequently found in *B. thuringiensis* strains isolated from tropical regions where the insect diversity is high (Bravo *et al*., 1998). Also the dipteran specific *cry11* and *cyt* genes were more frequently found in the rainy tropical regions than in the semiarid regions, which correlates with the distribution of dipteran insects (Bravo *et al*., 1998). A similar correlation between the frequencies of active strains with the geographical origin of the samples was presented by Bernhard *et al*. (1997) who reported that high number of *B. thuringiensis* strains active against *Heliothis virescens* in samples collected from North America where this species is a major agricultural pest. These results suggest that Cry toxins and insects may coevolve, although more comprehensive studies are needed to support this assumption.

Phylogenetic analysis of the complete Cry toxin or protoxin protein showed a broad correlation with toxicity (Bravo, 1997). However, analyses of the phylogenetic relationships of the isolated domains revealed interesting features regarding the creation of diversity in this family of proteins (Bravo, 1997; de Maagd *et al*., 2001). The analyses of phylogenetic relationships of isolated domain I and domain II sequences revealed that these domains coevolved. In the case of domain II, phylogenetic relationships showed a topology clearly related to the specificity of the toxin proteins (Bravo, 1997). This result is not surprising in spite of the fact that domain II is involved in receptor recognition and is therefore a determinant of insect selectivity (Bravo, 1997; de Maagd *et al*., 2001). Surprisingly, phylogenetic relationships of domain I sequences, that is involved in the pore formation of the toxin, showed a topology also clearly related to the selectivity of the toxin proteins (Bravo, 1997; de Maagd *et al*., 2001), suggesting that different types of domain I have been selected for acting in particular membrane conditions of their target insect (Bravo, 1997; de Maagd *et al*., 2001). The analysis of domain III sequences revealed a different topology due to the fact that several examples of domain III swapping among toxins occurred in nature (Bravo, 1997; de Maagd *et al*., 2001). Some toxins with dual specificity (coleopteran, lepidopteran) are clear examples of domain III swapping among coleopteran and lepidopteran specific toxins (Bravo, 1997; de Maagd *et al*., 2001). Cry1B toxins are good examples that illustrate domain III swapping in natural toxins. Five different Cry1B toxins have been described. These toxins share almost identical domain I and domain II sequences. However, Cry1B domain III sequences cluster with several Cry genes suggesting a very active process of domain III exchanges. The Cry1Ba domain III sequence is closely related to domain III sequences of Cry1Jb, Cry8Aa, and Cry9Da (Figure 5) but, in contrast, Cry1Bb and Cry1Bc share similar domain III sequences between them. In the case of Cry1Be, domain III clusters with domain III from Cry1Cb and Cry1Eb. Finally Cry1Bd domain III is similar to domain III of Cry1Ac toxin. Indeed Cry1B toxins

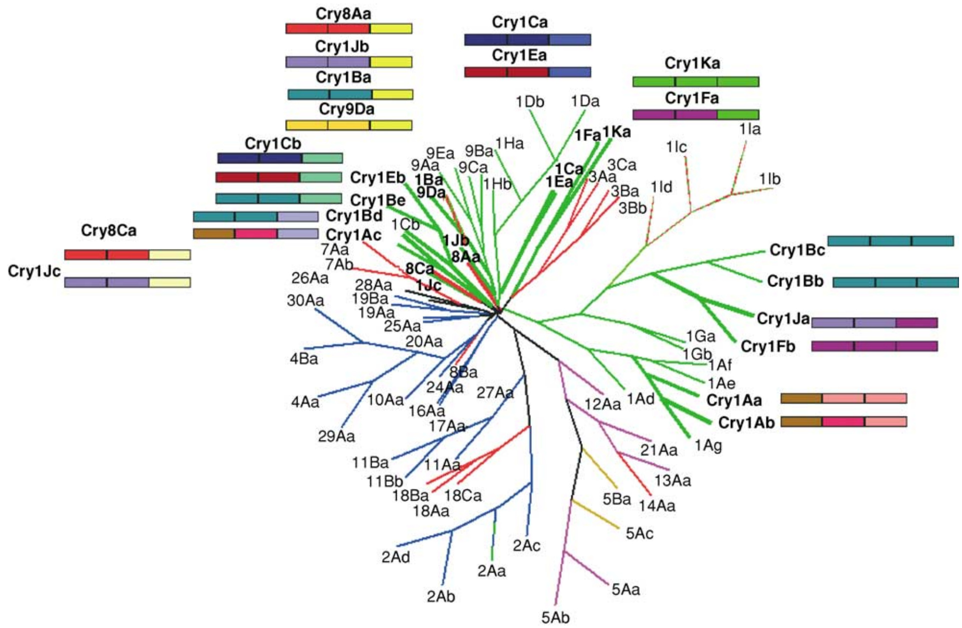

Figure 5 Phylogenetic relationships of Cry domain III sequences. Genes with similar domain III sequences are shown in the same color.

bioassays show that some of these toxins have different insect selectivities. For example, Cry1Ba is active against the coleopteran Colorado potato beetle, *Leptinotarsa decemlineata*, while Cry1Bd has higher activity against the lepidopteran diamondback moth, *Plutella xylostella,* than Cry1Ba and Cry1Bb toxins. A more comprehensive analysis of toxicity of Cry1B toxins could establish the relevance of domain III swapping in toxicity. However, this result suggests that domain III swapping could create novel specificities. Indeed, *in vitro* domain III swapping of certain Cry1 toxins results in changes in insect specificity as demonstrated for the hybrid protein containing domain I and II of Cry1Ab toxin and domain III of Cry1C which resulted in a toxin protein with increased toxicity towards *Spodoptera* sp. (Bosch *et al*., 1994; de Maagd *et al*., 2000, 2001). **Figure 5** shows the topology of the phylogenetic relationships of domain III sequences and the representation of Cry toxins in which domain III swapping occurred in nature during evolution of these proteins.

Phylogenetic analyses of the Cry toxin family shows that the great variability in the biocidal activity of this family has resulted from two fundamental evolutionary processes: (1) independent evolution of the three structural domains, and (2) domain III swapping among different toxins. These two processes have generated proteins with similar modes of action but with very different insect selectivities (Bravo, 1997; de Maagd *et al*., 2001).

6.6.4. Mode of Action of Three-Domain Cry Toxins

6.6.4.1. Intoxication Syndrome of Cry Toxins

As mentioned above (see Section 6.6.3.2), it is widely accepted that the primary action of Cry toxins is to lyse midgut epithelial cells in the target insect by forming lytic pores in the apical microvilli membrane of the cells (Gill *et al*., 1992; Schnepf *et al*., 1998; Aronson and Shai, 2001; de Maagd *et al*., 2001). In order to exert its toxic effect, Cry protoxins in the crystalline inclusions are modified to membrane-inserted oligomers that cause ion leakage and cell lysis. The crystal inclusions ingested by susceptible larvae dissolve in the environment of the gut, and the solubilized inactive protoxins are cleaved by midgut proteases yielding 60–70 kDa protease resistant proteins (Choma *et al*., 1990). Toxin activation involves the proteolytic removal of an N-terminal peptide (25–30 amino acids for Cry1 toxins, 58 for Cry3A, and 49 for Cry2Aa) and approximately half of the remaining protein from the C-terminus in the case of the long Cry protoxins (130 kDa protoxins). The activated toxin then binds to specific receptors on the brush border membrane of the midgut epithelium columnar cells of susceptible insects (Schnepf *et al*., 1998; de Maagd *et al*., 2001) before inserting into the membrane (Schnepf *et al*., 1998; Aronson and Shai, 2001). Toxin insertion leads to the formation of

lytic pores in microvilli apical membranes (Schnepf *et al*., 1998; Aronson and Shai, 2001). Cell lysis and disruption of the midgut epithelium releases the cell contents providing spores a rich medium that is suitable for spore germination leading to a severe septicemia and insect death (Schnepf *et al*., 1998; de Maagd *et al*., 2001).

6.6.4.2. Solubilization and Proteolytic Activation

Solubilization of long protoxins (130 kDa) depends on the highly alkaline pH that is present in guts of lepidopteran and dipteran insects, in contrast to coleopteran insect guts that have a neutral to slightly acidic pH (Dow, 1986). In a few cases, protoxin solubilization has been shown to be a determinant for insect toxicity. Cry1Ba is toxic to the coleopteran *L. decemlineata* only if the protoxin is previously solubilized *in vitro*, suggesting insolubility of the toxin at the neutral–acidic pH of coleopteran insects (Bradley *et al*., 1995). The C-terminal portion of protoxins contains many cysteine residues that form disulfide bonds in the crystal inclusions and, therefore, reducing the disulfide bonds is a necessary step for the solubilization of long Cry protoxins (Du *et al*., 1994). Differences in the midgut pH between lepidopteran and coleopteran midguts may be a reason for the bias in the utilization of arginine as basic amino acid over lysine in the lepidopteran specific toxins Cry1, Cry2, and Cry9 with exception of the Cry1I toxin, which is also active against coleopteran insects (Grochulski *et al*., 1995; de Maagd *et al*., 2001). The higher pK_a of arginine, compared with that of lysine, might be required for maintaining a positive charge even at the high pH of lepidopteran guts (up to pH 11) resulting in soluble toxins at alkaline pH.

Proteolytic processing of Cry toxins is a critical step involved not only on toxin activation but also on specificity (Haider and Ellar, 1989; Haider *et al*., 1989) and insect resistance (Oppert *et al*., 1997; Shao *et al*., 1998). Besides pH, lepidopteran and coleopteran insects differ in the type of proteases present in the insect gut; serine proteases are the main digestive proteases of Lepidoptera and Diptera, whereas cysteine and aspartic proteases are abundant in the midguts of Coleoptera (Terra and Ferreira, 1994). It has been reported that enhanced degradation of Cry toxins is associated with the loss of sensitivity of fifth instar *Spodoptera litoralis* larvae to Cry1C (Keller *et al*., 1996) and that serine protease inhibitors enhanced the insecticidal activity of some *B. thuringiensis* toxins up to 20-fold (MacIntosh *et al*., 1990). More recently, it was found that the low toxicity of Cry1Ab toxin to *S. frugiperda* could be explained in part by rapid degradation of the toxin on the insect midgut (Miranda *et al*., 2001). For several Cry proteins inactivation within the insect gut involves intramolecular processing of the toxin (Choma *et al*., 1990; Lambert *et al*., 1996; Audtho *et al*., 1999; Pang *et al*., 1999; Miranda *et al*., 2001). However, for several other Cry toxins, intramolecular processing is not always related to loss of toxicity and sometimes is required for proper activation of the toxin (Dai and Gill, 1993; Zalunin *et al*., 1998; Yamagiwa *et al*., 1999). Therefore, in some cases, differential proteolytic processing of Cry toxins in different insects could be a limiting step in the toxicity of Cry proteins (Miranda *et al*., 2001).

One interesting feature of Cry toxin activation is the processing of the N-terminal end of the toxins. The three-dimensional structure of Cry2Aa protoxin showed that two α-helices of the N-terminal region occlude a region of the toxin involved in the interaction with the receptor (Morse *et al*., 2001) (**Figure 3**). Several lines of evidences suggest that the processed N-terminal peptide of Cry protoxins might prevent binding to nontarget membranes (Martens *et al*., 1995; Kouskoura *et al*., 2001; Bravo *et al*., 2002b). *Escherichia coli* cells producing Cry1Ab or Cry1Ca toxins lacking the N-terminal peptide were severely affected in growth (Martens *et al*., 1995; Kouskoura *et al*., 2001). It was speculated that the first 28 amino acids prevented the Cry1A toxin from inserting into the membrane (Martens *et al*., 1995; Kouskoura *et al*., 2001). Recently, it was found that a Cry1Ac mutant that retains the N-terminus end after trypsin treatment binds nonspecifically to *Manduca sexta* membranes and was unable to form pores on *M. sexta* brush border membrane vesicles (Bravo *et al*., 2002b). Therefore, processing of the N-terminal end of Cry protoxins may unmask a hydrophobic patch of the toxin involved in toxin–receptor or toxin–membrane interaction (Morse *et al*., 2001; Bravo *et al*., 2002b).

6.6.4.3. Receptor Identification

The major determinant of Cry toxin selectivity is the interaction with specific receptors on the insect gut of susceptible insects (Jenkins and Dean, 2000). Therefore, receptor identification is fundamental for determining the molecular basis of Cry toxin action and also in insect resistance management that in many cases has been shown to correlate with defects in receptor binding (Ferré and Van Rie, 2002). A number of putative receptor molecules for the lepidopteran specific Cry1 toxins have been identified. In *M. sexta*, the Cry1Aa, Cry1Ab,

and Cry1Ac proteins bind to a 120 kDa aminopeptidase-N (APN) (Knight *et al*., 1994; Garczynski and Adang, 1995; Denolf *et al*., 1997) and to a 210 kDa cadherin-like protein ($Bt\text{-}R_1$) (Belfiore *et al*., 1994; Vadlamudi *et al*., 1995). Cadherins represent a large family of glycoproteins that are classically responsible for intercellular contacts. These proteins are transmembrane proteins with a cytoplasmic domain and an extracellular ectodomain with several cadherin repeats (12 in the case of $Bt\text{-}R_1$). The ectodomain contain calcium binding sites, integrin interaction sequences, and cadherin binding sequences. In *Bombyx mori*, Cry1Aa binds to a 175 kDa cadherin-like protein ($Bt\text{-}R_{175}$) (Nagamatsu *et al*., 1998, 1999) and to a 120 kDa APN (Yaoi *et al*., 1997). In *H. virescens* Cry1Ac binds to two proteins of 120 kDa and 170 kDa both identified as APN (Gill *et al*., 1995; Oltean *et al*., 1999). Also, a cadherin-like protein is involved in the mode of action of Cry1Ac toxin in *H. virescens* (Gahan *et al*., 2001). In *P. xylostella* and *Lymantria dispar* APNs were identified as Cry1Ac receptors (Valaitis *et al*., 1995; Lee *et al*., 1996; Denolf *et al*., 1997; Luo *et al*., 1997). In *L. dispar*, besides APN and cadherin-like receptors, a high molecular weight anionic protein ($Bt\text{-}R_{270}$) that binds Cry1A toxins with high affinity was identified (Valaitis *et al*., 2001). For Cry1C toxin an APN receptor molecule was identified in *Spodoptera litura* (Agrawal *et al*., 2002). Sequence analysis of various APN from lepidopteran insects suggests that APN's group into at least four classes (Oltean *et al*., 1999). *Plutella xylostella* and *B. mori* produce the four classes of APN and it is anticipated that several other lepidopteran insects may also produce the four isoforms (Nakanishi *et al*., 2002). Cry1A binding to the different *B. mori* APN isoforms revealed that this toxin only binds the 115 kDa isoform in ligand blot binding analysis (Nakanishi *et al*., 2002).

Surface plasmon resonance experiments showed that the binding affinity of Cry1A toxins to the *M. sexta* APN is in the range of 100 nM (Jenkins and Dean, 2000), while that of cadherin-like receptors ($Bt\text{-}R_1$) is in the range of 1 nM (Vadlamudi *et al*., 1995). This difference in the binding affinities between APN and $Bt\text{-}R_1$ suggest that binding to $Bt\text{-}R_1$ might be the first event on the interaction of Cry1A toxins with microvilli membranes and, therefore, the primary determinant of insect specificity.

Different experimental evidence supports the involvement of both Cry1A toxins receptors (APN and cadherin-like) in toxicity. Expression of the *M. sexta* and *B. mori* cadherin-like proteins, $Bt\text{-}R_1$ and $Bt\text{-}R_{175}$ respectively, on the surface of different cell lines render these cells sensitive to Cry1A toxins, although the toxicity levels were low (Nagamatsu *et al*., 1999; Dorsch *et al*., 2002; Tsuda *et al*., 2003). Cry1Aa toxin was shown to lyse isolated midgut epithelial cells; this toxic effect was inhibited if the cells were preincubated with anti-$Bt\text{-}R_{175}$ antisera in contrast with the treatment with anti-APN antisera, suggesting that cadherin-like protein $Bt\text{-}R_{175}$ is a functional receptor of Cry1Aa toxin (Hara *et al*., 2003). Also, a single-chain antibody (scFv73) that inhibits binding of Cry1A toxins to cadherin-like receptor, but not to APN, reduced the toxicity of Cry1Ab to *M. sexta* larvae (Gómez *et al*., 2001). Moreover, disruption of a cadherin gene by a retrotransposon-mediated insertion and its linkage to high resistance to Cry1Ac toxin in *H. virescens* YHD2 (a laboratory selected line) larvae supports a role for cadherin as a functional receptor (Gahan *et al*., 2001). Overall, these results suggest that binding to the cadherin-like receptor is an important step in the mode of action Cry1A toxins (**Figure 6**).

Regarding the APN receptor, several reports argue against the involvement of this protein in toxin activity. Mutants of Cry1Ac toxin affected on APN binding retained similar toxicity levels to *M. sexta* as the wild-type toxin (Burton *et al*., 1999). However, there are several reports describing point mutations of Cry toxins located in domain II that affected both APN binding and toxicity (Jenkins and Dean, 2000). Expression of APN in heterologous systems did not result in Cry1A sensitivity (Denolf *et al*., 1997) and, as mentioned above, an APN antibody did not protect *B. mori* midgut cells from Cry1Aa toxic effect in contrast to a cadherin antibody (Hara *et al*., 2003). However, two recent reports clearly demonstrate the importance of this molecule on the mode of action of Cry1 toxins. Inhibition of APN production in *S. litura* larvae by dsRNA interference showed that insects with low APN levels became resistant to Cry1C toxin (Rajagopal *et al*., 2002). Also, heterologous expression of *M. sexta* APN in midguts and mesodermal tissues of transgenic *Drosophila melanogaster* caused sensitivity to Cry1Ac toxin (Gill and Ellar, 2002). Additionally, previous reports demonstrated that incorporation of *M. sexta* APN into black lipid bilayers lowers the concentration of toxin needed for pore formation activity of Cry1Aa toxin (Schwartz *et al*., 1997b). Finally, all Cry1A APN receptors are anchored to the membrane by a glycosyl phosphatidylinositol (GPI) (Knight *et al*., 1994; Garczynski and Adang, 1995; Denolf *et al*., 1997; Oltean *et al*., 1999; Agrawal *et al*., 2002; Nakanishi *et al*., 2002). And treatment of *Trichoplusia ni* brush border membrane vesicles with PI-PLC, which cleaves GPI-anchored proteins from the membrane,

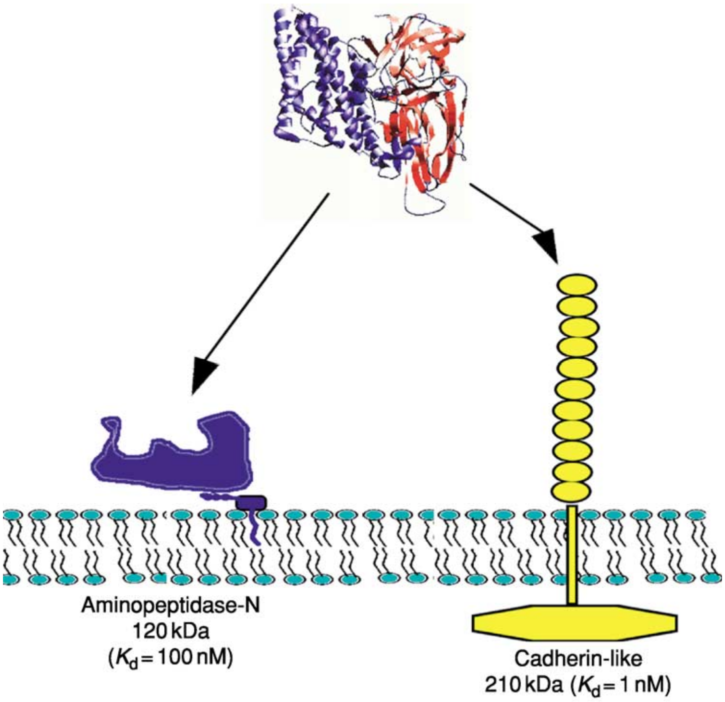

Figure 6 Receptor molecules of Cry1A proteins. K_d values are average affinity values of Cry1A toxins to aminopeptidase-N and cadherin receptors.

reduced Cry1Ac pore formation activity (Lorence *et al.*, 1997). These reports suggest that APN binding is also an important step in the mode of action of Cry1 toxins.

In the case of the dipteran specific Cry11A and Cry4B toxins, two binding proteins of 62 and 65 kDa were identified on brush border membrane vesicles from *Aedes aegypti* larvae (Buzdin *et al.*, 2002). The identity of these binding molecules and their role as receptors of Cry11A and Cry4B toxins still remains to be analyzed.

One interesting feature of the Cry1 receptor molecules identified so far is that all these proteins are glycosylated. As mentioned before, it is interesting to note that domain II and domain III of Cry toxins have structural homology to several protein domains that interact with carbohydrates. In the case of Cry1Ac, Cry5, and Cry14 toxins different experimental evidence suggest a role of carbohydrate recognition in the mode of action of these toxins. The domain III of Cry1Ac interacts with a sugar *N*-acetylgalactosamine on the aminopeptidase receptor (Masson *et al.*, 1995). In *Caenorhabditis elegans* resistance to the Cry5B and Cry14 toxins arises because of changes in the expression of enzymes involved in glycosylation (Griffits *et al.*, 2001). However, the structural similarities of domain II and III with carbohydrate binding proteins does not exclude the possibility that these domains may have protein–protein interactions with the receptor molecules. In fact some loop regions of domain II of Cry1Ab and the Bt-R_1 receptor do have protein–protein interaction (Gómez *et al.*, 2002a). The interaction between the toxin and its receptors can be complex involving multiple interactions with different toxin–receptor epitopes or carbohydrate molecules. Interestingly, the binding of Cry1Ac to two sites on the purified APN from *M. sexta* has been reported, and *N*-acetylgalactosamine could inhibit 90% of Cry1Ac binding, which does not inhibit the binding of Cry1Aa and Cry1Ab to the same APN receptor (Masson *et al.*, 1995). Only one of the Cry1Ac binding sites on APN is shared and recognized by Cry1Aa and Cry1Ab toxins (Masson *et al.*, 1995).

6.6.4.4. Toxin Binding Epitopes

The identification of epitopes involved in Cry toxin–receptor interaction will provide insights into the molecular basis of insect specificity and could help in the characterization of insect resistant populations in nature. Such studies would also aid in developing strategies to design toxins that could overcome receptor point mutations leading to Cry toxin resistance.

The toxin binding epitopes have been mapped for several Cry toxins. Domains II and III are the most variable regions of Cry toxins and had, therefore,

been subject to mutagenesis studies to determine their role in receptor recognition. Domain II was first recognized as an insect toxicity determinant domain based on hybrid toxin construction using *cry* genes with different selectivities (Ge *et al*., 1989). Site-directed mutagenesis studies of Cry1A toxins showed that some exposed loop regions, loop α-8, loop 2, and loop 3, of domain II are involved in receptor recognition (Rajamohan *et al*., 1996a, 1996b; Jenkins *et al*., 2000; Lee *et al*., 2000, 2001). Specifically, the loop 2 region of Cry1Ab toxin was shown to be important in the interaction with *M. sexta* brush border membrane vesicles. Characterization of mutants affected at Arg368-Arg369 in loop 2 indicated that these residues have an important role in the reversible binding of the toxin to brush border membrane vesicles, while Phe371 is involved in the irreversible binding of the toxin (Rajamohan *et al*., 1995, 1996b; Jenkins and Dean, 2000). Reversible binding is related to the initial interaction of the toxin to the receptor while irreversible binding is related to the insertion of the toxin into the membrane (Rajamohan *et al*., 1995). This result was interpreted as suggesting that Phe371 might be involved in membrane insertion (Rajamohan *et al*., 1995, 1996b). Also, evidence has been provided showing that Arg368-Arg369 in loop 2 of Cry1Ab are involved in APN binding since this mutant showed no binding to purified APN in surface plasmon resonance experiments (Jenkins and Dean, 2000; Lee *et al*., 2000). In this regard it is interesting to note that a truncated derivative of Cry1Ab toxin containing only domains II and III was still capable of receptor interaction but was affected in irreversible binding (Flores *et al*., 1997). Therefore, it is likely that mutations in Phe371 affect membrane insertion probably by interfering with conformational change, necessary for membrane insertion, after initial recognition of the receptor or as originally proposed this residue could be directly involved in membrane interaction (Rajamohan *et al*., 1995). Phylogenetic relationship studies of different Cry1 loop 2 sequences show that there is a correlation between the loop 2 amino acid sequences and cross-resistance with several Cry1 toxins in resistant insect populations, implying that this loop region is an important determinant of receptor recognition (Tabashnik *et al*., 1994; Jurat-Fuentes and Adang, 2001). Overall these results suggest that loop 2 of Cry1A toxins plays an important role in receptor recognition. Regarding loop α-8 and loop 3, mutations of some residues in these regions of Cry1A toxins affected reversible binding to brush border membrane vesicles or the purified APN receptor (Rajamohan *et al*., 1996a; Lee *et al*., 2001). The closely related toxins Cry1Ab and Cry1Aa have different loop 3 amino acid sequences even though they interact with the same receptor molecules (Rajamohan *et al*., 1996a). Analysis of Cry1Ab and Cry1Aa binding to the cadherin-like Bt-R_1 receptor in ligand blot experiments and competition with synthetic peptides corresponding to the toxin exposed loop regions, showed that, besides loop 2, loop 3 of Cry1Aa toxin was important for Bt-R_1 recognition (Gómez *et al*., 2002a). Although the Cry1A loop 1 region seems not to play an important role in receptor recognition this is certainly not the case for other Cry toxins. Mutagenesis of Cry3A loop 1 residues showed that this region, besides loop 3, is important for receptor interaction in coleopteran insects (Wu and Dean, 1996). Loop 1 residues of two Cry toxins with dual insecticidal activity (Cry1Ca and Cry2Aa, active against dipteran and lepidopteran insects) are important for toxicity against mosquitoes but not against lepidopterous insects (Widner and Whiteley, 1990; Smith and Ellar, 1994; Morse *et al*., 2001). Besides loop1 of Cry1C toxin, loops 2 and 3 are important for toxicity to dipteran and lepidopteran insects (Abdul-Rauf and Ellar, 1999). In the case of Cry2Aa toxin, an amino acid region involved in lepidopteran activity was not located in loops 1, 2, or 3 regions but was located to a different part of domain II in loops formed by β-5 and β-6, and by β-7 and β-8 (Morse *et al*., 2001). These results show that the loop regions of domain II are important determinants for receptor interaction, although other regions of this domain, in certain toxins, could also participate in receptor recognition.

As mentioned previously (see Section 6.6.3.3), domain III swapping indicated that this domain is involved in receptor recognition (Bosch *et al*., 1994; de Maagd *et al*., 2000), and it has been proposed that domain swap has been used as an evolutionary mechanism of these toxins (Bravo, 1997; de Maagd *et al*., 2001). The swapping of domain III between Cry1Ac and Cry1Ab toxins showed that the Cry1Ac domain III was involved in APN recognition (Lee *et al*., 1995; de Maagd *et al*., 1999a). The interaction of Cry1Ac domain III and APN was dependent on *N*-acetylgalactosamine (Gal-Nac) residues (Burton *et al*., 1999; Lee *et al*., 1999). Mutagenesis studies of Cry1Ac domain III identified Gln509-Asn510-Arg511 Asn506, and Tyr513 as the epitope for sugar recognition (Burton *et al*., 1999; Lee *et al*., 1999). The three-dimensional structure of Cry1Ac in the presence of the sugar confirmed that these residues are important for Gal-Nac recognition and that sugar binding has a conformational effect on the pore forming domain I (Li *et al*., 2001). In

the case of Cry1Ac toxin, a sequential binding mechanism to the APN receptor has been proposed (Jenkins *et al.*, 2000). The interaction of domain III to an *N*-acetylgalactosamine moiety in the receptor precedes the binding of loop regions of domain II (Jenkins *et al.*, 2000).

6.6.4.5. Receptor Binding Epitopes

In regard to the receptor binding epitopes, a region of 63 residues (Ile135–Pro198) involved in Cry1Aa binding was identified by analysis of truncated derivatives of *B. mori* APN. This site was specific for Cry1Aa toxin since it was not involved in Cry1Ac binding (Yaoi *et al.*, 1999; Nakanishi *et al.*, 2002). Nevertheless, this binding region is present in other APN molecules that do not bind Cry1Aa toxin when assayed by toxin overlay assays (Nakanishi *et al.*, 2002). This result can be explained if the epitope mapped was not accessible in native conditions. In fact it has been shown that denaturation of *M. sexta* APN exposes binding epitopes hidden under nondenaturating conditions (Daniel *et al.*, 2002). Therefore, the role of the mapped binding epitope in *B. mori* APN in toxicity remains to be analyzed.

Regarding cadherin-like receptors, a Cry1A binding epitope was mapped in Bt-R_1 and Bt-R_{175} receptor molecules by the analysis of truncated derivatives of these receptors in toxin overlay assays (Nagamatsu *et al.*, 1999; Dorsch *et al.*, 2002). In the case of Bt-R_1 and Bt-R_{175}, a toxin binding region of 70 amino acid residues was mapped in the cadherin repeat number 11 which is close to the membrane spanning region (Nagamatsu *et al.*, 1999; Dorsch *et al.*, 2002). The binding epitope was narrowed to 12 amino acids (^{1331}IPLPASILTVTV^{1342}) by using synthetic peptides as competitors. Binding of Cry1Ab toxin to the 70 residue toxin binding peptide was inhibited by synthetic peptides corresponding to loop α-8 and loop 2, suggesting that these loop regions are involved in the interaction with this receptor epitope (Gómez *et al.*, 2003). Using a library of single-chain antibodies displayed in M13 phage, a second Cry1A toxin binding region was mapped in the Bt-R_1 receptor (Gómez *et al.*, 2001). An scFv antibody (scFv73) that inhibited binding of Cry1A toxins to the cadherin-like receptor Bt-R_1, but not to APN, and reduced the toxicity of Cry1Ab to *M. sexta* larvae was identified (Gómez *et al.*, 2001). Sequence analysis of CDR3 region of the scFv73 molecule led to the identification of an eight amino acid epitope of *M. sexta* cadherin-like receptor, Bt-R_1 (^{869}HITDTNNK^{876}) involved in binding of Cry1A toxins. This amino acid region maps in the cadherin repeat 7 (Gómez *et al.*, 2001). Using synthetic peptides of the exposed loop regions of domain II of Cry1A toxins, loop 2 was identified as the cognate binding epitope of the *M. sexta* receptor Bt-R_1 ^{869}HITDTNNK^{876} site (Gómez *et al.*, 2002a). This finding highlights the importance of the ^{869}HITDTNNK^{876} binding epitope since extensive mutagenesis of loop 2 of Cry1A toxins has shown that this loop region is important for receptor interaction and toxicity (Rajamohan *et al*, 1995, 1996b; Jenkins and Dean, 2000; Jenkins *et al.*, 2000). Nevertheless, binding to cadherin repeat 7 was only observed in small truncated derivatives of Bt-R_1 (Gómez *et al.*, 2003) in contrast with larger truncated derivatives (Nagamatsu *et al.*, 1999; Dorsch *et al.*, 2002). Analysis of the dissociation constants of Cry1Ab binding to similar 70 amino acid peptides containing both toxin binding regions revealed that the toxin binds the epitope located in cadherin repeat 7 with sixfold higher affinity than cadherin repeat 11. Based on these results a sequential binding mechanism was proposed where binding of toxin to cadherin repeat 11 facilitates the binding of toxin loop 2 to the epitope in cadherin repeat 7 (Gómez *et al.*, 2003). Accumulating evidence indicate that proteins can interact with amino acid sequences displaying inverted hydropathic profiles (Blalock, 1995). The interactions of loop 2 with Bt-R_1 ^{865}NITI-HITDTNN^{875} region and of loops α-8 and 2 with ^{133}1IPLPASILTVTV^{1342} region were shown to be determined by hydropathic complementarity (Gómez *et al.*, 2002a, 2003).

As mentioned previously, it is generally accepted that the toxic effect of Cry proteins is exerted by the formation of a lytic pore. However, the fact that Cry1A toxins interact with protein molecules involved in cell–cell interactions (cadherin) within susceptible hosts could be relevant for the intoxication process as has been described for several other pathogens (Dorsch *et al.*, 2002). Targeting cell junction molecules seems to be representative of those bacteria that disrupt or evade epithelial barriers in their hosts. In this regard, it is remarkable that Cry1A toxins interact with at least two structural regions that are not close together in the primary sequence of Bt-R_1 (cadherin repeats 7 and 11). Although we cannot exclude the possibility that both sites could be located close together in the three-dimensional structure of Bt-R_1, we speculate that binding of Cry1A toxins could cause a conformational change in cadherin molecule that could interact with other cell-adhesion proteins, and consequently disrupt the epithelial cell layer (**Figure 7**).

As mentioned previously, mutagenesis studies have shown that besides domain II loop 2 and α-8,

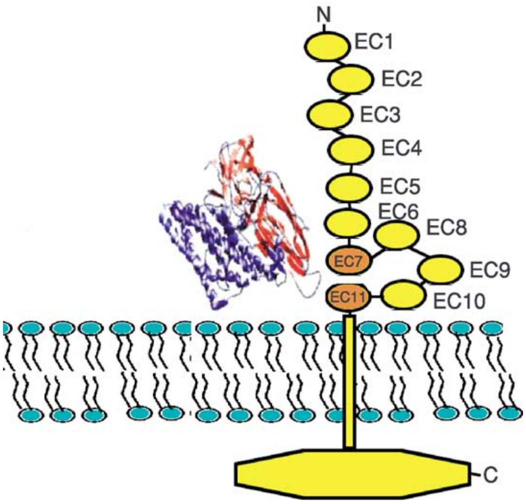

Figure 7 Structural regions on *Manduca sexta* cadherin receptor (Bt-R_1) involved in Cry1A binding. Ectodomains (EC) 7 and 11 contain Cry1A binding epitopes.

loop 3 of Cry1A toxins is important for receptor interaction and toxicity (Rajamohan *et al*., 1996a; Lee *et al*., 2001). The Bt-R_1 and the APN epitope involved in binding loop 3 regions still remains to be identified.

6.6.4.6. Cry Toxin–Receptor Binding Function in Toxicity

It is proposed that, following binding, at least part of the toxin inserts into the membrane resulting in pore formation (Schnepf *et al*., 1998). However, it is still largely unknown what is the role of receptor binding in promoting the insertion and oligomerization of the toxin. In the case of Cry1A toxins the differences of binding affinities between APN and Bt-R_1 (100 nM versus 1 nM K_d respectively) suggest that binding to Bt-R_1 is the first event in the interaction of Cry1A toxins with microvilli membranes.

In other noninsecticidal pore forming toxins, receptor binding facilitates a complete proteolytic activation of the toxin resulting in the formation of functional oligomers that are membrane insertion competent (Abrami and Van der Goot, 1999). In the case of Cry1A toxins, Gómez *et al*. (2002b, 2003) provided evidence that interaction of Cry toxin with its cadherin-like receptor is a necessary step for a complete proteolytic of the toxin. Incubation of Cry1Ab protoxin with the single-chain antibody scFv73 that mimics the cadherin-like receptor or with the toxin-binding peptides of Bt-R_1, and treatment with *M. sexta* midgut juice, resulted in toxin preparations with high pore formation activity *in vitro*. In contrast toxin preparations activated with same midgut juice proteases in the absence of the antibody showed very low pore formation activity (Gómez *et al*., 2002b, 2003). The high pore formation activity correlated with the formation of a 250 kDa oligomer composed of four Cry toxins that lacked the α-1 helix of domain I. The oligomer, in contrast to the 60 kDa monomer, has higher hydrophobicity as judged by 8-anilino-1-naphthalenesulfonate binding (Gómez *et al*., 2002b). The oligomer was membrane insertion competent in contrast with the monomer, as judged by measuring toxin membrane insertion using the intrinsic fluorescence of tryptophan residues (Raussel and Bravo, unpublished data). The 250 kDa oligomer could also be obtained by incubation of the Cry1Ab protoxin with brush border membrane vesicles isolated in the absence of protease inhibitors, presumably by the action of a membrane associated protease (Gómez *et al*., 2002b). Therefore toxin binding to cadherin facilitates the complete proteolytic activation of the toxin and the formation of a prepore structure that consists of four monomers. Characterization of the membrane insertion capabilities of the prepore, the kinetic properties of the ionic pore formed by this structure, and solving its three-dimensional structure could be important steps towards understanding the role of this insertion-intermediate structure in the mode of action of Cry toxins.

As mentioned previously APN receptors are also key molecules involved in the toxicity of Cry1 toxins. Cry1A APN receptors are anchored to the membrane by a GPI anchor. An indication of its possible role came from the characterization of membrane microdomains (lipid rafts) from microvilli membranes of *M. sexta* and *H. virescens* (Zhuang *et al*., 2002). Like their mammalian counterparts, *H. virescens* and *M. sexta* lipid rafts are enriched in cholesterol, sphingolipids, and glycosylphosphatidylinositol anchored proteins (Zhuang *et al*., 2002). Lipid rafts have been implicated in membrane and protein sorting and in signal transduction (Simons *et al*., 2000). They have also been described as portals for different viruses, bacteria and toxins. The interaction of different bacterial toxins with their receptors located in lipid rafts is a crucial step in the oligomerization and insertion of toxins into the membrane (Cabiaux *et al*., 1997; Abrami and van der Goot, 1999; Rosenberg *et al*., 2000). Several Cry1A receptors, including the GPI anchored proteins, 120 and 170 kDa APNs from *H. virescens*, and the 120 kDa APN from *M. sexta* were preferentially partitioned into lipid rafts. After toxin exposure, Cry1A toxins were associated with lipid rafts and the integrity of these

microdomains was essential for *in vitro* Cry1Ab pore forming activity (Zhuang *et al*., 2002). Additionally, PI-PLC treatment of *T. ni* brush border membrane vesicles, resulting in cleavage of GPI-anchored proteins from membrane, reduced drastically Cry1Ac pore formation (Lorence *et al*., 1997). Therefore, the possible role of APN binding could be to drive Cry1A toxins, probably the prepore, to lipid rafts microdomains where the toxin inserts and forms pores. The participation of lipid rafts in the mode of action of Cry toxins could suggest a possible role of signal transduction events and/or the internalization of Cry toxins, since lipid rafts have an active role in these cellular processes. In the case of Cry5 toxin evidence was provided showing that toxin is internalized into the epithelial midgut cells after exposure of *C. elegans* nematodes to the toxin (Griffits *et al*., 2001).

Binding of Cry1A toxins to cadherin and APN receptors are key steps in the mode of action of these toxins. However, the participation of other uncharacterized molecules in the process of membrane insertion and pore formation of these toxins cannot be excluded.

6.6.4.7. Toxin Insertion

Following binding to their receptors, Cry toxins insert into membrane of midgut epithelial cells to form lytic pores. Insertion of Cry toxins into membranes requires a major conformational change in the toxin to expose a hydrophobic surface that can interact with the membrane bilayer. Domain I has been recognized as the pore forming domain based on mutagenesis studies (Wu and Aronson, 1992; Cooper *et al*., 1998), and on the similarity of the structure of this domain with other pore forming domains of bacterial toxins, such as colicin Ia, diphtheria translocation domain, and hemolysin (Aronson and Shai, 2001). The α-helices of domain I of Cry1 toxins are long enough to span the membrane and have an amphipathic character (Aronson and Shai, 2001). Helix α-5 is highly hydrophobic and conserved (conserved block 1) among all three-domain Cry toxin families (de Maagd *et al*., 2001). Cross-linking experiments done in Cry1Ac, that was genetically engineered to create disulfide bridges between some α-helices of domain I, showed that domain I swings away from the rest of the toxin exposing the α-7 helix for the initial interaction with the membrane, resulting in membrane insertion of the hairpin formed by helices α-4 and α-5 (Schwartz *et al*., 1997b). Analyses of the insertion capabilities of synthetic peptides corresponding to the seven α-helices of domain I from Cry3A showed that α-1 is the only helix that does not interact with the membrane, in contrast to the other helices (Gazit *et al*., 1998). Helices α-4 and α-5 were the only helices capable of adopting a transmembrane orientation (Aronson and Shai, 2001; Gazit *et al*., 1998). These results suggest that helices α-4 and α-5 insert into the membrane, while the rest of the helices remain on the membrane surface. These data agree with the proposed "umbrella model" of toxin insertion in which helices α-4 and α-5 insert into the membrane, leaving the rest of the α-helices in the interface of the membrane (Schwartz *et al*., 1997b). In view of the proposed role of the prepore structure in toxin insertion (Gómez *et al*., 2002b), it is tempting to speculate that in the three-dimensional structure of the prepore, four helices α-7 are exposed and form an hydrophobic surface that participates in the initial interaction of the tetramer with the membrane. Subsequently, the four hairpins formed by helices α-4 and α-5 insert into the membrane. The location of domains II and II in the membrane inserted state is unknown. However, with exception of helix α-1, membrane inserted Cry1Ac toxin resist proteinase K treatment suggesting that domains II and III might also, somehow, be inserted into the membrane (Aronson, 2000).

A different model of the inserted toxin, based on calorimetric determinations, proposed that the three-dimensional structure of the toxin does not change dramatically compared to the structure of the soluble monomer (Loseva *et al*., 2001). This model proposed that helices α-1 to α-3 are cleaved, and that the pore lumen is provided by residues of domain II and III, while the domain I hydrophobic surface (without helices α-1 to α-3) faces the lipid bilayer in a oligomeric structure (Loseva *et al*., 2001). In this regard it is interesting to note that mutagenesis of conserved arginine residues in Cry1Aa domain III affected the pore formation activity of Cry1Aa toxin, suggesting that domain III participates in channel activity (Schwartz *et al*., 1997b). Analysis of the pore formation activity of several Cry1 chimeric proteins established that the characteristics of the pore are influenced by domain II and domain III, because combination of domain III from Cry1Ab with domains I and II of Cry1C gave a protein that was more active than Cry1C in spodoptera frugiperda (Sf9) cells (Rang *et al*., 1999). Solving the structure of Cry toxins in the membrane inserted state will be important to determine the possible roles of domains II and III in pore formation.

6.6.4.8. Pore Formation

Based on the observation of large conductance states formed by several Cry toxins in synthetic planar lipid

bilayers (Lorence *et al.*, 1995; Peyronnet *et al.*, 2002) and the estimation of pore size at 10–20 Å (Von-Tersch *et al.*, 1994), it has been proposed that the pore could be formed by an oligomer of Cry toxins containing four to six toxin monomers. Moreover, intermolecular interaction between Cry1Ab toxin monomers is a necessary step for pore formation and toxicity (Soberón *et al.*, 2000). This conclusion was derived from studies that used two Cry1Ab mutant proteins that affected different steps in toxicity (binding and pore formation). Individually these mutant proteins had decreased toxicity to *M. sexta*; however, when assayed as a mixture of the two toxins, pore formation activity and toxicity against *M. sexta* larvae was recovered. These results show that monomers affected in different steps of their mode of action can form functional heterooligomers, and that oligomerization is a necessary step for toxicity (Soberón *et al.*, 2000). Recently, the structure of the pore formed by Cry1Aa toxin was analyzed by atomic force microscopy showing that the pore is a tetramer (Vie *et al.*, 2001). These data are in agreement with the proposition of a prepore structure composed of four monomers (Gómez *et al.*, 2002b). The regions of the toxin involved in oligomerization have not been determined; however, based on mutagenesis studies and analysis of toxin aggregation it has been suggested that some residues of helixα-5 may be implicated in this process (Aronson *et al.*, 1999; Vie *et al.*, 2001).

The pore activity of Cry toxins has been studied by a variety of electrophysiological techniques (Schwartz and Laprade, 2000), for example using synthetic membranes without receptor or in isolated brush border membrane vesicles containing natural receptors (Lorence *et al.*, 1995; Peyronnet *et al.*, 2001, 2002; Bravo *et al.*, 2002a). Also ion channels induced by various activated Cry1 toxins in its monomeric form – Cry1Aa (Grochulski *et al.*, 1995; Schwartz *et al.*, 1997a), Cry1Ac (Slatin *et al.*, 1990; Schwartz *et al.*, 1997a; Smedley *et al.*, 1997), and Cry1C (Schwartz *et al.*, 1993; Peyronnet *et al.*, 2002) – have been analyzed in black lipid bilayers. The channel formation of these toxins was extremely inefficient and in some studies was only achieved mechanically (Peyronnet *et al.*, 2001, 2002). The toxin concentrations needed to achieve channel formation in these conditions were two to three orders of magnitude higher than their *in vivo* insecticidal concentration. Conductance varied from 11 to 450 pS and multiple subconducting states are frequently observed showing unstable traces with current jumps of intermediate levels that are difficult to resolve. These high conductances are probably related to clusters of various numbers of identical size pores operating synchronously rather than pore oligomer structures of different sizes (Peyronnet *et al.*, 2002). Under non-symmetrical ionic conditions, the shift in the reversal potential (zero current voltage E_{rev}) towards the K^+ equilibrium potential (E_K) indicated that channels of Cry1 toxins are slightly cation selective. In fact, several reports indicated that Cry toxins form pores that are poorly selective to cationic ions including divalent cations (Lorence *et al.*, 1995; Kirouac *et al.*, 2002). As mentioned previously, the presence of receptor (APN) diminished the concentration, more than 100-fold, of Cry1Aa toxin required for pore formation activity in synthetic planar bilayers (Schwartz *et al.*, 1997a). Studies performed in lipid bilayers containing fused brush border membrane vesicles isolated from the target insect suggested that the channels formed by Cry1 toxins in the presence of their receptors have higher conductance than those formed in receptor free bilayers. The conductance of monomeric Cry1C induced channels ranged from 50 pS to 1.9 nS in bilayers containing brush border membrane vesicles from *S. frugiperda* (Lorence *et al.*, 1995). Similarly, the conductance of channels induced by the monomeric form of Cry1Aa toxin in bilayers containing membranes from *L. dispar* were about eightfold larger than the channels formed in the absence of receptor (Peyronnet *et al.*, 2001). However, the presence of multiple conductances is still observed and the instability of the currents induced in these studies suggested that even in the presence of receptors the insertion of monomers into the membrane does not involve a single conformation. In contrast, preliminary analysis of the currents induced by pure oligomer preparations in the absence of receptor showed highly stable conductance, suggesting a stable insertion of a single conformation of the toxin into the membrane (Muñoz-Garay and Bravo, unpublished data). Finally it is important to mention that, in contrast to other pore forming toxins, the pore formation activity of Cry1 proteins is not regulated by low pH, suggesting that Cry toxins are not internalized into acidic vesicles for insertion as other pore forming toxins (Tran *et al.*, 2001).

Overall, the mode of action of Cry toxins can be visualized as follows (**Figure 8**):

1. Solubilization of the crystal and activation of the protoxin by midgut proteases resulting in the monomer toxin production.
2. Binding of the monomer to the cadherin receptor located in the apical membrane of midgut cells, probably accompanied by a mild denaturation of the monomer that allows proteolytic cleavage of helix α-1. This cleavage might result in a conformational change and the formation of a

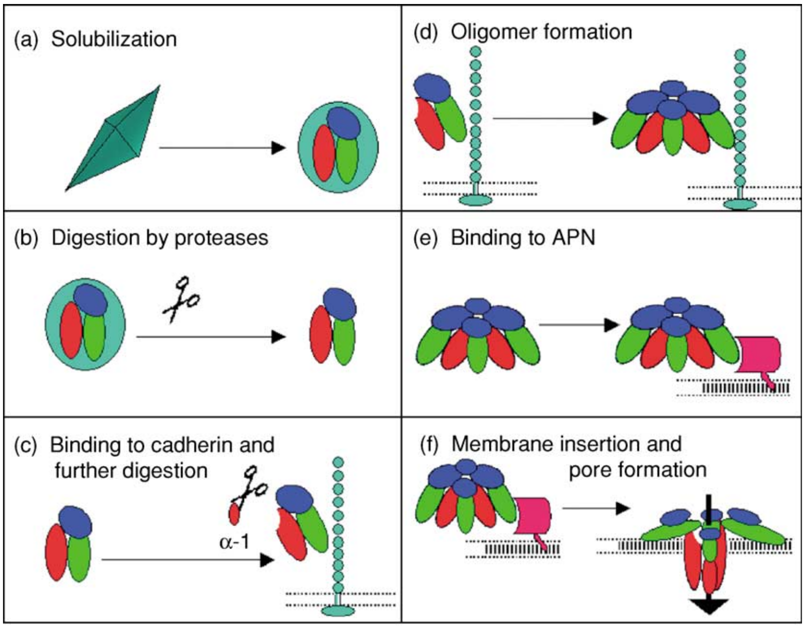

Figure 8 Mode of action of Cry toxins. (a) Crystals are solubilized and activated give rise to the monomeric toxin. (b) The toxin monomer binds the cadherin receptor, followed by proteolytic cleavage of helix α-1. (c) The tetramer is formed by intermonomeric contacts. (f) Following a conformational change the oligomer inserts into membrane forming a tetrameric pore.

molten globule state of the monomer exposing hydrophobic regions.

3. Formation of a tetramer by intermonomeric contacts.
4. Binding of the toxin oligomer to the APN receptor.
5. Mobilization of the APN receptor and Cry toxin to membrane microdomains.
6. A second conformational change of the oligomer, resulting in the insertion of the toxin into the membrane and formation of the membrane active tetrameric pore.

6.6.5. Synergism of Mosquitocidal Toxins

As previously mentioned (see Section 6.6.3.1) Cyt toxins synergizes the insecticidal effect of some Cry toxins. *Bacillus thuringiensis* subsp. *israelensis* is highly toxic to different mosquito species like *Aedes* spp., *Culex* spp., and blackfly, and also to *Anopheles* spp. but with lower toxicity (Margalith and Ben-Dov, 2000). This bacterium produces a crystal inclusion composed of at least four toxins: Cry4A, Cry4B, Cry11A, and Cyt1A (Huber and Luthy , 1981; Guerchicoff *et al.*, 1997). The toxicity of the crystal inclusion is greater, by far, than the toxicity of the isolated Cry and Cyt components. These Cry toxins are more toxic against mosquito larvae than Cyt1A with a difference in toxicity of at least 25-fold (Wirth *et al.*, 1997). However, the Cyt1A toxin synergizes the effect of the other Cry toxins. Toxicity of different combinations of Cry toxins with CytA1 was higher than the addition of expected toxicities of the isolated components (Crickmore *et al.*, 1995; Khasdan *et al.*, 2001). Also, the Cyt toxins synergize the toxicity of the binary toxins produced by *Bacillus sphaericus*. A ratio of 10 : 1 of *B. sphaericus* toxins to Cyt1A was 3600-fold more toxic to *A. aegypti* than *B. sphaericus* alone (Wirth *et al.*, 2001), and the presence of Cyt toxin can overcome the resistance of *Culex quinquefasciatus* to the binary toxins (Wirth *et al.*, 2001).

The mode of action of Cyt toxins includes the following steps: solubilization of the toxin under the alkaline pH and reducing conditions of the midgut, proteolytic processing of the protoxin, binding of the toxin to the epithelium surface of midgut cells, and pore formation leading to cell lysis (Li *et al.*, 1996, 2001). An important difference between Cyt and Cry toxins is the lack of a protein receptor for the Cyt toxin. Cyt toxins bind phospholipids and are capable of forming pores in cell lines of different origin (Gill *et al.*, 1987; Chow *et al.*, 1989; Li *et al.*, 1996, 2001). There are currently two proposed mechanisms of insertion and membrane perturbation by Cyt toxins. The first mechanism proposes that multimers of four Cyt toxin subunits form a β-barrel structured pore within the membrane, where the transmembrane region involves

the long β-sheets of the toxin (Promdonkoy and Ellar, 2003), whereas the second proposed mechanism suggests that the Cyt toxins exert their effect through a less specific detergent action (Butko *et al*., 1997; Butko, 2003).

Besides the synergistic effect of Cyt toxins, these proteins overcome or suppress resistance of mosquitoes to the Cry toxins (Wirth *et al*., 1997). *Culex quinquefasciatus* populations resistant to Cry4A, Cry4B, or Cry11A recovered sensitivity when assayed in the presence of Cyt toxin (Wirth *et al*., 1997). Furthermore, it has not been possible to select resistant mosquitoes against Cry toxins when selection is performed in the presence of Cyt toxin (Wirth *et al*., 1997). As mentioned previously (see Section 6.6.3.1), Cyt toxins are principally found in dipteran-active strains. However, a coleopteran-active strain containing a Cyt toxin has been described, although the possible synergistic effect of this Cyt toxin to other Cry proteins has not been analyzed (Guerchicoff *et al*., 2001). The molecular mechanism of the synergistic effect of Cyt toxins is still unknown. Cyt toxins could enhance any of the steps in the mode of action of Cry toxins, such as proteolytic activation, receptor binding, or toxin insertion. One plausible mechanism could be that Cyt toxins bind to microvilli membranes and then act as receptors of Cry toxins thus providing a binding site even in resistant insect populations where the Cry receptor molecules are affected. It would be interesting to investigate whether mosquitocidal Cry proteins are able of interacting with Cyt toxins and, if so, to map the binding epitopes. Engineering Cyt toxins for synergizing coleopteran- and lepidopteran-active toxins could be very useful in preventing the development of Cry resistant insect populations in nature.

6.6.6. Genomics

The genome size of different *B. thuringiensis* strains is in the range of 2.4–5.7 Mb (Carlson *et al*., 1994). Comparison of physical maps with that of *B. cereus* strains suggests that all *B. cereus* and *B. thuringiensis* have chromosomes with very similar organizations (Carlson *et al*., 1996). In May 2003 the complete genome sequence of type strains of the close *B. thuringiensis* relatives, *B. anthracis* (GenBank Accession no. AE016879) and *B. cereus* (GenBank Accession no. AE016877), were completed (Ivanova *et al*., 2003; Read *et al*., 2003). The *B. cereus* strain ATCC 14579 could be considered a *B. thuringiensis* strain based on its ribosomal 16S sequence, but does not produce crystals inclusions. The complete sequenced genome of *B. cereus* strain ATCC 1479 has 5.427 Mb (Ivanova *et al*., 2003). Analysis of putative coding regions and comparison to the sequence of the *B. anthracis* type strain showed that this group of bacteria lacks the capacity of metabolizing diverse types of carbohydrates that characterize typical soil bacteria like *Bacillus subtilis*. Carbohydrate catabolism in the *B. cereus* group is limited to glycogen, starch, chitin, and chitosan (Ivanova *et al*., 2003). In contrast, *B. cereus, B. anthracis*, and presumably *B. thuringiensis*, have a wide variety of peptide, amino acid transporters, and amino acid degradation pathways indicating that peptides and amino acids may be the most preferred nitrogen and carbon sources for these bacteria. These data led to the speculation that probably the habitat of the common ancestor of the *B. cereus* group was the insect intestine (Ivanova *et al*., 2003). The presence in the genome of several hydrolytic activities support this speculation, chitinolytic activities could participate in the degradation of chitin present in the peritrophic membrane, while the zinc metalloprotease could enhance degradation of the major component of the peritrophic membrane mucin. Also, several genes related to possible invasion, establishment, and propagation in the host were identified in both genome sequences (Ivanova *et al*., 2003; Read *et al*., 2003). Finally, the analysis of putative PlcR regulated genes gave a figure of 55 PlcR boxes controlling over 100 genes including four other transcriptional activators implying that the PlcR regulon is more complex than expected (Ivanova *et al*., 2003).

6.6.6.1. Sequence of Plasmid pBtoxis

Bacillus thuringiensis isolates usually harbor large plasmids, which are self-transmisible, containing δ-endotoxin genes that distinguish them from *B. cereus* strains (Schnepft *et al*., 1998). Therefore, the sequencing of plasmids containing *cry* genes could help to understand the evolution of *B. thuringiensis* and the spread of *cry* genes in nature. In 2002, the complete 128 kb sequence of a toxin encoded plasmid from *B. thuringiensis* subsp. *israelensis* (pBtoxis) was released (Berry *et al*., 2002). This plasmid contains 125 putative coding sequences with an average gene length of 725 bp (Berry *et al*., 2002). Sequence analysis showed that besides the known Cry toxins genes (*cry4Aa, cry4Ba, cry11A, cry10Aa, cyt2Ba*, and *cyt1Aa*) a putative novel *cry* gene was identified. Based on phylogenetic relationships with other Cyt toxins, the novel gene was named *cyt1Ca* (Berry *et al*., 2002). In contrast to the Cyt toxins, Cyt1Ca contains an additional domain located on the C-terminus (280 residues) which shares similarity

with domains present in other bacterial toxins that are involved on carbohydrate recognition (Berry *et al*., 2002). Therefore, it was proposed that Cyt1Ca could act by recognizing carbohydrate moieties in the cell surface (Berry *et al*., 2002). Based on sequence analysis, eight pseudogenes were identified. Among these, several gene fragments that shared significative sequence identity to described *cry* genes were identified, suggesting that the ancestors of plasmid pBtoxis contained other *cry* genes that were lost subsequently (Berry *et al*., 2002). Interestingly the *cry* gene fragments are located in nearby transposon related sequences indicating that gene transposition may have caused these genetic rearrangements and could be an important mechanism for toxin gene spread and evolution (Berry *et al*., 2002). Beside *cry* genes, the plasmid pBtoxis contains several putative genes coding for virulence factors (Berry *et al*., 2002). A second *plcA* gene, coding for Pl-PLC, was identified. However, this gene is probably not translated and no PlcR box was found in the promoter region of this gene. Interestingly, a PlcR box was identified in front of a peptide antibiotic production and export system, and this peptide antibiotic may be a novel virulence factor (Berry *et al*., 2002). Other genes related to sporulation and germination were identified, suggesting that plasmids could influence the sporulation and germination of the host strain (Berry *et al*., 2002). An interesting feature of the plasmid pBtoxis is that it shares similarity with a limited number of genes of plasmid pXO1, the virulence plasmid of *B. anthracis*; 29 of 125 open reading frames show amino acid sequence similarity to open reading frames present in pXO1 (Berry *et al*., 2002).

6.6.7. Mechanism of Insect Resistance

One of the major concerns regarding the use of *B. thuringiensis* is the generation of insect populations resistant to Cry toxins. Resistance to these toxins could be obtained by interfering with any of the steps involved in the mode of action of Cry toxins. The analysis of the molecular mechanism of insect resistance to *B. thuringiensis* toxins has been, for the most part, based on the study of insect resistant populations selected under laboratory conditions. These studies could provide important knowledge that allows for the rational design of procedures needed for resistance management in the field. However, resistance mechanisms of natural insect populations are likely not to compromise significantly the fitness of the insects to guarantee the fixation of resistant mutant alleles in the population. Therefore, the mutant alleles found in laboratory selected insect populations may not necessarily be found in nature although alleles found in nature are likely to be present in laboratory selected lines.

Selection of insects resistant to *B. thuringiensis* toxins in the laboratory has been performed for a variety of insect species. Lepidopteran insects resistant to *B. thuringiensis* toxins include *Plodia interpunctella, P. xylostella, H. virescens*, and *Spodoptera exigua* (Ferré and Van Rie, 2002), while coleopteran insect species include *L. decemlineata* and *Chrysomela scripta* (Ferré and Van Rie, 2002). As mentioned above (see Section 6.6.5), selection of Cry toxin resistant dipteran insects has been performed for *C. quinquefasciatus* (Wirth *et al*., 1997). Finally resistance to Cry toxins has also been achieved for the (noninsect) nematode *C. elegans* (Griffits *et al*., 2001). Until now only one insect species, *P. xylostella*, has developed resistance to Cry toxins in the field (Ferré and Van Rie, 2002). Only the resistance mechanisms in lepidopteran insects and in *C. elegans* nematode, have been characterized biochemically. Below we will summarize recent findings on the mechanisms involved in resistance to *B. thuringiensis* toxins.

6.6.7.1. Proteolytic Activation

As mentioned previously (see Section 6.6.4.2) Cry protoxins are activated by the action of midgut proteases. A line of *P. interpunctella* resistant to *B. thuringiensis* toxin had lower protease and protoxin activating activities. These differences were shown to be due to the lack of a major trypsin-like proteinase in the gut. Genetic analysis showed a cosegregation for the lack of the major protease and insect resistance to Cry1Ab toxin (Oppert *et al*., 1997). The consequence of reduced gut protease was a lower concentration of the activated toxin in the gut (Oppert *et al*., 1997). The resistant strain showed altered growth and morphology suggesting that this allele is unlikely to be selected in natural populations.

6.6.7.2. Receptor Binding

The most frequent mechanism of resistance to Cry toxins is altered receptor binding (Ferré and Van Rie, 2002). Different resistant populations from different lepidopteran species show an effect on toxin binding (Ferré and Van Rie, 2002). In a *P. interpunctella* strain selected for resistance to Cry1Ab, toxin binding affinity (K_d) was reduced 50-fold. Interestingly, this strain showed an increased susceptibility to Cry1C toxin which correlated with an increase number of binding sites to

this toxin (Ferré and Van Rie, 2002). Several receptor molecules for Cry1 toxins in *H. virescens* and *P. xylostella* have been hypothesized based on cross-resistance and susceptibility of different Cry1 resistant populations (Ferré and Van Rie, 2002). For *H. virescens*, three different receptors have been proposed: receptor A which binds Cry1Aa, Cry1Ab, and Cry1Ac toxins; receptor B which binds Cry1Ab and Cry1Ac toxins; and receptor C which recognizes Cry1Ac toxin. Based on the susceptibility of resistant insect populations, it was concluded that receptors B and C are unlikely to be involved in toxicity (Ferré and Van Rie, 2002). In the case of *P. xylostella*, four binding sites have been proposed (Ferré and Van Rie, 2002): receptor 1 is only recognized by Cry1Aa toxin; receptor 2 binds Cry1Aa, Cry1Ab, Cry1Ac, Cry1F, and Cry1J; receptor 3 binds Cry1B; and receptor 4 binds Cry1C (Ferré and Van Rie, 2002). Cross-resistance of Cry1A toxins with Cry1F and Cry1J correlates with sequence similarity of loop regions in domain II, in particular loop 2, of these toxins (Tabashnik *et al.*, 1994; Jurat-Fuentes and Adang, 2001) (see Section 6.6.3.3). In the case of four *P. xylostella* strains that developed resistance in the field, reduced Cry1A binding correlated with resistance (Schnepf *et al.*, 1998; Ferré and Van Rie, 2002).

In the majority of the selected resistant insect lines described above there is no information regarding the characterization at the molecular level of mutations that leads to Cry resistance. In the case of the laboratory selected *H. virescens* Cry1Ac resistant line, YHD2, it was shown that a single mutation was responsible for 40–80% of Cry1Ac resistance levels. The mutation was mapped and shown to be linked to a retrotransposon insertion in the cadherin-like gene (Gahan *et al.*, 2001). As mentioned previously (see Section 6.6.4.5), this result shows that binding of Cry1A toxins to cadherin-like receptors is an important event in the mode of action of these toxins. Based on these results, it has been suggested that if mutations of cadherin genes are the primary basis of resistance in the field, the characterization of cadherin alleles could be helpful in monitoring field resistance (Morin *et al.*, 2003). The characterization of cadherin alleles in field derived and laboratory selected strains of the cotton pest pink bollworm (*Pectinophora gossypiella*) revealed three mutated cadherin alleles that were associated with resistance in this lepidopteran insect (Morin *et al.*, 2003). **Figure 9** shows the structural features of the four mutated alleles of cadherin genes associated with resistance in *H. virescens* and *P. gossypiella*.

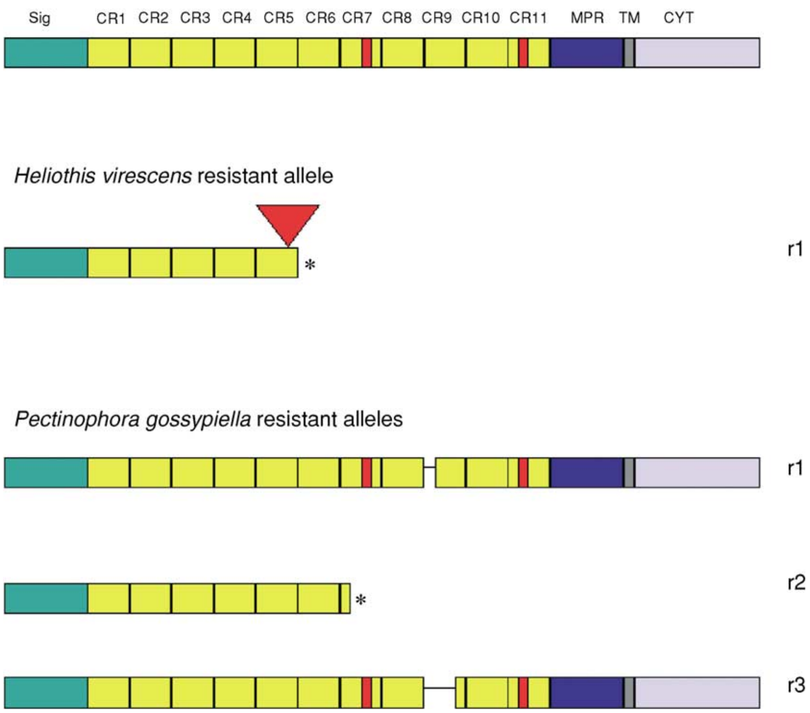

Figure 9 Gene structure of resistant cadherin alleles of *Heliothis virescens* (Gahan *et al.*, 2001) and *Pectinophora gossypiella* (Morin *et al.*, 2003). Sig corresponds to signal sequence for protein export; CR, cadherin repeat or repeated ectodomains; MPR, membrane proximal region; TM, transmembrane region; CYT, cytosolic domain; ∗, stop codon; red triangle, retrotransposon insertion; solid lines, deletions. Red sections on CR7 and CR11 are Cry1A binding epitopes mapped on *M. sexta* Bt-R_1 cadherin receptor.

6.6.7.3. Oligosaccharide Synthesis

Domain II and domain III of Cry toxins show structural similarity to carbohydrate binding domains present in other proteins, and in the case of Cry1Ac toxin, binding to the APN receptor involves the carbohydrate moiety *N*-acetylgalactosamine (de Maagd *et al*., 1999a; Burton *et al*., 1999) (see Section 6.6.3.3). Nevertheless, the most compelling evidence of the involvement of carbohydrate moieties on the mode of action of Cry toxins has come from the selection and characterization of nematode *C. elegans* Cry5B resistant lines (Griffits *et al*., 2001). Five independent *C. elegans* resistant strains were selected by feeding with *E. coli* cells expressing Cry5B toxin. Cloning and sequence of one gene responsible for the resistant phenotype (*bre-5*) showed that the mutated gene shares high sequence similarity to β-1,3-galactosyltransferase enzyme involved in carbohydrate synthesis (Griffits *et al*., 2001). The *bre-5* mutation confers cross-resistance to the Cry14A toxin which also has been shown to be toxic to insects (Griffits *et al*., 2001). The *bre-5* mutation had no effect on the fitness of the resistant nematodes (Griffits *et al*., 2001). These results suggest that carbohydrate moieties could play an important role in the mode of action (probably binding) of some Cry toxins.

In the case of the *H. virescens* YHD2 Cry1Ac resistant line, an altered pattern of glycosylation of two microvillar proteins of 63 and 68 kDa was shown to correlate with resistance (Jurat-Fuentes *et al*., 2002). As mentioned above (see Section 6.6.4.5), YHD2 strain contains several mutations responsible for its Cry1Ac resistant phenotype. Although the most important resistant allele is the disruption of the cadherin-like gene, altered glycosylation of microvilli membrane proteins increases its resistant phenotype (Jurat-Fuentes *et al*., 2002).

6.6.8. Applications of Cry Toxins

6.6.8.1. Forestry

One of the most successful applications of *B. thuringiensis* has been the control of lepidopteran defoliators that are pests of coniferous forests mainly in Canada and the United States. The strain HD-1, producing Cry1Aa, Cy1Ab, Cry1Ac, and Cry2Aa toxins, has been the choice for controlling these forests defoliators. Use of *B. thuringiensis* for the control spruce worm (*Choristoneura fumiferana*) started in the mid-1980s (van Frankenhuyzen, 2000). Afterwards *B. thuringiensis* has been used for the control of jackpine budworm (*C. pinus pinus*), Western spruce worm (*C. occidentalis*), Eastern hemlock looper (*Lambdina fiscellaria fiscellaria*) gypsy moth (*L. dispar*), and white-marked tussock moth (*Orgyia leucostigma*) (van Frankenhuyzen, 2000). In Canada, for the control of spruce worm, up to 6 million ha have been sprayed with *B. thuringiensis*, while up to 2.5 million ha have been sprayed for the control of other defoliators. In the case of United States up to 2.5 million ha are known to have been sprayed with *B. thuringiensis*. In these countries, 80–100% of the control of forests defoliators relies on the use of *B. thuringiensis*. In Europe, *B. thuringiensis* use for the control of defoliators greatly increased in the 1990s, reaching up to 1.8 million ha of forests treated by the end of the decade (van Frankenhuyzen, 2000). Successful application for the control of defoliators is highly dependent on proper timing, weather conditions, and high dosage of spray applications. These factors combine to determine the probability of larvae ingesting a lethal dose of toxin (van Frankenhuyzen, 2000). The use of *B. thuringiensis* in the control of defoliators has resulted in a significant reduction in the use of chemical insecticides for pest control in forests.

6.6.8.2. Control of Mosquitoes and Blackflies

As mentioned previously (see Section 6.6.5), *B. thuringiensis* subsp. *israelensis* is highly active against disease vector mosquitoes like *Aedes aegypti* (the vector of dengue fever), *Simulium damnosum* (the vector of onchocerciasis), and certain *Anopheles* species (vectors of malaria). The high insecticidal activity, the lack of resistance to this *B. thuringiensis* subspecies, the lack of toxicity to other organisms, and the appearance of insect resistant populations to chemical insecticides have resulted in the rapid use of *B. thuringiensis* subsp. *israelensis* as an alternative method for control of mosquitoes and blackfly populations.

In 1983, very soon after the discovery of *B. thuringiensis* subsp. *israelensis*, a control program for the eradication of onchocerciasis was launched in 11 countries in West Africa. This program was needed since the *S. damnosum* populations had developed resistance to organophosphates used for larval control (Guillet *et al*., 1990). At the present time, more than 80% of the region is protected by applications of this bacterial formulation and 20% with temephos (Guillet *et al*., 1990). As a consequence the disease has been controlled, protecting over 15 million children without the appearance of resistance this bacteria (Guillet *et al*., 1990).

In the Upper Rhine Valley in Germany, *B. thuringiensis* subsp. *israelensis* along with *B. sphaericus*

has been used to control *Aedes vexans* and *Culex pipiens pipiens* mosquitoes. Each year, approximately 300 km of river and 600 km^2 inundation areas are treated. Since 1981, more than 170 000 ha of mosquito breeding sites have been treated with different *B. thuringiensis* subsp. *israelensis* formulations. This program (KABS) has resulted in the reduction of mosquito populations by over 90% each year (Becker, 2000). These results are comparable to the use of *B. thuringiensis* subsp. *israelensis* for the control of *A. vexans* in the United States and in southern Switzerland (Becker, 2000). Again, no resistance to has been observed even after more than 20 years of the launch of the program (Becker, 2000).

High incidences of malaria in Hubei Province in China were reduced by more than 90% by the application of *B. thuringiensis* subsp. *israelensis* and *B. sphaericus* into the Yangtze River. The vector mosquitoes *Anopheles sinensis* and *A. anthropophagus* populations were reduced 90% by weekly applications of fluid formulations of two *B. thuringiensis* subsp. *israelensis* and *B. sphaericus* strains (Becker, 2000). In Brazil the outbreak of *A. aegypti* resistant populations to chemical insecticides in Rio de Janeiro and São Paulo led to the application of *B. thuringiensis* subsp. *israelensis* formulations for mosquito control (Regis *et al.*, 2000).

The success of vector control using *B. thuringiensis* subsp. *israelensis* will certainly spread the use of this *B. thuringiensis* subspecies around the world. However, the low activity of *B. thuringiensis* subsp. *israelensis* against certain vector mosquitoes, particular *Anopheles* spp., will require the isolation of strains with novel *cry* genes that are effective against different disease vectors.

6.6.8.3. Transgenic Crops

Bacillus thuringiensis is the leading biopesticide used in agriculture. However, only 2% of the insecticidal market consists of *B. thuringiensis* sprayable products; the rest consists mostly of chemical insecticides (Navon, 2000). Since the discovery of the HD-1 strain, formulations for lepidopteran pests control were released and products for the control of coleopteran insects are also available. However, the use of sprayable *B. thuringiensis* for insect control has been limited. Many reasons have contributed to this low acceptance of such commercial *B. thuringiensis* products. These include: the higher costs of commercial *B. thuringiensis* products; the lower efficacy of *B. thuringiensis* as compared to chemical insecticides; the limited persistence of *B. thuringiensis* products; the narrow insect spectrum of *B. thuringiensis;* and the fact that sucking and borer insects are poorly controlled (Navon, 2000).

However, the creation of transgenic crops that produce crystal *B. thuringiensis* proteins has been a major breakthrough, and substitution of chemical insecticides provides environmental friendly alternatives. In transgenic plants Cry toxin is produced continuously protecting the toxin from degradation and making it available to chewing and boring insects. Cry protein production has been improved by engineering *cry* genes with a codon usage compatible with that of plants, by removal of putative splicing signal sequences and by deletion of the C-terminal region of the protoxin (Schuler *et al.*, 1998). The first *B. thuringiensis* crop (Bt-potato) was commercialized in 1995. These transgenic plants expressed the Cry3A protein for protection against Colorado potato beetles resulting in 40% reduction in insecticidal use in 1997 (Schuler *et al.*, 1998). In 1996 Bt-cotton, producing the Cry1Ac toxin, was released to protect cotton from tobacco budworm, cotton bollworm, and pink bollworm. Also in 1996 Bt-maize, producing Cry1Ab toxin, was released for the control of European corn borer (*Ostrimia nubilalis*) larvae (Schuler *et al.*, 1998). By 2000, transgenic crops were grown on 44.3 million ha globally. Of this, 23% were insect resistant Bt-maize and 74% were herbicide resistant crops (James, 2001). Yield effects of insect resistant crops in the United States are less than 10% on average, but nevertheless use of insect resistant crops has considerably reduced the use of chemical pesticides (Qaim and Zilberman, 2003). However, the use of Bt-cotton in countries like China, Mexico, and India has showed that the use of this Bt-crop has a significant effect on yields and also in the use of chemical pesticides, since in underdeveloped countries yield loss is mainly due to technical and economical constraints that are overcome in part by the use of insect resistant crops (Qaim and Zilberman, 2003; Toenniessen *et al.*, 2003).

6.6.9. Public Concerns on the Use of *B. thuringiensis* Crops

Three major concerns have been raised on the use of Bt-crops: insect resistance, a direct effect on nontarget insects, and transgene flow to native landraces.

Widescale introduction of Bt-crops endangers the durability of *B. thuringiensis* as an insecticide in crops and in sprays since continuous exposure to Bt-plants will lead to selection for Cry toxin resistant insect populations. In response to this threat, resistance management strategies associated with the release of Bt-crops have been developed. The predominant approach involves the combination of

high production levels of the Cry protein combined with the establishment of refuge zones (de Maagd *et al*., 1999b; Conner *et al*., 2003). Refuges are areas of nontransgenic crops that are within close proximity of fields with Bt-plants. This procedure aims to maintain a population of susceptible insects that contain wild-type alleles. In most cases studied, resistance to Cry toxins is conferred by recessive mutations (de Maagd *et al*., 1999b; Ferré and Van Rie, 2002; Conner *et al*., 2003). Thus mating of homozygous individuals having susceptible alleles with heterozygous individuals having a resistant allele will give rise to susceptible heterozygote progeny, thereby delaying the development of resistance. Also, second generation transgenic crops are now being developed that produce two different Cry proteins that bind to different receptor molecules in the same insect. Thus, the possibilities of selecting mutants affected in receptor–toxin interaction are diminished exponentially (de Maagd *et al*., 1999b).

The massive use of *B. thuringiensis* sprays for forest defoliators raised concern on the effect of *B. thuringiensis* toxins on nontarget insects (Scriber *et al*., 2001). More recently, public concerns over the impact of Bt-crops on nontarget insects has increased based on results obtained on the toxicity of Bt-maize pollen to the Monarch butterfly (*Danaus plexippus*) (Losey *et al*., 1999). In this study, pollen, from a commercial variety of Bt-maize (N4640) expressing the *cry1Ab* gene, when spread onto milkweed (*Asclepias syriaca*) leaves was lethal to Monarch butterfly caterpillars in the laboratory (Losey *et al*., 1999). However, follow-up studies showed that low expression of *B. thuringiensis* toxin genes in pollen of most commercial transgenic hybrids, the lack of toxicity at the expected field rates, the absence of overlap between the pollen shed and larval activity, and the limited overlap in distribution of Bt-maize and milkweed, made field risks to the Monarch populations negligible (Gatehouse *et al*., 2002; Hellmich *et al*., 2001; Oberhauser *et al*., 2001; Pleasants *et al*., 2001; Sears *et al*., 2001; Stanley-Horn *et al*., 2001; Zangerl *et al*., 2001).

Concerns have also been raised about the effects of transgene introduction, or gene flow, on the genetic diversity of crop landraces and wild relatives in areas from which the crop originated. In 2001 the presence of transgenic DNA (from Bt-maize) constructs was reported in native maize landraces in Oaxaca, Mexico (Quist and Chapela, 2001). Oaxaca is considered part of the Mesoamerican center of origin and diversification of maize. Transgenic DNA was identified by polymerase chain reaction (PCR) based methodology, and the 35S promoter sequence was found in five of seven different native Criollo maize samples analyzed (Quist and Chapela, 2001). Moreover, inverse PCR reactions of genomic DNA of native landraces showed a high frequency of transgene insertion into a range of genomic contexts (Quist and Chapela, 2001). Nevertheless, based on criticisms on the interpretation of these data and possible false priming in the PCR reactions (Kaplinsky *et al*., 2002; Metz and Futterer, 2002), the journal *Nature* reconsidered its previous judgement on the acceptability of the results reported by Quist and Chapela, and concluded that the evidence provided was not sufficient to justify the publication (Editorial, 2002). However, more recent independent studies performed by the Mexican government (National Institute of Ecology (INE) and National Commission of Biodiversity (Conabio) claim to have evidence on the presence of transgenic DNA in native maize landraces, although publication of these results is still pending. In any case, gene flow is not restricted to transgenic plants, and naturally selected hybrids could also impact the populations and gene content of native landraces. Even if gene flow is confirmed, further studies on the possible impact of the gene flow from commercial hybrids (transgenic or nontransgenic) to native landraces should include long-term studies on the integrity of the transgenic constructs (or genes from nontransgenic hybrids) and the maintenance of these genes in the native landraces. These studies should provide a rational framework for taking decisions regarding the introduction and commercialization of transgenic crops in center of origin and diversification of crops. The final goal should be to assure the use of this environmental friendly technology without affecting the genetic diversity of natural landraces.

6.7 Mosquitocidal *Bacillus sphaericus*: Toxins, Genetics, Mode of Action, Use, and Resistance Mechanisms

J-F Charles, Institut Pasteur, Paris, France
I Darboux and D Pauron, INRA, Sophia Antipolis, France
C Nielsen-Leroux, Institut Pasteur, Paris, France

6.7.1. Introduction

6.7.1.1. Generalities

Bacillus thuringiensis was the first bacterium described to have insecticidal activity. The discovery of a particular strain of *B. thuringiensis* serovar *israelensis* in the late seventies (Goldberg and Margalit, 1977; de Barjac, 1978) opened up the possibility of using microorganisms to control Diptera Nematocera vectors of disease agents, such as mosquitoes (Culicidae) and black-flies (Simuliidae).

The first strains of *B. sphaericus* to be active against mosquito larvae were isolated from moribund mosquito larvae (Kellen *et al*., 1965). The larvicidal activity of these isolates was very low, so they could not be used to control mosquitoes (**Table 1**). The identification of the SSII-1 strain in India (Singer, 1973) renewed interest in the use of this species as a biological control agent. However, it was only after the isolation of strain 1593 from dead mosquito larvae in Indonesia (Singer, 1974) that the potential of *B. sphaericus* as a real biological control agent for mosquito populations was taken seriously (Singer, 1977). This occurred because of the high level of mosquitocidal activity of this strain.

6.7.1.2. Comparison of the Properties of Mosquitocidal Strains of *Bacillus sphaericus*

B. sphaericus Meyer and Neide (Neide, 1904) is an aerobic bacterium that produces terminal spherical spores. It lacks a number of biochemical pathways, meaning that it is unable to metabolize sugars. This species is generally considered to be heterogeneous, based on the findings obtained through a variety of genetic and biochemical analyses. Given the large number of strains isolated, it became difficult to distinguish between toxic and atoxic strains, or between the toxic strains themselves.

The relationships between *B. sphaericus* strains have been examined by DNA homology (Krych *et al*., 1980). Five groups were initially identified but group II has since been further subdivided into IIA (over 79% identity, containing all toxic strains), and IIB. Two further systems were then developed: bacteriophage typing (Yousten *et al*., 1980; Yousten *et al*., 1984) and serotyping using flagellar antigens as for *B. thuringiensis* (de Barjac *et al*., 1985; de Barjac, 1990). Both techniques gave very similar classifications, with the mosquitocidal strains in group IIA. Currently, nine serotypes containing active strains have been identified (**Table 1**). Other

techniques such as numerical classification based on the taxonomy of phenotypic features (Alexander and Priest, 1990; Guerineau *et al.*, 1991), cellular fatty acid composition analysis (Frachon *et al.*, 1991), ribotyping (Aquino de Muro *et al.*, 1992; Miteva *et al.*, 1998), and random amplified polymorphic DNA analysis (Woodburn *et al.*, 1995) showed that most of the pathogenic strains are grouped in a few clusters. None of these methods can be used to predict the level of toxicity of a given strain. Strains can be divided into three groups according to their toxicity, but these groups do not correspond to the groups defined by any other classification method (**Table 1**). The genes encoding a number of toxins have been cloned (see below), and it has been suggested that hybridization experiments could be used to predict activity (Woodburn *et al.*, 1995). However, some strains that harbor toxin genes but display only weak mosquitocidal activity have been reported. Therefore, the only way to identify potentially valuable strains and to increase our knowledge of the real nature of the mosquito-larvicidal activity is to determine toxicity experimentally using mosquito larvae.

B. sphaericus strains are generally highly active against *Anopheles* and *Culex* larvae but are poorly, or are not toxic to *Aedes* larvae. However, susceptibility appears to depend on the species of mosquito considered, and thus can vary within a given genus (Berry *et al.*, 1993). Toxicity levels vary greatly between the larvicidal serotypes and even within the same serotype (Thiéry and de Barjac, 1989). Therefore, the relative potency of each strain is expressed as the specific titer on the different mosquito species and as the activity ratios derived from such titers (Thiéry and de Barjac, 1989).

Singer was the first to suggest that *B. sphaericus* produces toxins, rather than producing septicemia, like *B. thuringiensis* on Lepidoptera (Singer, 1973). A few years later, Davidson and Myers (Davidson and Myers, 1981) observed parasporal inclusions that they believed to participate in the toxic action of *B. sphaericus*. Indeed, all the most toxic strains produce such inclusions during sporulation (**Figure 1**). These inclusions have a crystalline ultrastructure and are released into the medium along with the spore after the completion of sporulation. The relationship between sporulation, crystal formation, and mosquitocidal activity, was first clearly established for strains belonging to serotype H5a,5b (Myers *et al.*, 1979; Broadwell and Baumann, 1986), H25 (Yousten and Davidson, 1982; de Barjac and Charles, 1983; Kalfon *et al.*, 1984), and H6 (de Barjac *et al.*, 1988). Later on, the partial purification of crystals toxic to mosquito larvae (Payne and Davidson, 1984) and studies showing mutants that failed to make crystals were not mosquitocidal (Charles *et al.*, 1988), confirmed the toxic nature and protein composition of the crystals. More recently, toxins different to the crystal toxins (Mtx toxins) were identified, thus renewing interest in *B. sphaericus* as a mosquitocidal agent (Thanabalu *et al.*, 1991; Thanabalu and Porter, 1995).

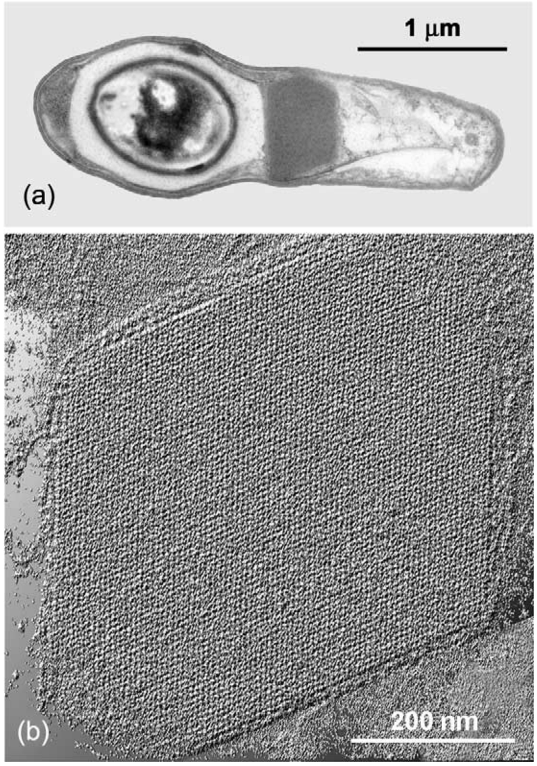

Figure 1 (a) *B. sphaericus* strain 2297 spore and crystal during the lysis of the sporangium, at the end of the sporulation process. (b) Detail of the crystal lattice.

There are three reviews summarizing *B. sphaericus* genetics, toxins and mode of action (Baumann *et al.*, 1991; Porter *et al.*, 1993; Charles *et al.*, 1996). The increasing field use of *B. sphaericus* has led to some cases of resistance. It is important to understand the nature and mode of action of *B. sphaericus* toxins and the mechanisms of resistance, if we are to restrict the development of resistance. These issues have been extensively investigated and an overview is given below.

6.7.2. Biochemistry and Genetics of *B. sphaericus* Toxins

At least two kinds of toxin (crystal toxins, or Bin toxins, and Mtx toxins) seem to account for the larvicidal activity of *B. sphaericus*. They differ both in their composition and time of synthesis. The crystal toxins are present in all highly active

strains (Table 1) and are produced during sporulation. The Mtx toxins are responsible for the activity of most of the less active strains, and seem to be synthesized only during the vegetative phase.

6.7.2.1. Crystal Toxins

The crystal toxin is composed of a 42-kDa protein and a 51-kDa protein, hereafter designated BinA and BinB, respectively (Baumann *et al*., 1987; Berry and Hindley, 1987; Hindley and Berry, 1987; Arapinis *et al*., 1988; Baumann *et al*., 1988; Hindley and Berry, 1988; Berry *et al*., 1989). These two proteins are synthesized in approximately equimolar amounts, assembled in crystal structures and visible at about stage III of sporulation (Yousten and Davidson, 1982; Kalfon *et al*., 1984; Baumann *et al*., 1985). The genes encoding both proteins have been cloned from several highly toxic strains. They encode proteins with predicted molecular masses of 51.4 and 41.9 kDa (Baumann *et al*., 1987; Berry and Hindley, 1987; Hindley and Berry, 1987; Arapinis *et al*., 1988; Baumann *et al*., 1988; Hindley and Berry, 1988; Berry *et al*., 1989). They appear to be organized in an operon, with a 174- to 176-bp intergenic region. A stem-loop structure (characteristic of transcription terminators) has been identified downstream from the *binA* gene (Figure 2, top; Hindley and Berry, 1987; Baumann *et al*., 1988). No sequences similar to *B. subtilis* sporulation promoters have been found upstream from the *binB* gene. However, both genes are expressed only during sporulation in *B. subtilis* (Baumann and Baumann, 1989). Moreover, *lacZ* fusion experiments have shown that transcription begins immediately before the end of exponential growth and continues into stationary phase in *B. sphaericus* (Ahmed *et al*., 1995). This probably allows sufficient amounts of the proteins for crystal formation to accumulate by stage III.

In mutants of *B. sphaericus* 2362 strain in which *spo0A* or *spoIIAC* sporulation genes have been disrupted by insertional mutations, toxicity on mosquito larvae is greatly reduced and no crystal

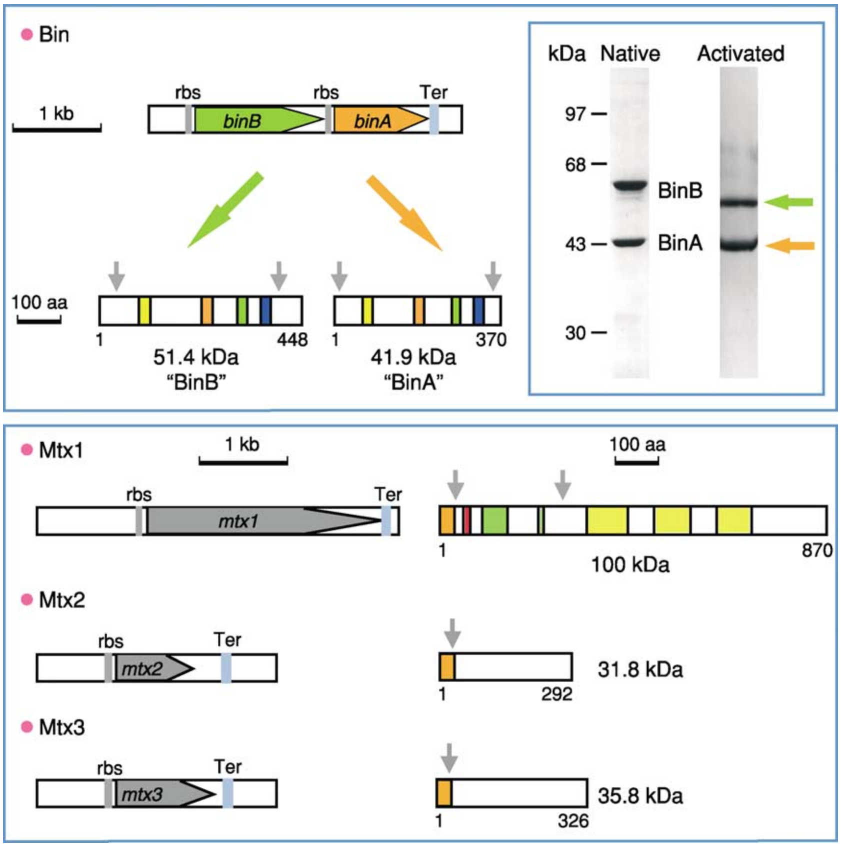

Figure 2 *B. sphaericus* toxin genes and schematic representation of corresponding polypeptides. Top, crystal (Bin) toxin: regions shared by BinB and BinA are represented by identical colors. Inset: SDS-PAGE (PolyAcrylamide Gel Electrophoresis) of native toxin and of toxin after activation by trypsin or by mosquito midgut juice. Bottom, Mtx toxins: the orange boxes indicate potential signal sequences; the colors in Mtx1 represent the potential transmembrane sequence (red), the two regions shared with ADP-ribosyltransferase toxins (green), and internal repeated sequences (yellow). Tryptic cleavage sites for each toxin are represented by gray arrows. Potential ribosome binding sites (rbs) and terminator sequences (Ter) are also indicated.

proteins are detected by SDS-PAGE or Western blotting (El-Bendary *et al.*, 2004). These results indicate that crystal protein synthesis is dependent on early and late mother cell sigma factors, as is the synthesis of most crystal proteins in *B. thuringiensis*.

In all the studied strains, toxin genes are chromosomal, although these strains contain plasmids (Aquino de Muro *et al.*, 1992). Both *binA* and *binB* have been identified in a wide variety of strains, and DNA hybridization has shown that all highly toxic strains tested contain very similar sequences (Aquino de Muro and Priest, 1994). The amino acid sequences of BinB and BinA are not similar to those of dipteran active toxins produced by *B. thuringiensis* serovar *israelensis* (*Bti*), or to any other toxins. However, BinB and BinA share four segments of sequence similarity (**Figure 2**, top; Baumann *et al.*, 1988), the significance of which remains unclear. Nevertheless, this indicates that BinB and BinA of *B. sphaericus* constitute a separate family of insecticidal toxins (Baumann *et al.*, 1988).

The toxin coding and flanking regions of strains 1593, 2362 and 2317.3 are identical over a span of 3479 nucleotides, whereas the sequences in strains IAB-59 and 2297 differ by 7 and 25 nucleotides, respectively (Berry *et al.*, 1989). These differences result in 5 and 3 amino acid differences in BinB, respectively, and in 1 and 5 amino acid differences in BinA, respectively. Partial or total sequencing of toxin genes led to the establishment of a classification system including four types of Bin toxin (types 1 to 4) (**Table 2**) (Priest *et al.*, 1997; Humphreys and Berry, 1998). The amino acid differences at positions 99, 135 (hydrophobic) and 267 (basic) of BinA are conservative. Type 1 and 2 BinA have a His at position 125, whereas types 3 and 4 contain an Asn. Type I BinA contains an acidic amino acid at position 104, whereas the other three types do not. Interestingly, BinA from type 4 (from strain LP1-G, only weakly active on mosquito larvae) has a serine (polar) at position 93 whereas types 1 to 3 contain a hydrophobic residue (Leu) (**Table 2**). Replacement of the serine at position 93 of BinA from LP1-G with a leucine restored the toxicity of the mutated type 4 toxin, whereas the replacement of the leucine with a serine at position 93 of the type 2 BinA from strain 1593 led to a significant loss in toxicity (Yuan *et al.*, 2001). This confirms that the amino acid at position 93 plays a key role in the toxicity of the BinA part of Bin toxins.

Amino acid residue substitutions at selected sites in the N- and C-terminal regions of type 2 BinA revealed the importance of other amino acids at the C-terminal end of the BinA peptide. For example, replacement of the Arg residue at position 312 by lysine or histidine (positively charged amino acids) completely destroys the biological activity of the binary toxin on *C. quinquefasciatus*, even though the binding of these mutants to mosquito brush border membranes is not altered (Elangovan *et al.*, 2000).

Table 2 Nomenclature and comparison of the four known Bin amino acid sequences from various *B. sphaericus* strains

		Type 1	*Type 2*	*Type 3*	*Type 4*
Polypeptide	*Amino acid position*	*IAB-59*[a], *IAB-872*[b] *IAB-881*[b], *9002*[b]	*1593*[a], *2362*[a], *2317.3*[a] *BSE18*[c], *C3-41*[d]	*2297*[a]	*LP1-G*[b]
BinA (41.9 kDa)		BinA1	BinA2	BinA3	BinA4
	93	Leu	Leu	Leu	Ser
	99	Val	Val	Phe	Val
	104	Glu	Ala	Ser	Ser
	125	His	His	Asn	Asn
	135	Tyr	Tyr	Phe	Phe
	267	Arg	Arg	Lys	Lys
BinB (51.4 kDa)		BinB1	BinB2	BinB3	BinB4
	69	Ala	Ser	Ser	Ser
	70	Lys	Asn	Asn	Asn
	110	Ile	Thr	Thr	Ile
	314	His	Leu	Tyr	His
	317	Leu	Phe	Leu	Leu
	389	Leu	Leu	Met	Met

[c]Berry (personal communication).
[d]Yuan *et al.* (1998).

The replacement of alanine at some sites in the N- and C-terminal regions of both the BinA and BinB peptides results in the total loss of mosquitocidal activity. Surprisingly, toxicity is restored by mixing two nontoxic derivatives of the same peptide; *i.e.*, one mutated at the N-terminal end and the other mutated at the C-terminal end of either BinA or BinB (Shanmugavelu *et al.*, 1998). Thus, the altered binary toxins can functionally complement each other by forming oligomers.

The aggregation of both BinB and BinA has been analyzed by expressing crystal toxin components separately or together in homologous or heterologous *Bacillus* hosts. The proteins form amorphous inclusions when expressed independently in *B. subtilis* and in *B. sphaericus* or *B. thuringiensis* crystal-negative hosts (Charles *et al.*, 1993; Nicolas *et al.*, 1993). In contrast, crystals similar to those produced by natural *B. sphaericus* strains are found when the two genes are simultaneously expressed in either *B. sphaericus* or *B. thuringiensis* (Charles *et al.*, 1993; Nicolas *et al.*, 1993). No crystals can be detected in *B. subtilis* when both genes are present, unless they are fused, eliminating the intergenic region (Charles *et al.*, 1993). These results suggest that *B. sphaericus* and *B. thuringiensis*, but not *B. subtilis*, contain factors that help stabilize their protein and subsequent crystallization.

In vivo, BinA is slowly converted into a stable ~39-kDa protein, whereas BinB is rapidly converted into a stable ~43-kDa fragment (Baumann *et al.*, 1985; Broadwell and Baumann, 1987). *In vitro* deletion analysis was used to delineate the minimal active fragments of both proteins, which indeed correspond to the activated fragments (Broadwell *et al.*, 1990b; Clark and Baumann, 1990; Oei *et al.*, 1990; Sebo *et al.*, 1990). Thirty-two and 53 amino acids, at the N- and C-termini of BinB, respectively, can be eliminated without loss of toxicity (Clark and Baumann, 1990); deletions of 10 and 17 amino acids, at the N- and C-terminus of BinA, respectively, result in a protein similar to the 39-kDa activated fragment (**Figure 2**, top; Broadwell *et al.*, 1990b).

Sub-cloning experiments have shown that BinA alone is toxic for mosquito larvae (*C. pipiens*), although the activity is weaker than that of crystals containing both proteins (Nicolas *et al.*, 1993). In contrast, BinB alone is not toxic, although its presence enhances the larvicidal activity of BinA, suggesting synergy between the two polypeptides (de la Torre *et al.*, 1989; Broadwell *et al.*, 1990b; Oei *et al.*, 1990; Nicolas *et al.*, 1993). *In vitro* assays confirmed that the activated form of BinA alone is toxic for *C. quinquefasciatus* cells, whereas BinB appears to be inactive; however, no synergy between the components was observed *in vitro* (Baumann and Baumann, 1991). Although the simultaneous presence of both proteins appears necessary for full toxicity, the differing activities of the different *B. sphaericus* strains towards various mosquito species depends on the origin of BinA, as shown by analysis of *in vitro* mutated toxins (Berry *et al.*, 1993). Indeed, when amino acids were substituted in a region centered around position 100 of BinA, rendering BinA from strains IAB-59 and 2297 similar to that from strain 2362, the activity and specificity of these mutant toxins towards *Culex* and *Aedes* larvae was comparable, unlike the wild-type, indicating that this region is involved in specificity. Taken together, these observations suggest that BinA is the most important determinant of specificity and activity.

6.7.2.2. Mtx Toxins

Three types of Mtx toxin have been described to date: Mtx1, Mtx2 and Mtx3, with molecular weights of 97, 31.8 and 35.8 kDa, respectively (**Figure 2**, bottom). The genes encoding these proteins were initially cloned from the SSII-1 strain (Thanabalu *et al.*, 1991; Thanabalu and Porter, 1995; Liu *et al.*, 1996a), which has a moderate mosquitocidal activity (**Table 1**). In contrast to the crystal toxin genes, *mtx* genes are expressed during the vegetative growth phase, and sequences resembling vegetative promoters from *B. subtilis* have been found upstream from each gene (Thanabalu *et al.*, 1991; Thanabalu and Porter, 1995; Liu *et al.*, 1996a). *lacZ* fusion experiments confirmed these findings (Ahmed *et al.*, 1995). These proteins possess short N-terminal leader sequences characteristic of Gram-positive bacterial signal peptides (Thanabalu *et al.*, 1991; Thanabalu and Porter, 1995; Thanabalu and Porter, 1996). However, these toxins have been found associated with the cell membrane of *B. sphaericus*, indicating little or no cleavage of the signal sequence. The mature Mtx1 toxin can be further processed by gut proteases, leading to two fragments of 27 and 70 kDa, corresponding to the N- and C-terminal regions, respectively (Thanabalu *et al.*, 1992). The 70-kDa fragment possesses three repeated regions of about 90 amino acids (**Figure 2**, bottom), the function of which is unknown. The 27-kDa fragment contains a short putative transmembrane domain. These toxins do not display any similarity with each other or with crystal proteins or any other insecticidal proteins. In contrast, the 27-kDa fragment shares weak sequence similarities with the catalytic domains of various bacterial ADP-ribosyltransferases (**Figure 2**, bottom; Thanabalu

et al., 1991; Thanabalu *et al.*, 1992). Mtx2 and Mtx3 show similarities to two toxins active against mammalian cells; namely the epsilon-toxin from *Clostridium perfringens* and the cytotoxin from *Pseudomonas aeruginosa*, respectively (Thanabalu and Porter, 1995; Liu *et al.*, 1996a). The genes encoding Mtx toxins are found in numerous *B. sphaericus* strains (Liu *et al.*, 1993; Thanabalu and Porter, 1995; Liu *et al.*, 1996a; Thanabalu and Porter, 1996), including low, moderate and high toxicity strains (see **Table 1**).

6.7.3. Mode of Action of *B. sphaericus* Toxins

6.7.3.1. The Crystal Toxins

The mode of action of *B. sphaericus* crystal toxins has only been studied in mosquito larvae. However, there is one report of activity in adult *C. quinquefasciatus* after introduction by enema into the midgut, whereas no effect was recorded for *A. aegypti* adults (Stray *et al.*, 1988). Following ingestion of the spore/crystal complex by mosquito larvae, the protein crystal matrix is quickly dissolved in the lumen of the anterior stomach (Yousten and Davidson, 1982; Charles and Nicolas, 1986; Charles, 1987) by the combined action of midgut proteinases and of the high pH (Dadd, 1975; Charles and de Barjac, 1981). The toxin is released from *B. sphaericus* crystals in all species, even in the midgut lumen of nonsusceptible species such as *A. aegypti* (**Figure 3a**). Indeed, a number of studies have shown that the differences in susceptibility to *B. sphaericus* between mosquito species are not due to differences in the solubility and/or activation of the binary toxin (Baumann *et al.*, 1985; Davidson *et al.*, 1987; Nicolas *et al.*, 1990).

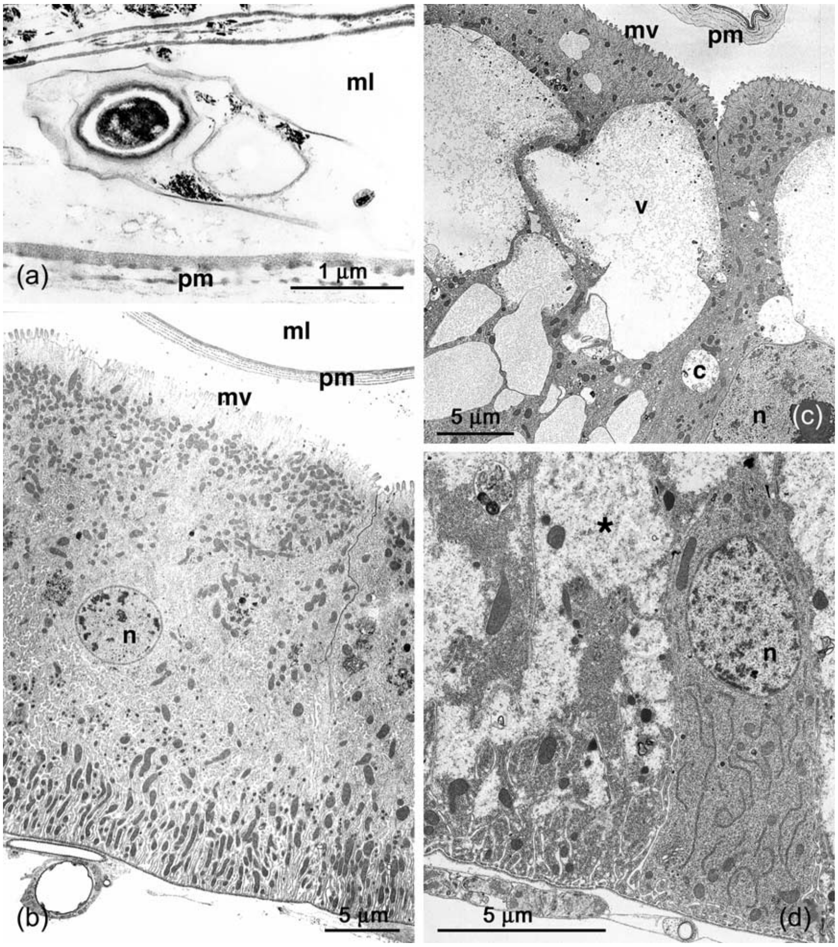

Figure 3 (a) Solubilization of the *B. sphaericus* 2297 crystal matrix within the midgut of an *Aedes aegypti* larva, under the combined action of proteinases and alkaline pH: only the envelopes initially surrounding the crystal are still visible. (b) Control midgut cell of an untreated *A. stephensi* larva. (c) Midgut cell of *C. pipiens* after feeding on *B. sphaericus*. (d) Midgut cell of *A. stephensi* after feeding on *B. sphaericus*. c, cytolysosome; ml, midgut lumen; mv, micovilli; n, nucleus; pm, peritrophic membrane; v, vacuoles; arrows indicate cytolysosomes; the star indicate areas of low electron density.

6.7.3.1.1. Cytopathology and physiological effects *Bti* toxins completely breakdown the larval midgut epithelium, whereas *B. sphaericus* does not. Nevertheless, midgut alterations start within 15 min of feeding on *B. sphaericus* spore/crystal complex (Davidson, 1981; Karch and Coz, 1983; Charles, 1987; Singh and Gill, 1988). There is no difference between midgut damage in *C. pipiens* after ingestion of spore/crystals from strains 1593 or 2297 (Davidson, 1981; Charles, 1987; Singh and Gill, 1988), even though these two strains belong to different Bin types. In contrast, symptoms of intoxication are not identical in different mosquito species. Large vacuoles (and/or cytolysosomes) appear in *C. pipiens* midgut cells, whereas large areas of low electron density appear in *Anopheles stephensi* midgut cells (compare **Figure 3c and d** with the control, **Figure 3b**). Mitochondrial swelling is a general feature described for *C. pipiens* and *A. stephensi*, as well as for *A. aegypti*, when intoxicated with a very high dose of spore/crystals (Charles, 1987). The midgut cells, especially cells of the posterior stomach and the gastric caecae, are the most severely damaged by the toxin, and Singh and Gill (Singh and Gill, 1988) also reported late damage to neural tissue and skeletal muscles.

Ultrastructural effects have also been observed in cultured cells of *C. quinquefasciatus* within few minutes of treatment with soluble and activated *B. sphaericus* toxin. These alterations consisted mainly in the swelling of mitochondria cristae and endoplasmic reticula, followed by the enlargement of vacuoles and the condensation of the mitochondrial matrix (Davidson *et al.*, 1987).

The physiological effects of *B. sphaericus* crystal toxin have been very poorly documented. The oxygen uptake of mitochondria isolated from *B. sphaericus*-treated *C. quinquefasciatus* larvae is inhibited, as is the activity of larval choline acetyl transferase (Narasu and Gopinathan, 1988). In addition, oxygen uptake by mitochondria isolated from rat liver is reduced by the *B. sphaericus* toxin (Narasu and Gopinathan, 1988).

6.7.3.1.2. Binding to a specific receptor in the brush border membrane As the differences in susceptibility between mosquito species do not seem to be due to the ability to solubilize and/or to activate the binary toxin, the variation in susceptibility is presumably due to cellular differences. Indeed, fluorescently-labeled toxin binds to the gastric caecae and the posterior stomach only in very susceptible *Culex* species. BinB does not bind to the gut of *Aedes aegypti*, whereas BinA weakly and nonspecifically binds in this species, and no regionalized binding occurs for *Anopheles* (Davidson, 1988; Davidson, 1989; Davidson and Yousten, 1990; Oei *et al.*, 1992). Furthermore, in *C. quinquefasciatus*, only BinB binds to the caecae and posterior stomach, and the binding of BinA appears to be conditioned by the binding of the BinB (**Figure 4b**), whereas BinA alone binds nonspecifically throughout the midgut (**Figure 4a**). This indicates that only one of the two components of the crystal toxin (putatively BinB) specifically binds to the midgut of susceptible larvae. The hypothesis that the N-terminal region of BinB is involved in regional binding of this protein in the larval midgut, and that the C-terminal region of BinB, as well as both the N- and C-terminal regions of BinA are involved in the interaction of the two components leading to the binding of BinA in the same regions as BinB, was supported by early *in vivo* binding studies using nontoxic deletion mutants of the crystal toxin (Oei *et al.*, 1992). The same authors also showed that the Bin toxin is only internalized when both components are present. However, further intracellular investigations are required to determine whether one or both components are internalized.

In vitro binding assays, using ^{125}I-labeled activated crystal toxin and brush border membrane fractions (BBMFs) isolated from susceptible or nonsusceptible mosquito larvae, confirmed this hypothesis. Indeed, direct binding experiments with *C. pipiens* BBMFs indicated that the toxin binds to a single class of specific receptor (**Figure 5**, left; Nielsen-LeRoux and Charles, 1992). No significant specific binding was detected with BBMFs from *A. aegypti* (**Figure 5**, right), which is consistent

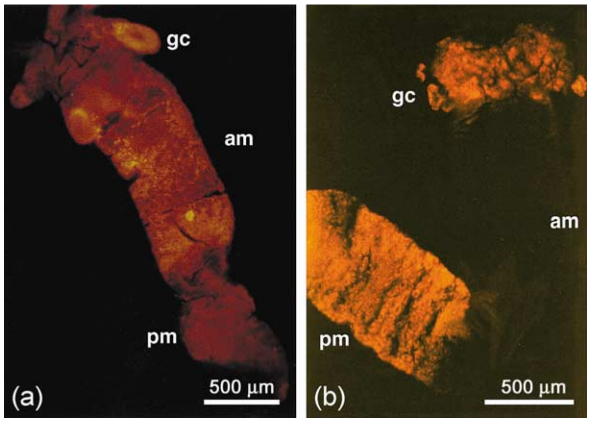

Figure 4 (a) Midgut of *C. quinquefasciatus* larvae only fed with fluorescently-labeled BinA. BinA weakly binds over the entire midgut. (b) Larvae fed with fluorescently-labeled BinA and unlabeled BinB; BinA binding is restricted to the gastric caecae and posterior stomach. am, anterior stomach; gc, gastric caeca; pm, posterior stomach. (Micrographs kindly provided by Dr C. Berry, Department of Biochemistry, Cardiff.)

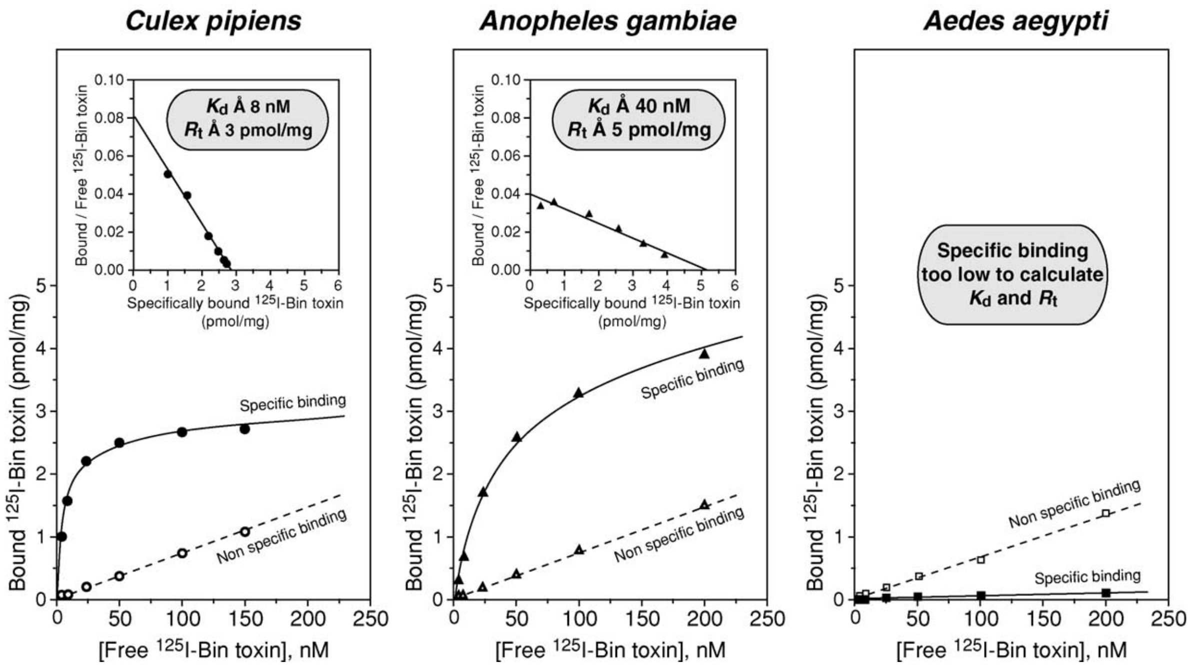

Figure 5 Binding of ^{125}I-labeled *B. sphaericus* Bin toxin to midgut brush border membranes of *C. pipiens*, *A. gambiae* and *A. aegypti*. Insets, specific binding in Scatchard plots. Values of dissociation constant (K_d) and receptor concentrations (R_t) are given when known.

with the lack of specific binding in fluorescence-labeling studies (Davidson, 1989; Davidson *et al.*, 1990). Similar results were obtained with other Culicidae species such as *Anopheles gambiae*, with minor differences in the values of the toxin/receptor binding characteristics: dissociation constants (K_d) were ~8 nM for *C. pipiens* and ~40 nM for *A. gambiae*, and receptor concentrations (R_t) were about 3 and 5 pmol mg^{-1} of BBMF protein respectively (**Figure 5**, center; Silva-Filha *et al.*, 1997). Both crystal toxin components bound to the membranes of all susceptible species, but the linearity of the Scatchard plots clearly indicated that only one of the components specifically bound to the receptor (**Figure 5**, insets).

Binding studies in which radiolabeled BinA or BinB were exposed separately to BBMFs confirmed that only BinB was able to bind specifically to *C. pipiens* midgut membranes, but that BinA alone was also able to bind midgut membranes from *A. gambiae* (Charles *et al.*, 1997).

6.7.3.1.3. Permeabilization of artificial lipid membranes Complementary studies using artificial lipid vesicles have been carried out to investigate further the respective roles of BinA and BinB in the toxic effect of the crystal toxin. This revealed that the whole Bin toxin and its individual components (BinA and BinB) are able to permeabilize receptor-free, large unilamellar phospholipid vesicles (LUVs) and planar lipid bilayers (PLBs) by forming pores (Schwartz *et al.*, 2001). Calcein-release experiments showed that LUV permeabilization is optimal at alkaline pH (which corresponds to the pH inside the mosquito larval midgut *in vivo*) and in the presence of acidic lipids. BinA is more efficient than BinB, and BinB facilitates the BinA effect. Stoichiometric (1:1) mixtures are more effective than the full Bin toxin, consistent with previous *in vivo* bioassay observations (Broadwell *et al.*, 1990a; Oei *et al.*, 1990; Baumann and Baumann, 1991; Nicolas *et al.*, 1993). In PLBs, BinA forms voltage-dependent channels of 100–200 pS with long open times and a high open probability. Larger channels (~400 pS) have also been observed. BinB, which inserts less easily, forms smaller channels (~100 pS) with shorter mean open times. The channels formed after the sequential addition of the two components, or when they are mixed in equal amounts (w/w), display BinA-like activity, supporting the hypothesis that BinA is principally responsible for pore formation in lipid membranes whereas BinB, the binding component of the toxin, promotes channel activity (Schwartz *et al.*, 2001).

6.7.3.1.4. Identification and cloning of the Bin toxin receptor Two important biochemical features have made it possible to purify the Bin toxin

receptor: (1) the availability of an iodinated derivative of the toxin that strongly binds to its receptor both in intact and solubilized membranes prepared from susceptible *Culex* mosquitoes (Nielsen-LeRoux and Charles, 1992); (2) the availability of midgut brush border membrane fractions (BBMFs) prepared from 4th instar larvae, constituting a rich source of receptors (Silva-Filha *et al.*, 1999). The Bin toxin receptor can be purified from BBMFs prepared from the midguts of larvae of a susceptible laboratory strain of *C. pipiens* (IP) by means of a classical protocol including solubilization with CHAPS plus anion exchange chromatography (Silva-Filha *et al.*, 1999). This receptor is a protein of approximately 60 kDa that is thought to be linked to the plasma membrane by a glycosylphosphatidylinositol (GPI) moiety, given the effect of phosphatidylinositol-specific phospholipase C (PI-PLC). This protein displays α-amylase-like activities, i.e., it has α-glucosidase (or maltase) and α-amylase *stricto sensu* activities. Moreover, partial microsequencing of the 60 kDa protein revealed significant similarities with identified insect maltases. Hence, this protein was named Cpm1 for *Culex pipiens* maltase 1 (Silva-Filha *et al.*, 1999).

The full-length *cpm1* cDNA was first cloned from the IP strain (Darboux *et al.*, 2001). The coding sequence is 1740 base pair-long and corresponds to a 580-amino acid protein (with a theoretical molecular weight of 66 kDa). It contains the tryptic peptides previously identified (Silva-Filha *et al.*, 1999) and peculiar structural features on both ends of the molecule. A hydrophobic signal peptide located at the N-terminal end of the protein targets the protein to the cell membrane. The C-terminal end contains a domain composed of three small amino acids (Ser^{558}-Ser^{559}-Ala^{560}) followed by hydrophilic residues and then a hydrophobic tail. These sequences fulfill the criteria for posttranslational maturation by linkage of a GPI moiety (Udenfriend and Kodukula, 1995; Eisenhaber *et al.*, 1998). Multiple alignments showed that this sequence shares a high level of similarity with maltase-like proteins from insects, especially over the first two-thirds of the molecule that are thought to bear the enzymatic activity responsible for hydrolyzing the terminal (α-1,4-linked glucose residues of various carbohydrates. Northern blotting experiments identified a single transcript of about 2 kb in the midgut of *Culex* larvae (Darboux *et al.*, 2001).

Cpm1 is not fully processed when expressed in *Escherichia coli*, but it is able to bind the Bin toxin specifically and has weak but significant α-glucosidase activity by hydrolyzing 4-nitrophenyl α-D-glucopyranoside. Much more conclusive data were obtained when *cpm1* cDNA was cloned in the insect Sf9 cell line. These cells are derived from pupal ovarian tissue originating from the Lepidoptera *Spodoptera frugiperda*. They have the enzymatic equipment required to maturate Cpm1 by adding the GPI moiety (Darboux *et al.*, 2002). Cpm1 can easily be detected at the surface of Sf9-IP cells, which express the receptor. Western blotting on the expression product of the *cpm1*/Sf9 construct, using a polyclonal antibody directed against the C-terminal end of the molecule (Darboux *et al.*, 2002), detects only one protein of about 66 kDa in the membrane fraction of transfected cells. Moreover, when transfected cells are treated with PI-PLC, no signal is observed in the membrane compartment whereas a strong signal is observed in the soluble fraction, indicating that the Cpm1 produced in Sf9 cells is indeed attached to the cell membranes by a GPI (Darboux *et al.*, 2002). The number of GPI-anchored proteins found in vertebrates and in invertebrates is increasing rapidly. They have numerous physiological roles (enzymatic activities, cell adhesion, transport and cell–cell signaling), but seem to be present in specialized micro-domains of the plasma membranes known as lipid rafts. Many studies have concentrated on the role of these rafts in cell trafficking and signal transduction (Simons and Toomre, 2000). When cells are transfected with a truncated *cpm1* sequence lacking its 3′ end (IP-Mut), no Cpm1 is found in the membrane fraction. Instead, Cpm1 is secreted and recovered in the culture medium. This secreted form exhibits strong α-glucosidase activity but little α-amylase activity compared to untransfected Sf9 cells (Darboux *et al.*, 2002). Binding experiments on *cpm1*/Sf9 cell membrane preparations showed that the native receptor is indeed expressed as the affinity of Bin for its site is very similar to that reported for *in vitro* experiments done on *Culex* BBMFs (about 10 nM). An anti-Cpm1 antibody was used to localize receptor expression sites in mosquito tissues. In the midguts of 4th instar larvae, a strong signal was detected both in the gastric caecum and in the posterior midgut, with a clear cutoff between the intermediate and posterior midguts (Darboux *et al.*, 2002). These data confirmed the localization of the Bin toxin binding site, which had been previously reported by use of fluorescently labeled derivatives (Davidson, 1988; Oei *et al.*, 1992).

6.7.3.2. The Mtx1 Toxin

Almost nothing is known about the mode of action of Mtx toxins other than Mtx1, because few studies have been carried out. The mosquitocidal activity of

Mtx1 was initially measured using fusion proteins synthesized in *E. coli*: Mtx1 is highly active against *C. quinquefasciatus* larvae (Thanabalu *et al.*, 1992), as the LC_{50} value is comparable to that of the crystal Bin proteins (15 ng/ml). Deletion analysis suggested that the 27 kDa fragment of Mtx1 is able to self ADP-ribosylate, whereas the 70 kDa fragment is assumed to play a role in the toxicity to cultured *C. quinquefasciatus* cells; however, both regions are necessary for toxicity to mosquito larvae (Thanabalu *et al.*, 1993).

Due to its cytotoxicity towards bacterial cells, the 27 kDa enzyme fragment cannot be produced alone, in the activated form, in *E. coli* expression systems. However, a nontoxic 32 kDa N-terminal truncated version of Mtx1 has been successfully expressed in *E. coli* and subsequently cleaved to an active 27 kDa enzyme fragment (Schirmer *et al.*, 2002b). *In vitro*, this 27 kDa fragment of Mtx1 is able to ADP-ribosylate numerous proteins in *E. coli* lysates, especially a 45 kDa protein identified as the *E. coli* elongation factor, Tu (EF-Tu). The inactivation of EF-Tu by Mtx1-mediated ADP-ribosylation and the resulting inhibition of bacterial protein synthesis probably play important roles in the cytotoxicity of the 27 kDa enzyme fragment of Mtx1 towards *E. coli* (Schirmer *et al.*, 2002b). Glu^{197} of the 27 kDa enzyme component was identified as the "catalytic" glutamate that is conserved in all ADP-ribosyltransferases (Schirmer *et al.*, 2002a). Transfection of mammalian HeLa cells with a vector encoding the 27 kDa fragment fused with a green fluorescent protein leads to cytotoxic effects characterized by cell rounding and formation of filopodia-like protrusions (Schirmer *et al.*, 2002a).

In vitro binding assays using isolated BBMFs from *C. pipiens* midguts indicate the presence of a membrane receptor to the 70-kDa fragment. The affinity of this receptor/toxin interaction is low (K_d ~1.4 μM), indicating that the 70-kDa component has a very low affinity for its binding site (**Figure 6a**; Charles and Berry, unpublished data). In addition, saturation of this binding site was not possible. Complementary competition experiments, using either the labeled P70 or the labeled Bin toxin as the labeled component, and unlabeled P70 or Bin toxin as the unlabeled competitors, showed that the Bin toxin can compete with the labeled P70 component, whereas the opposite is not true (**Figure 6b** and **c**). This suggests that the P70-Mtx1 component shares a common binding site with the Bin toxin, and that the Bin toxin can also bind to this binding site with a very low affinity.

After cleavage of Mtx1 by chymotrypsin-like proteases, the P70 proteolytic fragment of Mtx1 remains noncovalently bound to the N-terminal 27-kDa fragment (Schirmer *et al.*, 2002a). Thus, from a functional point of view, the binding of the P70 component of the toxin to a membrane receptor may play a key role in carrying the 27-kDa enzymatic fragment to its target site in mosquito midgut cells.

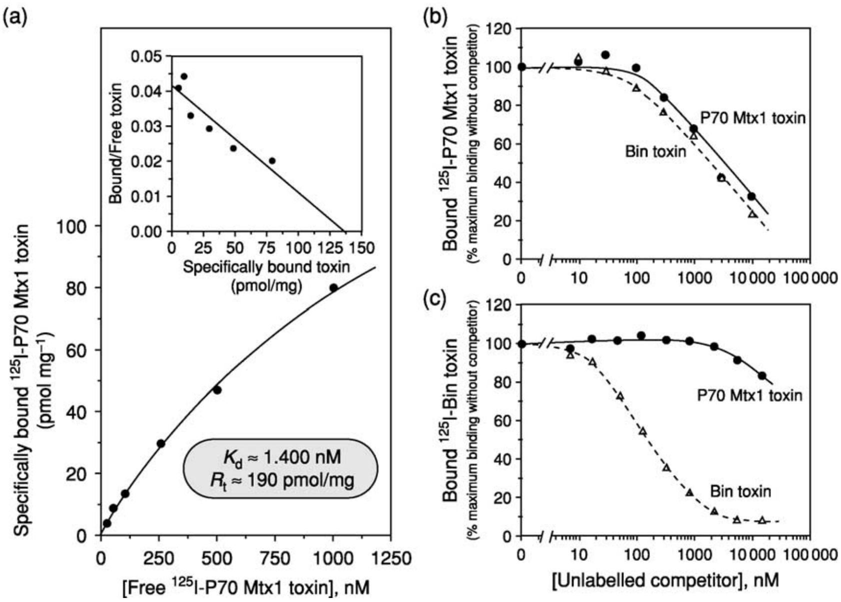

Figure 6 Direct binding of ^{125}I-labeled *B. sphaericus* P70-Mtx1 toxin to midgut brush border membranes of *C. pipiens* (a). Inset, specific binding in Scatchard plots. Competition experiments between ^{125}I-P70 and unlabeled P70 or Bin toxin (b), or between ^{125}I-Bin toxin and unlabeled P70 or Bin toxin (c).

6.7.4. Field Use of *B. sphaericus*

Due to the special properties of mosquitocidal *Bti* and *B. sphaericus* (e.g., environmental safety, high specificity of *B. sphaericus* and *Bti* toxins, relative ease of mass production, formulation and application, suitability for integrated control programs, and relatively low cost for development and registration), these bacilli were rapidly developed and used in many mosquito and/or black fly control programs. *Bti* has a broader application because unlike *B. sphaericus* it also has larvicidal activity against important vectors belonging to the *Aedes* and *Simulium* genera (see **Chapter 2.1**). *B. sphaericus* has been used to control *C. pipiens* and *C. quinquefasciatus* larvae since the late 1980s, and it is also used to control *Anopheles* spp. in some areas (**Table 3**; Karch *et al.*, 1992; Hougard *et al.*, 1993; Kumar *et al.*, 1994). Even though the larvicidal activity of *B. sphaericus* is mainly restricted to *Culex* and *Anopheles* species, it is stable, can recycle in organically polluted water (major breeding sites of *Culex* species), and is highly persistent (Lacey *et al.*, 1987; Correa and Yousten, 1995), giving it an advantage over *Bti*. Both *B. sphaericus* and *Bti* overcome the resistance of *Culex* and *Anopheles* to conventional insecticides.

In temperate regions, *B. sphaericus* is mainly used to reduce nuisance due to mosquito bites. It has been used on a large scale in Germany, especially in the Rhine Valley (Becker, 2000), and in France, where it was used to control *C. pipiens* (resistant to the organophosphate insecticide temephos) on the Mediterranean coast for more than 7 years before any problems of resistance arose (Sinègre *et al.*, 1993). However, the main interest (amount of product used and treated areas) is in tropical regions where *B. sphaericus* is used to control *Culex* and *Anopheles* populations, particularly to reduce the incidence of vector-born diseases like filariasis and malaria. In Goa (India), the use of *B. sphaericus* against *A. stephensi* larvae resulted in a notable reduction in the number of cases of malaria (Kumar *et al.*, 1994). This was also the case in China against *A. sinensis* (Becker, 2000; Yuan *et al.*, 2000). In the Democratic Republic of Congo, successful experimental field trials were run against *A. gambiae* in rice fields (Karch *et al.*, 1992). *C. quinquefasciatus* populations were reduced in the town of Maroua in Cameroon (Barbazan *et al.*, 1997). In the city of Recife, in Brazil, the experimental application of *B. sphaericus* successfully reduced the number of cases of filariasis by reducing the adult vector population of *C. quinquefasciatus* (Regis *et al.*, 1995).

Table 3 Examples of large-scale field use of *Bacillus sphaericus* against mosquito populations and the development of resistance

Target species	B. sphaericus *strain*	*Treatment frequency*	*Treatment period*	*Treated area*	*Locality/country*	*Resistance RR*[a]	*References*
A. stephensi	B-101	Weekly	9 months	2 km^2	Panaji city (India)	–	Kumar *et al.* (1996)
C. pipiens	2362	Every 21 days to 6 months	7 years	210 villages	Mediterranean Coast (France)	>20 000[b]	Sinègre *et al.* (1993, 1994)
C. quinquefasciatus	2362	Monthly/fortnightly	26 months	1.2 km^2	Recife city (Brazil)	10	Silva–Filha *et al.* (1995)
C. quinquefasciatus	1593M	Fortnightly	2 years	8 km^2	Kochi (India)	146	Rao *et al.* (1995)

C. quinquefasciatus	2362	Every 3 months	4 years	200 ha	Yaoundé (Cameroon)	–	Hougard *et al.* (1993)
C. quinquefasciatus	2362	Twice a year	2 years	2000 ha	Maroua (Cameroon)	–	Barbazan *et al.* (1997)

[a] The level of resistance is calculated as the ratio of the LC_{50} values of the resistant population to that of susceptible laboratory colonies.
[b] At isolated breeding sites.
–, resistance ratio value not reported.

Only a few of the highly larvicidal *B. sphaericus* strains are commercially sold: strain 2362 (VectoLex® and Spherimos®, Valent–Bioscience Corporation, USA) in the USA and Europe, strains 1593 (Biocide-S®) and 101-B (Sphericide®, Biotech International Ltd) in India, and strain C3-41 in China. These products are more or less adapted to various applications and larval breeding sites. As the success of a given strain is strongly dependent on the performance of the formulation, they have been improved over recent years, so that new products are now much more efficient (Skovmand and Bauduin, 1997; Fillinger *et al.*, 2003). There have been several attempts to produce these products locally in both Asia (Wuhan, China) and South America (Rio de Janeiro, Brazil), but only a few large international companies remain on the market.

6.7.5. Resistance To *B. sphaericus*

6.7.5.1. Introduction

Unlike *Bti*, towards which no cases of field resistance have appeared so far, several cases of larval resistance to *B. sphaericus* crystal toxin have been reported in *C. pipiens* and *C. quinquefasciatus* (**Table 3**). However, no resistance has yet been found in *B. sphaericus*-treated *Anopheles* populations. Indications for resistance to *B. sphaericus* were first reported in laboratory-selected populations (Georghiou *et al.*, 1992; Rodcharoen and Mulla, 1994), then by Pei *et al.* (2002), and a bit later from field-treated populations: from France (Sinègre *et al.*, 1994), India (Rao *et al.*, 1995), and Brazil (Silva-Filha *et al.*, 1995), and more recently from China (Yuan *et al.*, 2000) and Thailand (Mulla *et al.*, 2003) (**Table 4**).

The emergence of resistance was not that surprising given: (1) the apparent "one site" mode of action of the Bin toxin; (2) the ability of *B. sphaericus* to recycle and to persist in larval breeding zones, thus leading to increasing selection pressure (Lacey *et al.*, 1987; Correa and Yousten, 1995); and (3) the apparent high natural variation in susceptibility of *Culex* to *B. sphaericus* (Georghiou and Lagunes-Tejeda, 1991). However, resistance to *B. sphaericus* is also characterized by a large variation in resistance level, speed of appearance, and stability, indicating that factors such as selection pressure and the initial frequencies of resistance alleles in the mosquito population are very important.

We will summarize what is presently known about the genetics and mechanism of resistance to *B. sphaericus* with examples from both *C. pipiens* and *C. quinquefasciatus*. We will also discuss the mode of action and mechanism of resistance of the Bin toxin, as well as issues concerning the preservation of *B. sphaericus* as a mosquito control agent by searching for either natural or recombinant strains with low cross-resistance. Finally, we will discuss implications for application strategies.

Table 4 reports several examples of both laboratory-selected and initially field-selected resistance, from tropical and temperate areas, from places with high and low treatment frequencies and from various types of breeding sites. All populations reach very high levels of resistance (resistance ratio >10 000), either directly in the field or following further laboratory selection (Rao *et al.*, 1995; Nielsen-LeRoux *et al.*, 1997; Yuan *et al.*, 2000; Mulla *et al.*, 2003).

6.7.5.2. Genetics and Mechanisms of Resistance

Investigations into mosquito resistance to the Bin toxin under laboratory conditions were pioneered by Georghiou and co-workers. This group treated large numbers of early-4th instar larvae of a Californian population of susceptible *C. quinquefasciatus* (CpqS) with high concentrations of spore-crystal mixtures (Georghiou *et al.*, 1992; Wirth *et al.*, 2000b). Selection was very effective and resistance arose so rapidly in this colony (named CpqR or GEO) that the larvae were virtually insensitive to the *B. sphaericus* toxins by generation 12 (resistance ratio >100 000). Moreover, the F_1 offspring resulting from crosses between resistant and susceptible mosquitoes were almost totally susceptible, indicating that the resistance is recessive and borne by a single locus (Nielsen-LeRoux *et al.*, 1995; Wirth *et al.*, 2000b). Interestingly, a high level of resistance was also detected in first instar larvae, which suggests that the genetic factor of resistance is constitutive and not related to a particular developmental stage. Similar investigation with field-selected *B. sphaericus* resistant *C. pipiens* also showed monofactorial and recessive resistance, as F_1 progenies were as susceptible as the parental susceptible colony. In addition, dose-mortality Probit lines from back-cross progenies indicated that resistance of these colonies were likewise due to one major gene (Nielsen-LeRoux *et al.*, 1997; Oliveira *et al.*, 2003a). Until now, all studied cases of resistance were due to one major recessive gene that is sex linked in Mediterranean populations of *C. pipiens* (Nielsen-LeRoux *et al.*, 1997; Chevillon *et al.*, 2001; Nielsen-LeRoux *et al.*, 2002) but autosomally inherited in *C. quinquefasciatus* from Brazil and China (Oliveira *et al.*, 2003a) and possibly also in the GEO (CpqR) colony (Wirth *et al.*, 2000b). In general, no signs of a fitness cost have been reported in the laboratory (Oliveira *et al.*, 2003b), except for

one, the stable low level resistant JRMM-R (Rodcharoen and Mulla, 1994; Rodcharoen and Mulla, 1997). In the field, resistance appears to be unstable in the absence of selection pressure because, as soon after *B. sphaericus* treatment is interrupted, the exposed *C. quinquefasciatus* populations become susceptible to *B. sphaericus* again (Silva-Filha and Regis, 1997; Yuan *et al.*, 2000).

6.7.5.2.1. Molecular basis of laboratory-selected resistance As described above, the binding of BinB to the α-glucosidase (Cpm1) receptor at the apical membrane of midgut cells is essential for larvicidal activity. Thus, when resistance to *B. sphaericus* was first reported, the mechanisms of resistance were analyzed by comparing the kinetics of Bin receptor binding in the midguts of GEO and susceptible *C. quinquefasciatus* larvae (CpqS). As expected, the binding characteristics of ^{125}I-Bin to CpqS BBMFs were very similar to those previously reported for *C. pipiens* membranes (Nielsen-LeRoux and Charles, 1992). In contrast, Bin cannot specifically bind BBMFs from GEO mosquitoes (Nielsen-LeRoux *et al.*, 1995). In addition, when assayed on BBMFs prepared from F_1 (CpqS X GEO) larvae, ^{125}I-Bin bound to a single class of receptor, which is consistent with the suspected recessive nature of the resistance trait. Analysis of binding data with BBMFs from the backcross (BC) progeny showed that the binding sites are not saturated in the range of toxin concentrations used, and that the total amount of bound toxin is much lower than for the susceptible parental strain. LIGAND analysis showed that the experimental data obtained with the BC progeny fit a two-site model better than a one-site model. This possible existence of two classes of binding sites in the BC population is suggestive of genetic heterogeneity.

The next step was to determine whether this receptor was absent from the GEO mosquito midgut or whether it was present in a form that could no longer recognize the Bin toxin. In Northern blot experiments, total RNA extracted from GEO midguts was probed with a *cpm1* DNA fragment. The 2-kb transcript previously identified in IP mosquitoes was present in similar amounts in GEO mosquitoes (Darboux and Pauron, unpublished data). *In situ* hybridization experiments confirmed that *cpm1* transcripts are equally distributed both quantitatively and qualitatively in CpqS and GEO midguts. These transcripts were found in the regions that had been previously identified as Cpm1 reservoirs, i.e., cardia cells, the gastric caecae and the posterior midgut (Darboux *et al.*, 2002).

Nevertheless, the amount of Cpm1 protein differed completely in the two populations. Firstly, immunolocalization performed on the same type of cryosections as the *in situ* hybridizations failed to detect Cpm1 in any of the above-mentioned structures or anywhere else in the larval midgut. Secondly, Cpm1 was not detected in BBMFs from GEO mosquitoes by Western blotting (Darboux *et al.*, 2002). Taken together, these results suggest that the sequence encoding Cpm1 is altered in GEO. Analysis of the full cDNA sequence of $cpm1_{GEO}$ confirmed this hypothesis. The $cpm1_{GEO}$ sequence contains seven nonsilent mutations compared to $cpm1_{IP}$. Six of these mutations result in amino acid substitutions in the protein itself (Ala95Asp; Lys115Met; Glu178Thr; Asp230His; Asn265Asp; Leu486Met), and the seventh introduces a termination signal in the hydrophobic tail of the protein (Leu569Stop). To determine which of these mutations were involved in the resistance mechanism, Sf9 cells were transfected with various constructs corresponding to natural or chimeric forms of Cpm1. Western blotting, binding experiments and enzymatic assays were performed on the expression products of each construct. The $Cpm1_{GEO}$ form was unable to link to the plasma membranes of Sf9 cells (Figure 7), but accumulated in the extracellular medium, which explains why no signal could be detected both in BBMF Western blotting and by immunolocalization in midgut sections. Concomitantly, no binding activity was detected on membranes prepared from Sf9/$Cpm1_{GEO}$ cells, which confirms the previous results of *in vitro* binding of ^{125}I-Bin toxin to $BBMF_{GEO}$ (Darboux *et al.*, 2002).

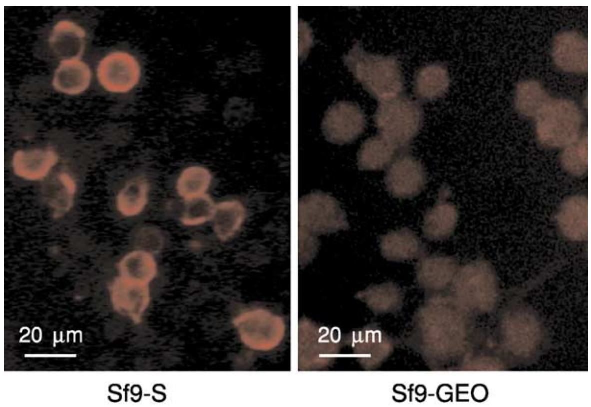

Figure 7 Ectopic expression of Cpm1. Sf9 cells were transfected with the $cpm1_{IP}$ sequence (Sf9-S) or the $cpm1_{GEO}$ one (Sf9-GEO). The anti-Cpm1 antibody gives a signal only on the plasma membrane of the Sf9-S cells (Castella and Pauron, unpublished data).

A chimeric form of Cpm1 was also constructed, where the GEO sequence was modified by replacing the early TAG codon by TTG (Stop569Leu) by site-directed mutagenesis in order to recover a "susceptible-like" hydrophobic tail. When transfected into Sf9 cells, this construct, named Sf9-GEOMut, was able to mature fully, and $Cpm1_{GEOMut}$ was detected in the membrane fraction of the cells to which it was linked by a GPI, as shown by its sensitivity to PI-PLC (Darboux *et al.*, 2002). Moreover, competition as well as saturation binding assays showed that ^{125}I-Bin binds membranes prepared from Sf9-GEOMut cells with the same affinity as those prepared from Sf9-IP cells. Hence, the six mutations present in the protein itself have no effect on the capacity of the receptor to recognize the toxin and are not involved in the resistance mechanism. They have no effect on the enzymatic activity of Cpm1, as shown by measurements done using the secreted form of $Cpm1_{GEO}$ (**Figure 8**).

$Cpm1_{GEO}$ hydrolyzes 4-nitrophenyl α-D-glucopyranoside as well as $Cpm1_{IPMut}$, which suggests that $Cpm1_{GEO}$ retains its physiological activity even when it is no longer bound to the membrane *in vivo*. If this is the case, this resistance mechanism may cause less pleiotropic effects than other mechanisms that result in the severe dysfunction in the physiology of the insect. In that respect, resistance to other *Bacillus* toxins may impair important functions such as cell–cell signaling in the case of the cadherin-like protein (Gahan *et al.*, 2001) or carbohydrate modifications in the case of the β-1,3-galactosyltransferase (Griffitts *et al.*, 2001). Resistance in GEO also contrasts with identified mechanisms of resistance to chemical insecticides by target modification, which is usually caused by a small number of point mutations in the receptor sequence that decrease its affinity for the pesticide (Pauron *et al.*, 1989; ffrench-Constant *et al.*, 1993; Mutero *et al.*, 1994).

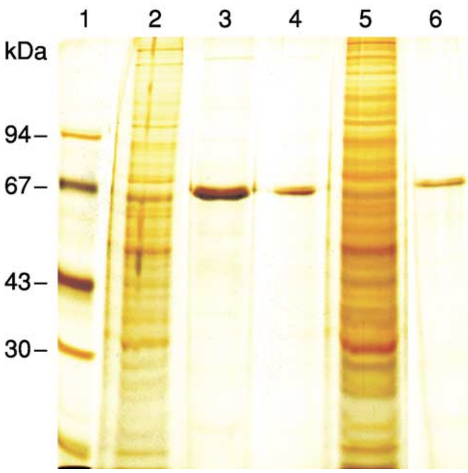

Figure 8 Silver staining of secreted forms of Cpm1. Lane 1, molecular weight markers. Lanes 2 and 5, crude extracellular medium of Sf9-IPMut and Sf9-GEO cells, respectively. Lanes 3 and 4, $Cpm1_{IPMut}$ purified by affinity chromatography. Lane 6 $Cpm1_{GEO}$ purified by affinity chromatography (Pauchet and Pauron, unpublished data).

A single point mutation in the $cpm1_{GEO}$ sequence results in Cpm1 molecules with a shortened hydrophobic tail (**Figure 9**). This hydrophobic stretch becomes too small to be recognized by the transamidase complex, thus preventing Cpm1 from being matured by the anchoring of a GPI moiety. Nevertheless, the unprocessed form of the receptor is translocated towards the apical membrane of the cell, where it is secreted. In the extracellular space, $Cpm1_{GEO}$ may still encounter and bind the Bin toxin but the complex formed can no longer promote the cytopathological effects of the toxin and the larva is not affected. This mechanism is the first example of a putative combination of two types of resistance mechanism to insecticides, i.e., target modification and sequestration of the toxic ligand.

6.7.5.2.2. Mechanisms of field-selected resistance

In vitro binding studies have also been conducted with other field-resistant mosquito colonies (see **Table 4**). In a number of cases, the mechanism of resistance was due to lack of measurable Bin toxin–receptor interaction. This was recently found for *C. quinquefasciatus* colonies from Brazil and China (Oliveira *et al.*, 2003a), from India (KOCHI colony, unpublished data), and for the *C. pipiens* BP colony from France (Nielsen-LeRoux *et al.*, 2002). Interestingly, the initial Bin toxin–receptor interactions of the highly *B. sphaericus*-resistant *C. pipiens* colonies SPHAE (Nielsen-LeRoux *et al.*, 1997) and TUNIS (Nielsen-LeRoux *et al.*, 2002), are similar to those of susceptible *C. pipiens* (*sensu lato*) colonies (reviewed in Nielsen-LeRoux *et al.*, 2002). Functional receptors have also been found in a low-level and stably resistant colony (Rodcharoen and Mulla, 1994; Nielsen-LeRoux, unpublished data). Another low-level resistant colony has been shown to have functional receptors, although the larvae collected in the field may not all have been homozygous resistant (Silva-Filha *et al.*, 1995).

There is evidence for more than one resistance mechanism to the Bin toxin in the *C. pipiens* complex worldwide and even within small areas like the West Mediterranean countries. Indeed, mutations in three West Mediterranean *C. pipiens* populations give rise to three different mutants: *sp-1*^{R} (SPHAE strain), *sp-2*^{R} (BP strain), and *sp-T*^{R} (TUNIS strain).

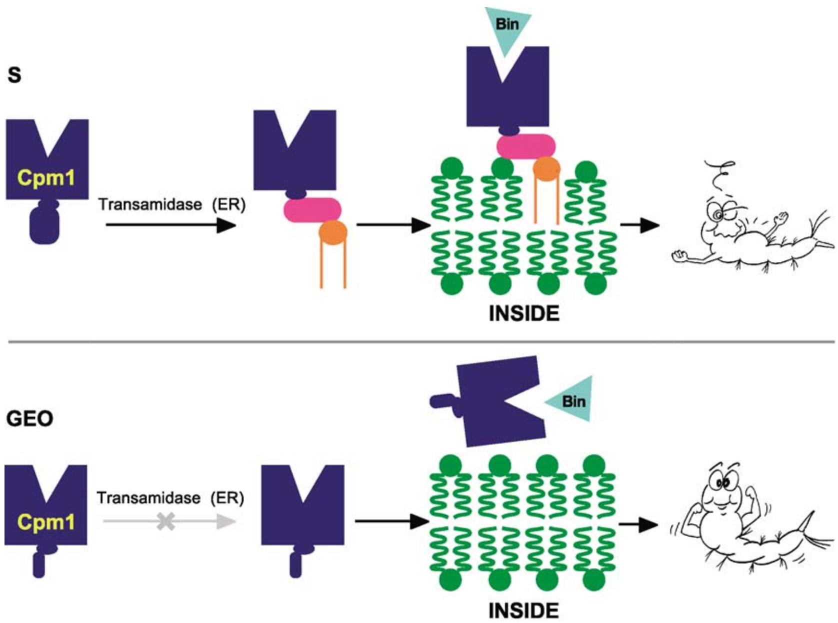

Figure 9 Schematic representation of the interaction between the Bin toxin and its receptor in a susceptible (S, top) and in a resistant (GEO, bottom) mosquito larva.

Mutations are all sex-linked and separately confer the same totally recessive resistance to *B. sphaericus*. However, binding experiments showed clear differences between the BP strain mutant and the other two mutants (Nielsen-LeRoux *et al.*, 2002). It is not clear whether mutations of TUNIS and SPHAE are identical or not, even though toxin receptor affinities are high in both cases and no gene recombination was observed when TUNIS and SPHAE were crossed (Chevillon *et al.*, 2001; Nielsen-LeRoux *et al.*, 2002). Moreover, the *cpm1* coding sequences of TUNIS and SPHAE are strictly identical (Darboux and Pauchet, unpublished data). *B. sphaericus* resistance in Californian *C. quinquefasciatus* populations may also be based on different mutations, as the laboratory-selected resistance of two Californian *C. quinquefasciatus* collected in the field was reported to be stable, one at a very high level (>100 000 fold, GEO strain) (Georghiou *et al.*, 1992; Wirth *et al.*, 2000b) and the other at a low level (35 fold, JRMM-R strain) (Rodcharoen and Mulla, 1994). A second study supports this hypothesis, because of the numerous *B. sphaericus*-resistant colonies tested for cross-resistance to other *B. sphaericus* strains, the only one that was resistant to all tested *B. sphaericus* strains was the JRMM-R colony (Nielsen-LeRoux *et al.*, 2001).

Cpm1 from the SPHAE strain appears to be totally functional, and its distribution in the larval midgut is indistinguishable from that in susceptible individuals (Castella and Pauron, unpublished data). In addition, the transcription pattern of $cpm1_{SPHAE}$ is identical to that of $cpm1_{IP}$ and the coding sequence of $cpm1_{SPHAE}$ displays no nonsilent mutations compared to the susceptible allele (Darboux and Pauchet, unpublished data). Hence, as no apparent differences in the activation process of the Bin toxin have been reported in SPHAE larvae (Nielsen-LeRoux *et al.*, 1997), the step involved in resistance in SPHAE presumably occurs after the Bin toxin interacts with its receptor. Determining whether this is dependent on the endocytosis of BinA, BinB, and/or the receptor, and whether they persist with $sp\text{-}1^{RR}$ larvae is likely to improve our understanding of how $sp\text{-}1^{R}$ interferes with the intoxication process.

When considering the mechanism underlying the resistance of the BP strain, it is worth noting the possibility of a tight physiological interaction between *sp-2* (BP) and *sp-1* (SPHAE). For example, the resistance of $sp\text{-}1^{RS}$ $sp\text{-}2^{RS}$ double heterozygotes is increased by over 100-fold, even though each mutation was totally recessive alone (Chevillon *et al.*, 2001). However, the BP colony may be different from SPHAE, as immunological characterization of Cpm1 in BP confirmed the binding data: no signal was ever detected either by Western blotting analysis of $BBMF_{BP}$ proteins or in cryosections of BP larva midgut (Castella and Pauron, unpublished data). In this strain, the resistance mechanism appears to be rather complex, as preliminary results

indicate that both the coding sequence and the pattern of transcription of *cpm1* are altered in BP (Darboux and Pauron, unpublished data).

6.7.6. Conclusions and Perspectives: Management of *B. sphaericus*-Resistance

The genes encoding BinA and BinB have been sequenced, and the regions important for the specificity and activity of these components identified. It is clear that both BinA and BinB are needed for full activity of the *B. sphaericus* crystal toxin: BinA alone is slightly toxic and might form pores in the cell membranes, and BinB appears to be responsible for the regionalized binding of the toxin to a specific midgut membrane receptor. Even if the nature of the Bin receptor, an α-glucosidase, is known in *Culex* spp., the possible intracellular actions of the Bin toxin(s) remain unclear. Indeed, immunolocalization investigations on the midguts of intoxicated *C. quinquefasciatus* larvae revealed that both BinA and BinB are present within cells a few hours after intoxication (Silva-Filha and Peixoto, 2003). These results show that the Bin toxin is internalized during the intoxication process and confirms previous results using fluorescently labeled Bin toxin (Davidson, 1988; Oei *et al.*, 1992). The importance of internalization of the Bin toxins into midgut cells is demonstrated by the fact that in the presence of the pore-forming or "detergent-like" Cyt1A toxin from *Bti*, the Bin toxin is internalized into *B. sphaericus*-resistant larval midgut cells (Federici *et al.*, personal communication). Further studies are required to elucidate the mode of action fully, as the final target molecules are unknown.

Further studies are also needed to determine the mode of action of the Bin toxin towards *Anopheles*, because there is some evidence suggesting that it differs from that towards *Culex*. As previously mentioned, no cases of resistance have yet been reported in *Anopheles* and *in vitro* binding experiments indicated that both BinA and BinB can bind to a receptor-binding site (Charles *et al.*, 1997).

The Mtx toxins have been studied less extensively than the Bin toxins, so further studies are needed, especially to determine how the enzymatic fragment from the Mtx1 toxin enters midgut cells to ADP-ribosylate target proteins.

As indicated above, there is a real risk that resistance to *B. sphaericus* will appear when it is used in large-scale *Culex* spp. control programs. Thus, it is important to investigate possible variations in toxic activity and specificity of different natural *B. sphaericus* strains, in order to evaluate the level of possible cross-resistance among different strains and the Bin toxins they produce. All *B. sphaericus*-resistant *Culex* spp. populations were selected using strains 2362, 1593 or C3-41 (Rodcharoen and Mulla, 1994; Nielsen-LeRoux *et al.*, 1995; Rao *et al.*, 1995; Yuan *et al.*, 2000), all of which belong to the same serotype and have identical Bin toxin genes (Bin2 type). However, there are small differences in the amino acid sequences of Bin toxins (**Table 2**), which may be important in the structure/function of the toxin/receptor complex, and therefore for larvicidal activity. Several groups have investigated the level of cross-resistance towards active *B. sphaericus* strains: 2297, IAB-881, IAB-872, LP1-G and IAB-59, in *Culex* spp. colonies resistant to strains 2362, 1593, or C3-41. The 2362-derived resistant JRMM-R colony is resistant to strains 2297 and 1593 (Rodcharoen and Mulla, 1994), and to IAB-59, IAB-881 and IAB-872 (Nielsen-LeRoux *et al.*, 2001). The GEO, SPHAE and the KOCHI colonies are resistant to all strains except IAB-59 (Poncet *et al.*, 1997; Poopathi *et al.*, 1999; Nielsen-LeRoux *et al.*, 2001). In addition, strain LP1-G is able to overcome resistance in *C. quinquefasciatus* larvae resistant to strain C3-41 from China (Yuan *et al.*, 2000).

Investigations on both strains IAB-59 and LP1-G suggested the presence of toxic factors other than the Bin and Mtx toxins. First, the crystals from LP1-G contain a natural nontoxic variant of the Bin toxin (Bin4 type) (Yuan *et al.*, 2001). Thus, although the whole strain is larvicidal, the toxic activity may come from other compounds produced by this strain. Second, crystals from the IAB-59 or IAB-872 Bin toxin (Bin1 type) are also nontoxic to the *B. sphaericus*-resistant *Culex* spp. colonies, which are also susceptible to the whole IAB-59 strain (Nielsen-LeRoux, unpublished data; Shi *et al.*, 2001; Pei *et al.*, 2002). In addition, the low level of cross-resistance to IAB-59 has recently been validated by selecting for resistance to this strain in laboratory conditions, in two *C. quinquefasciatus* populations collected in the field in China and Brazil (**Table 4**). The speed of appearance was much slower and the level of resistance much lower with the IAB-59 strain than with strains 2362 or C3-41. Finally, colonies that carry only a low level of resistance to IAB-59 are highly resistant to strains 2362 and C3-41, suggesting that resistance is directed against the Bin toxins regardless of whether it belongs to the Bin1 or Bin2 type. This is in agreement with *in vitro* toxin–receptor binding studies, which showed high competition among Bin toxins (Bin1, Bin2 and Bin4) and provided evidence for a common receptor-binding site (Nielsen-LeRoux *et al.*,

unpublished data). Further studies are required to evaluate whether strain IAB-59 is of commercial value as an alternative to *B. sphaericus* strains 1593, 2362, 101-B, and C3-41 (the only strains currently produced for use in the field). This depends on its potency and field performance. Additionally, several groups are currently trying to identify the genes encoding the additional toxic compounds from strains IAB-59 and LP1-G.

The fact that the Bin toxin behaves as a unique moiety during the binding step indicates that the probability of selecting resistance to *B. sphaericus* is much higher than for *Bti*, which contains at least four proteins that potentially act on different target molecules. Despite reports of laboratory and field resistance, the use of *B. sphaericus* for the control of mosquito larvae is still of interest. Nevertheless, it is important to collect information about baseline susceptibility before starting treatment. However, as resistance to *B. sphaericus* is recessive, it is only possible to detect resistance when it has already become homozygous and therefore difficult to handle. Thus, it may be possible to monitor the risk of resistance development in a given area by use of molecular nucleotide probes based on the mutation of resistance genes. However, resistance to *B. sphaericus* seems to be very complex and different probes would be needed to cover all possible mutations, only one of which has been identified so far (Darboux *et al.*, 2002).

Both from a practical and an ecological point of view, the best and most direct way to overcome and to manage *B. sphaericus* resistance is of course *Bti*, which is already commercialised. Fortunately, all *Culex* populations reported to display field resistance to *B. sphaericus* have been tested for susceptibility to *Bti*. No cross-resistance has been observed. There is even some evidence for increased susceptibility in some colonies (Rao *et al.*, 1995; Silva-Filha *et al.*, 1995; Yuan *et al.*, 2000). This was expected, because the multi-toxin complex of this bacterium does not share any receptor-binding sites with the *B. sphaericus* binary toxin (Nielsen-LeRoux and Charles, 1992). In several situations, it is recommended that *Bti* be used in rotation with *B. sphaericus* (Regis and Nielsen-LeRoux, 2000; Yuan *et al.*, 2000). Recent results obtained in Thailand have suggested that a mixture of *Bti* and *B. sphaericus* may help reduce the risk of appearance of *B. sphaericus* resistance while preserving the superior field performance of *B. sphaericus* compared to *Bti*, particularly in breeding sites rich in organic matter (Mulla *et al.*, 2003).

Alternatives to natural *Bti* and *B. sphaericus* strains include genetically modified organisms, as combining different toxins binding to different receptors in the same organism is also a good way of preventing resistance. In addition to the Bin toxins, other toxins from either *B. sphaericus* or other insecticidal microorganisms could be produced. For example, the expression of *Mtx1* genes in *B. sphaericus* during sporulation, i.e., under the control of a sporulation promoter, could allow the diversification of toxins. Similarly, *Bti* mosquitocidal toxin genes could be combined with *B. sphaericus* genes; some groups have already attempted this, for example by introducing the *Bti* genes encoding Cry4B, Cry4D or Cry11A into toxic *B. sphaericus* strains (Trisrisook *et al.*, 1990; Bar *et al.*, 1991; Poncet *et al.*, 1994; Poncet *et al.*, 1997). Conversely, *B. sphaericus* crystal toxin genes have been successfully introduced into toxic *Bti* (Bourgouin *et al.*, 1990). Although these studies did not demonstrate any increase in toxicity against *Anopheles* and *Culex*, such recombinants may delay the emergence of resistant insects.

Several attempts have been made to introduce or to combine toxin genes from *Bti*, *B. thuringiensis* serovar *jegathesan* (*Bt jeg*) and serovar *medellin* (*Bt med*), and to evaluate their activity towards both susceptible and *B. sphaericus*-resistant colonies. The introduction of Cry11A from *Bti* and Cry11Ba from *Bt jeg* partially restored the susceptibility of resistant colonies (Poncet *et al.*, 1997; Servant *et al.*, 1999). Nonspecific cytolytic toxins (Cyt1A and Cyt1B) also partially restored its toxicity towards two resistant colonies (Thiéry *et al.*, 1998; Wirth *et al.*, 2000a). A *Bti* strain harboring genes encoding the binary toxin as well as Cyt1 and Cry11B was more toxic than unmodified *Bti* IPS-82 (Park *et al.*, 2003). Several groups have also attempted to introduce and to overproduce entomopathogenic toxins into organisms living in the environment and serving as natural foods for mosquitoes, such as cyanobacteria (Liu *et al.*, 1996b), or to stably integrate the toxins encoding these genes into the chromosomes of other bacteria such as *Enterobacter amnigenus* (Tanapongpipat *et al.*, 2003). However, given our current knowledge of *B. sphaericus* resistance, the expression of Bin toxin as the only active compound should be avoided. No recombinant strains have yet proved to have a better field performance than the natural strains, and no products based on recombinant strains have yet been registered for use in mosquito control programs. Therefore there is a continuing need to identify new strains with novel modes of

action against the principal mosquito vectors of human diseases.

6.8 Baculoviruses: Biology, Biochemistry, and Molecular Biology

B C Bonning, Iowa State University, Ames, IA, USA

6.8.1. Introduction

Initial interest in baculoviruses stemmed from their potential use in insect pest management (Moscardi, 1999). Modern baculovirology is driven by genetic enhancement of their insecticidal properties (van Beek and Hughes, 1998; Bonning *et al.*, 2002), their use for the study of fundamental biological processes (Clem, 2001; Manji and Friesen, 2001), for protein expression (Jarvis, 1997), and for gene therapy (Ghosh *et al.*, 2002; Kost and Condreay, 2002). Addressing their limitations for these purposes allows for increased understanding of baculovirus biology. As a result of the various applications of baculoviruses, they represent the best studied of the invertebrate viruses.

Autographa californica multiple nucleopolyhedrovirus (AcMNPV), the type species of the *Nucleopolyhedrovirus* genus (Blissard *et al.*, 2000), has been particularly extensively studied both in terms of molecular biology and host range. Hence much of this review will focus on AcMNPV with particular emphasis on recent advances in baculovirus research. Relatively little molecular, genetic, and biochemical research has been conducted on granuloviruses (GV), in part because of the difficulty of establishing cell culture systems for GV propagation (Winstanley and Crook, 1993). Certain aspects of baculovirus biology such as baculovirus ecology (Cory *et al.*, 1997), epizootiology (Fuxa and Tanada, 1987), baculoviruses of nonlepidopteran hosts (Couch, 1991; Federici, 1997), and tritrophic interactions (Duffey *et al.*, 1995) are described elsewhere.

6.8.1.1. Taxonomy

Baculoviruses belong to the family Baculoviridae, a large family of bacilliform, occluded viruses that

infect arthropods, primarily the Lepidoptera (Adams and McClintock, 1991). Baculoviruses also have been isolated from members of the Diptera and Hymenoptera (Blissard *et al*., 2000). Members of the two genera within the Baculoviridae, *Nucleopolyhedrovirus* (NPV) and *Granulovirus* (GV), are distinguished by occlusion body (OB) morphology and the cytopathology that they cause (Blissard *et al*., 2000). NPVs produce large polyhedra (typically 1–5 μm in diameter) with many virions or occlusion-derived virus (ODV), while GV produce smaller occlusion bodies or granules (150 nm in diameter by 400–600 nm in length) with a single virion (**Figure 1**). NPVs are designated as SNPV or MNPV according to whether the ODV contains single (S) or multiple (M) nucleocapsids (**Figure 1**). There are many more described MNPVs than SNPVs (Volkman, 1997). Because all of the MNPV characterized to date infect species within the order Lepidoptera, while SNPV have been isolated from species within the Lepidoptera, Hymenoptera, and Diptera, the progenitor NPV is believed to be an SNPV (Rohrmann, 1996). Despite morphological similarity to baculoviruses, at least one of the shrimp baculoviruses, the white spot syndrome virus, is unrelated at the amino acid level (Yang *et al*., 2001) and has been reclassified in the family Nimaviridae, genus *Whispovirus*.

The NPVs are divided into two groups on the basis of phylogenetic relatedness (Zanotto *et al*., 1993; Herniou *et al*., 2001). Group I NPVs have 17 genes that are absent from group II NPVs (Herniou *et al*., 2001). The two groups have distinct budded virus (BV) envelope fusion proteins, with GP64 in group I NPVs, and F (fusion) proteins in group II NPVs (Ijkel *et al*., 1999; Pearson *et al*., 2000). Homologs of GP64 are present in the thogotoviruses (Orthomyxoviridae) (Morse *et al*., 1992), while proteins related to F proteins are present in the genus *Errantivirus* (Metaviridae) (Malik *et al*., 2000; Rohrmann and Karplus, 2001; Pearson and Rohrmann, 2002).

GVs are classified according to tissue tropism: type 1 GVs such as *Trichoplusia ni* GV enter the host via the midgut epithelium but infect only the fat body. Because other important tissues are not affected, infection may be prolonged with lethargy only a day or two before death. For type 2 GV, tissue tropism is similar to that of NPVs affecting most tissues, while type 3 GVs are restricted to the midgut epithelium. *Harrisina brillians* GV is the only type 3 GV characterized to date and causes acute disease (Federici, 1997). The pathogenesis of NPV diseases has been studied in much greater detail compared to GV disease. A fundamental difference between the cytopathology of NPV and GV infections is that the nuclear membrane breaks down during replication of GV but not NPV, resulting in mixing of cytoplasm and nucleoplasm (Winstanley and Crook, 1993). GV-infected cells separate from each other and from the basement membrane, resulting in proliferation of regenerative cells adjacent to the basement membrane, which become infected as they differentiate.

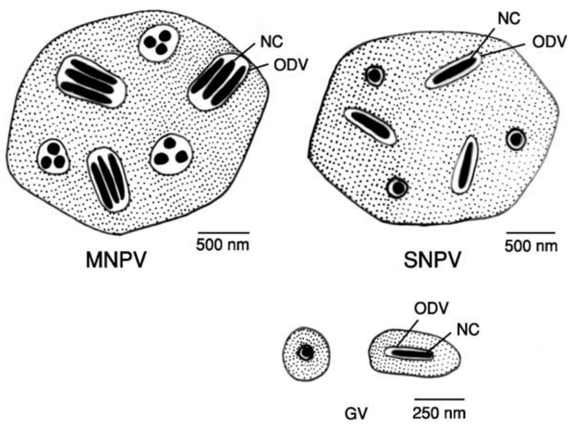

Figure 1 Schematic representation of occlusion bodies of multiple and single nucleopolyhedroviruses (MNPV and SNPV, respectively) and granuloviruses (GVs). The figure illustrates envelopment of multiple or single rod-shaped nucleocapsids (NC) within occlusion-derived virus (ODV) of the polyhedra of MNPV and SNPV, respectively. Each granule of the GV contains a virion with a single nucleocapsid. The relative sizes of the GV and NPV are indicated.

6.8.1.2. Nomenclature

Baculoviruses are named according to viral genus based on morphological characteristics, and the Latin name of the host from which they were first isolated. This system can be misleading because many baculoviruses infect more than one host species. AcMNPV for example, although first isolated from *A. californica*, infects at least 40 other species within the Lepidoptera (Gröner, 1986). Complexities also arise when the same virus is isolated from different host species (e.g., *Rachiplusia ou* MNPV and *Anagrapha falcifera* MNPV) (Hostetter and Puttler, 1991; Harrison and Bonning, 1999), and when different viruses are isolated from the same host species (e.g., *Mamestra configurata* MNPV A and B) (Li *et al*., 2002a, 2002b).

6.8.2. Structure

Baculoviruses exist as two phenotypes, BV and occlusion-derived virus (ODV), which have a common nucleocapsid structure and carry the same genetic information (Blissard, 1996; Rohrmann, 1992). ODV, contained within the occlusion bodies

(OB: polyhedra or granules), are responsible for transmission between host insects, while BV effect systemic transmission within the host, and virus propagation in cell culture.

6.8.2.1. Nucleocapsids

Nucleocapsids are tubular in shape with cap structures at each end (**Figure 2**). The genome is condensed to about 100-fold within the inner nucleoprotein core (Bud and Kelly, 1980). The supercoiled, circular genome of double-stranded DNA is complexed with a highly basic protein, P6.9 in NPV and VP12 in GV (Tweeten *et al.*, 1980; Wilson *et al.*, 1987). Binding of these arginine-rich molecules to the DNA produces a compact, insoluble DNA complex. The viral genomes appear to be prepackaged within the virogenic stroma (an electron-dense structure produced within the nucleus at the onset of viral DNA synthesis), before incorporation into the capsid shells (Fraser, 1986) (**Figure 3**). The end structures of nucleocapsids consist of a flat disk at the basal end and nipple structures at the apical end (Federici, 1986). Nucleocapsids attach to membranes at the apical end of the capsid. VP39 is the major component of the nucleocapsid in BV and OB of AcMNPV (Pearson *et al.*, 1988; Thiem and Miller, 1989). P80 and P24 are also associated with the capsid and PP78/83 is associated with the basal end complexed with EC27 and C42 (Braunagel *et al.*, 2001) (**Figure 2**). VP1054 and VP91 are associated with both BV and OB (Olszewski and Miller, 1997a; Russell and Rohrmann, 1997).

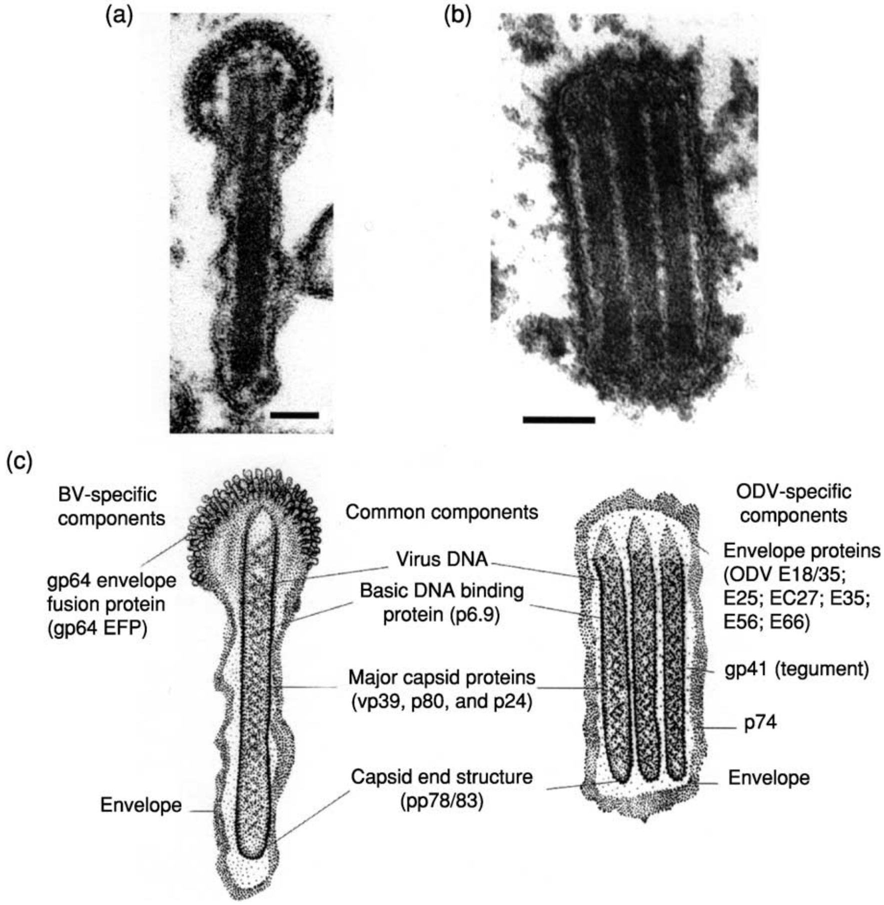

Figure 2 Structure of budded and occlusion-derived virus. (a) Transmission electron micrograph (TEM) of budded virus (BV) of *Lymantria dispar* MNPV showing glycoprotein spikes, or peplomers at the anterior end. Scale bar = 50 nm. (Reproduced with permission from Adams, J.R., Goodwin, R.H., Wilcox, T.A., **1977**. Figure 3 (a) Detail of the virogenic stroma (VS) and polyhedra (PH) within the nucleus of an AgipMNPV-infected hemocyte of *Agrotis ipsilon*. Scale bar = 1 µm. (b) Rod-shaped nucleocapsids (NC) produced within the virogenic stroma (VS). Scale bar = 500 nm.

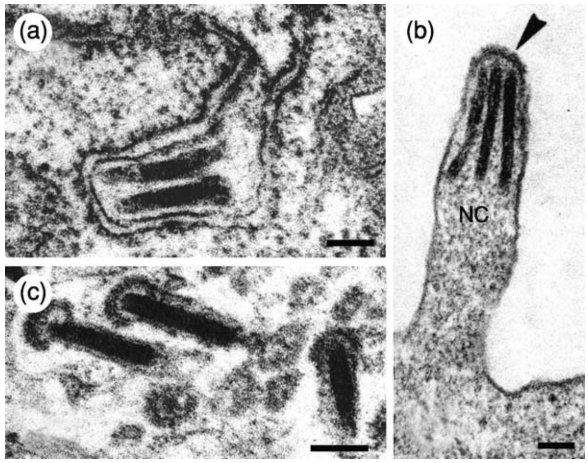

Figure 4 Production of budded virus. (a) Nucleocapsids become encased in a vesicle of nuclear membrane as they move out of the nucleus. Nucleocapsids are subsequently released into the cytoplasm as the vesicle breaks down. (*Autographa californica* MNPV in *Spodoptera exigua* fat body cell.) (b) Nucleocapsids move to and bud through regions of the plasma membrane that have been modified by virus-produced GP64 (arrow head). (*Helicoverpa zea* SNPV in *H. zea* cell line.) (c) Budded virus with distinctive peplomer structures at the anterior end. (*Trichoplusia ni* SNPV in *T. ni*.) Scale bars = 100 nm. (Reproduced with permission from Adams, J.R., Goodwin, R.H., Wilcox, T.A., **1977**. Electron microscopic investigations on invasion and replication of insect baculoviruses *in vivo* and *in vitro*. *Biol. Cellulaire 28*, 261–268.)

6.8.2.2. Budded Virus

Nucleocapsids initially move out of the nucleus for exit at the plasma membrane, and appear to move in vesicles derived from the nuclear membrane in association with filaments of actin. The presence of multivesicular aggregates containing many nucleocapsids suggests that fusion of vesicles may occur (Williams and Faulkner, 1997). The nuclear membrane-derived vesicle is lost in transit and unenveloped nucleocapsids align at the apical end with the plasma membrane, which is modified by the viral-encoded glycoprotein, GP64 (**Figures 4** and **5**). The GP64 envelope fusion protein is the major virus-encoded protein associated with the BV envelope. GP64 is expressed during the early and late phases (Blissard and Rohrmann, 1989; Whitford *et al*., 1989; Monsma and Blissard, 1995; Monsma *et al*., 1996) and accumulates at the plasma membrane (Volkman, 1986). On budding through the plasma membrane, nucleocapsids acquire a loose envelope with prominent spikes or peplomers consisting of GP64 at the apical end (Volkman and Goldsmith, 1984; Volkman, 1986). Ubiquitin is localized to the inner surface of the envelope (Guarino *et al*., 1995). GP64 is a membrane fusion protein that is activated at low pH and is involved in BV entry into the cell by endocytosis (Blissard and Wenz, 1992; Chernomordik *et al*., 1995; Monsma and Blissard, 1995). The BV envelope fuses with host endosomal membranes thereby releasing nucleocapsids into the cytoplasm. GP64 is essential for cell-to-cell movement of virus (Monsma *et al*., 1996). Baculovirus GP64 is related to the envelope glycoproteins of two orthomyxovirus-like arboviruses that are vectored by ticks. These proteins mediate membrane fusion and hemagglutination (Morse *et al*., 1992). GP64 is absent from ODV (Blissard and Rohrmann, 1989; Jarvis and Garcia, 1994) and also from the two variants of the single NPV of the S phenotype for which the genome has been completely sequenced (Chen *et al*., 2001, 2002).

GP64 is absent from group II NPVs, which have F proteins that serve a similar functional role. However, group I NPVs also encode F protein homologs that

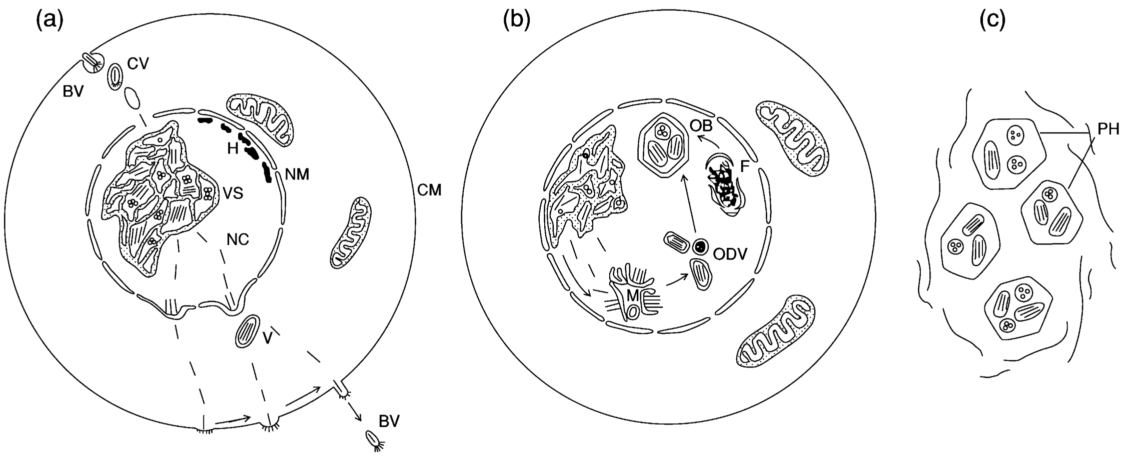

Figure 5 Production of budded virus and occlusion bodies during the late and very late phases of NPV infection, followed by cell lysis. (a) A budded virus (BV) binds to a putative receptor at the cell membrane (CM) and enters the cell by adsoprtive endocytosis within clathrin-coated vesicles (CV). The BV envelope fuses with host endosomal membranes thereby releasing nucleocapsids into the cytoplasm. Nucleocapsids uncoat at the nuclear membrane. Heterochromatin (H) becomes marginated and the virogenic stroma (VS) is produced at the onset of virus replication and the late phase of infection. Nucleocapsids (NC) produced within the virogenic stroma move out of the nucleus initially in vesicles (V) that appear to be derived form the nuclear membrane (NM). The vesicles dissociate and nucleocapsids bud through the GP64-modified regions of the plasma membrane to acquire a loose envelope with peplomers at the apical end. (b) A switch occurs at about 24 h after infection of the cell from BV to OB production, marking the onset of the very late phase of infection. Intranuclear vesicles dissociate to produce membranes (M) within the ring zone of the infected nucleus, which then envelope nucleocapsids to produce occlusion-derived virus (ODV). Fibrillar bodies (F) are produced that associate with polyhedral envelope precursor structures. ODV become embedded in the polyhedrin matrix, which is then surrounded by the polyhedral envelope. (c) Polyhedra (PH) are released on lysis of the infected cell.

are more divergent than those found in group II NPVs and GVs. The F protein homologs in group I NPVs appear to lack a fusion function (Pearson *et al.*, 2000; Lung *et al.*, 2003). There is overlap between the distribution of GP64 and the F protein homologs in the budded virus, but biochemical fractionation studies suggest that the F protein homologs are also associated with BV nucleocapsids. This localization suggests that the F protein homologs may play a role in the interaction between the budded virus envelope and the nucleocapsid potentially mediated by the cytoplasmic tail domain of the protein (Pearson *et al.*, 2001). However, the F protein homolog of AcMNPV is not essential for virus replication in cell culture or in insects. The AcMNPV F protein homolog has been shown to function as a viral pathogenicity factor that accelerates the mortality of infected hosts (Lung *et al.*, 2003).

The baculovirus F protein is related to the envelope protein of insect retroviruses in the genus *Errantivirus* (family Metaviridae). Evidence suggests that a *gypsy*-like noninfectious retrotransposon acquired a baculovirus F progenitor resulting in formation of a retrovirus (Malik *et al.*, 2000; Rohrmann and Karplus, 2001; Pearson and Rohrmann, 2002). A *Drosophila melanogaster* F homolog, which is not part of a retrovirus-like element, has also been identified, but it is unclear whether this is an insect gene, or a remnant of an integrated retrotransposon (Malik *et al.*, 2000; Rohrmann and Karplus, 2001). Hence the evolutionary events leading to the presence of F protein homologs in insects, baculoviruses, and insect retroviruses remain unclear. It is possible that the insect F homolog may represent the progenitor of both the baculovirus F protein and the envelope proteins of insect retroviruses.

Both viral and host-derived ubiquitin with an unusual phospholipid anchor have been found on the inner surface of the BV envelope (Guarino, 1990; Guarino *et al.*, 1995). Free ubiquitin is also present between the nucleocapsid and envelope and is almost as abundant as GP64, accounting for 2% of the weight of the virion. Ubiquitin is one of the most highly conserved of known proteins, but diverged considerably since acquisition by the baculoviruses. Baculovirus ubiquitin is the most divergent ubiquitin known with only 76% identity to animal ubiquitin (Guarino, 1990). A primary function of ubiquitin is to signal degradation of proteins by the 26S proteosome by covalent attachment of ubiquitin molecules to the protein. However, the viral protein supports protein degradation at only 40% the rate of the eukaryotic ubiquitin in *in vitro* assays, and multiubiquitination of some proteins was inhibited (Haas *et al.*, 1996). This suggests that virus ubiquitin may prevent degradation of

selected proteins during infection. Analysis of ubiquitin mutants of AcMNPV showed that ubiquitin may function in BV assembly although *ubi* is not an essential gene (Fraser *et al*., 1995; Reilly and Guarino, 1996). The baculovirus proteins IAP2, IE2, and PE38, which have RING finger domains, may function as ubiquitin ligase (E3) enzymes during baculovirus infection (Imai *et al*., 2003).

There are various other proteins that may be associated with BV including IE1 (Theilmann and Stewart, 1993) and actin (Lanier *et al*., 1996). The viral cathepsin V-Cath is associated with both the nucleocapsids and the envelopes of BV, and degrades actin (Lanier *et al*., 1996). This viral cathepsin L-like cysteine protease is required for liquefaction of the host insect during the final stages of virus infection. In the absence of this protease, tissues retain their integrity (Slack *et al*., 1995).

6.8.2.3. Occlusion-Derived Virus

At about 24 h post infection (p.i.), a switch occurs from BV to OB production, although the switch is not absolute (Faulkner, 1981) (**Figure 5**). The FP25K protein is a potential regulator of the switch from BV to OB production during baculovirus infection (Jarvis *et al*., 1992). During the very late phase, the nucleocapsids remain in the nucleus when sufficient FP25K protein is produced. The FP25K protein, which is expressed during the late phase, may be involved in the retention of the nucleocapsids within the nucleus (Harrison and Summers, 1995). FP25K is predominantly found in the cytoplasm of baculovirus-infected cells (Braunagel *et al*., 1999). Disruption of FP25K expression that occurs frequently on repeated passaging of virus in cell culture, leads to the few polyhedra (FP) phenotype with (1) enhanced BV production, (2) decreased polyhedra production, (3) increased synthesis of some BV structural proteins, (4) reduced levels of some ODV envelop proteins, (5) decreased polyhedrin protein synthesis, and (6) a block in the postmortem liquefaction of the host (Harrison and Summers, 1995; Harrison *et al*., 1996; Katsuma *et al*., 1999; Rosas-Acosta *et al*., 2001).

During the very late phase of infection, trilamellate membrane profiles appear within the ring zone of the nucleus and envelope nucleocapsids to form ODV (Stoltz *et al*., 1973; Fraser, 1986; Williams and Faulkner, 1997). These membranes may derive from invaginations of the inner nuclear membrane that produce microvesicles within the infected nucleus (Fraser, 1986; Hong *et al*., 1994) (**Figures 5** and **6**). Regulation of the ODV-specific components in the viral envelope may be important for the switch from BV to OB production (Braunagel and Summers, 1994; Braunagel *et al*., 1996b; Williams and Faulkner, 1997).

Nomenclature for some viral envelope proteins includes designation of protein source (BV or ODV), followed by location, E (envelope) or C (capsid), and the apparent molecular mass (Braunagel *et al*., 1996a). ODV-E66 (Hong *et al*., 1994, 1997) and ODV-E25 (Russell and Rohrmann, 1993) are both envelope proteins found in the virus-induced microvesicles in the cell nucleus. ODV-E56 is present in ODV envelopes, virus-induced intranuclear microvesicles, and the inner and outer nuclear membranes (Braunagel *et al*.,

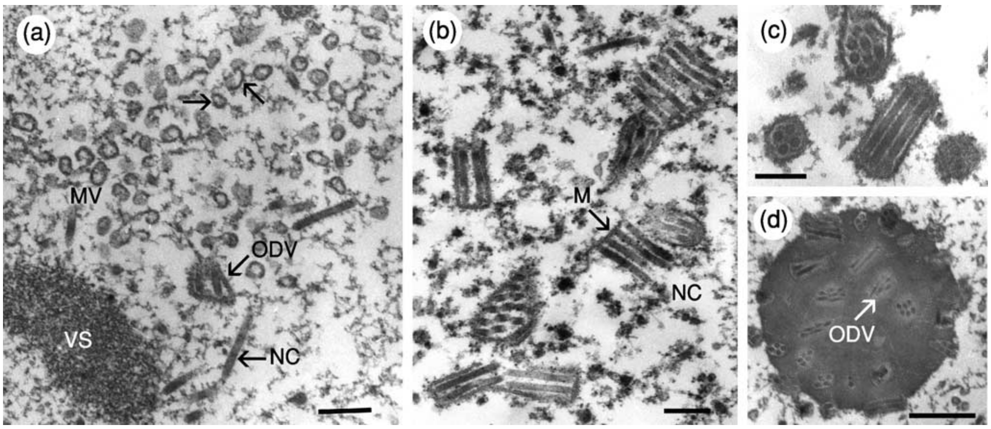

Figure 6 Production of occluded virus of AgipMNPV: intranuclear envelopment and occlusion of nucleocapsids. During the very late phase of infection, nucleocapsids (NC) are enveloped as they leave the virogenic stroma (VS). (a) Membrane profiles (arrows) appear to break down to produce microvesicles (MV), the occlusion-derived virus (ODV) envelope precursors in the ring zone of NPV-infected cells. (b) These microvesicles appear to produce trilamellar membrane profiles (M) distal to the nuclear membrane. Nucleocapsids (NC) align with these membranes, and (c) are enveloped to produce ODV. Transverse and longitudinal sections illustrate the bundling of multiple nucleocapsids within the ODV of MNPV. (d) The ODV are then occluded within the polyhedrin matrix. (a) and (d) fat body, (b) and (c) hemocyte of *Agrotis ipsilon*. Scale bar = 200 nm (a, b, and c), 500 nm (d).

1996a; Theilmann *et al.*, 1996). ODV-E35 shares the same N-terminus with ODV-E18 and may be translated from a transcript that includes both AcMNPV ORF143 (ODV-E18) and 144 (ODV-EC27) derived by ribosomal frameshifting at a step-loop structure (Braunagel *et al.*, 1996b). ODV-EC27 is present in ODV nucleocapsids and envelopes, and is also present in a modified form in BV (Braunagel *et al.*, 1996b). ODV-EC27 functions as a multifunctional viral cyclin with roles that may include arrest of the host cell cycle at G_2/M phase, or regulation of viral/cellular DNA replication (Belyavskyi *et al.*, 1998). P74 is associated with the ODV envelope and is essential for oral infectivity. It is hypothesized to function in attachment to or fusion with midgut epithelial cells (Kuzio *et al.*, 1989; Hill *et al.*, 1993; Faulkner *et al.*, 1997; Slack *et al.*, 2001). The *p74* gene lacks a conventional late promoter sequence, but is expressed at low levels during the late phase of infection.

The tegument protein GP41 is present between the envelope and the nucleocapsid of ODV (Whitford and Faulkner, 1992). GP41 is required for movement of the nucleocapsids out of the infected cell nucleus to produce BV (Olszewski and Miller, 1997b). Protein tyrosine phosphatase (PTP) has also been found associated with both BV and ODV (Li and Miller, 1995).

The lipid composition of the BV and ODV envelopes differs and ODV envelopes contain a greater density of protein (Braunagel and Summers, 1994). For AcMNPV BV derived from Sf9 cells, the major phospholipid constituent of the envelope is phosphatidylserine, comprising about 50% of the phospholipid content. For the ODV envelope, phosphatidylcholine and phosphatidylethanolamine are the predominant constituents. The BV envelope appears to be more fluid than that of ODV, which may be important for the different roles of these phenotypes in the baculovirus life cycle (Braunagel and Summers, 1994).

6.8.2.4. Occlusion Bodies

Large amounts of the occlusion matrix protein polyhedrin (or granulin) and a nonstructural protein P10 are produced during the very late phase of infection. These proteins accumulate in the cytoplasm (detectable at 10–12 and 14–16 h p.i.), and after about 20 h p.i. are also located in the nucleus. Polyhedrin becomes primarily intranuclear while P10 forms fibrillar bodies in both the cytoplasm and the nucleus (Vlak *et al.*, 1988; Williams *et al.*, 1989) (**Figure 7**). Large amounts of polyhedrin are required for production of OB. The ODV are embedded in the occlusion matrix of polyhedrin or granulin (Rohrmann, 1986, 1992; Funk *et al.*, 1997) (**Figure 6**). Polyhedrin is highly conserved (25–33 kDa) and related to the GV matrix protein granulin (with about 50% amino acid identity) that produces a paracrystalline lattice and accounts for 95% of the OB mass (Faulkner, 1981; Vlak and Rohrmann, 1985; Rohrmann, 1992). Point mutations in conserved domains of the polyhedrin gene have resulted in (1) a single cubic OB per cell with a paracrystalline matrix that occludes few virions (Brown *et al.*, 1980; Jarvis *et al.*, 1991), (2) small polyhedrin condensations that lack the lattice structure and do not occlude virions (Duncan *et al.*, 1983), and (3) large amorphous condensations of polyhedrin (Carstens *et al.*, 1992).

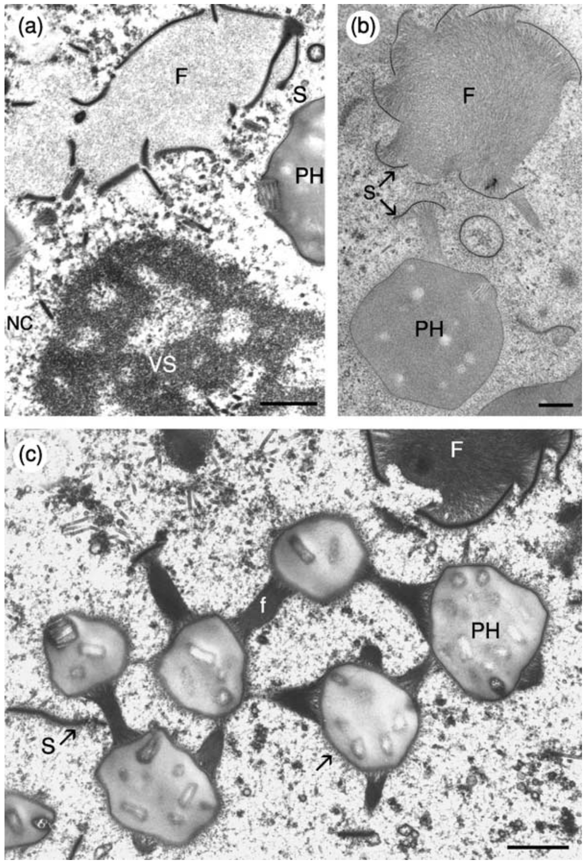

Figure 7 Maturation of the occlusion body. (a, b) Bilamellar fibrous sheets (S), which are calyx (polyhedral envelope) precursor structures, associate with the P10-rich fibrillar body (F). These sheets appear to form near to the nuclear membrane before incorporation into the fibrillar body. Nucleocapsids (NC), virogenic stroma (VS) and polyhedra (PH) are indicated. (c) The fibrillar bodies (F) and fibrillar structures (f) associated with the maturing polyhedra (PH) form a shell around the surface of the polyhedra prior to or during addition of the calyx (arrow). Addition of the calyx is the final step in OB maturation. (a), AgipMNPV, (b, c) *Rachiplusia ou* MNPV (RoMNPV). Scale bar = 500 nm.

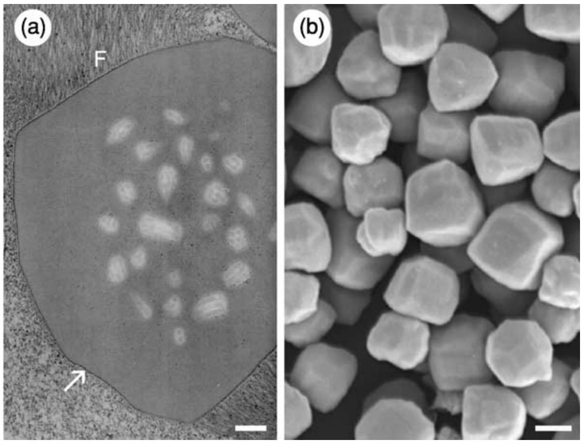

Figure 8 Occlusion bodies. (a) Mature polyhedron of RoMNPV showing polyhedral envelope or calyx (arrow) surrounding the polyhedron. The adjacent fibrillar body (F) is also indicated. Scale bar = 200 nm. (b) Scanning electron micrograph showing the polyhedral structure of occluded virus of RoMNPV derived from larvae of *Heliothis virescens*. Scale bar = 1 μm.

OB production is completed by addition of the polyhedron envelope or calyx (**Figure 8**), which consists primarily of carbohydrate and the phosphoprotein PP34, also known as the polyhedral envelope protein, PEP (Minion *et al.*, 1979; Gombart *et al.*, 1989). The precursor structures referred to as bilamellar fibrous sheets or electron-dense spacers form in the ring zone of the infected cell in association with P10 fibrillar bodies (Russell *et al.*, 1991) (**Figure 7**), although calyx formation is not dependent on the expression of P10 (van Lent *et al.*, 1990; Oers and Vlak, 1997). Thiol bonds link PP34 molecules to each other and to polyhedrin (Whitt and Manning, 1988). Mutants lacking the calyx show increased sensitivity to alkali and have pitted surfaces, suggesting possible loss of virions from the OB matrix (Zuidema *et al.*, 1989; Gross, 1994).

Occlusion bodies are resistant to desiccation and freezing (Jaques, 1985), and to putrefaction and various chemical treatments (Benz, 1986), but do not protect ODV well against the harmful effects of ultraviolet light (Ignoffo *et al.*, 1995, 1997). Baculoviruses lose most of their activity within 24 h as a result of damage to DNA when exposed to direct sunlight (Young and Yearian, 1974). On exposure to ultraviolet light, pyrimidine dimers are produced. Baculovirus expression of a pyrimidine dimer-specific glycosylase conferred some protection to BV but not to OB (Petrik *et al.*, 2003). It has been postulated that the baculovirus superoxide dismutase gene (*sod*) may function to protect OB from superoxide radicals generated on exposure to sunlight (Tomalski *et al.*, 1991; Ignoffo and Garcia, 1994).

6.8.3. Life Cycle

6.8.3.1. Infection

Baculoviruses infect the larval stages of insect hosts. Caterpillars typically ingest occlusion bodies (OB) (polyhedra or granules) on feeding, although NPVs can be transmitted via the egg. The polyhedrin or granulin matrix of the occlusion bodies dissolves rapidly in the alkaline conditions of the caterpillar midgut (pH 9.5–11.5), releasing the infectious ODV (**Figure 9**). Occlusion dissolution is also dependent on ionic strength (Kawanishi and Paschke, 1970) and is facilitated by midgut proteases (Granados and Williams, 1986). The ODV must then pass through the peritrophic membrane, an extracellular fibrous matrix of chitin, glycosaminoglycans, and protein that lines the midgut (Richards and Richards, 1977; Brandt *et al.*, 1978; Wang and Granados, 2001). GV and some NPV occlusions contain a viral enhancing factor, a metalloprotease called enhancin. Enhancin, which is released into the midgut on occlusion dissolution, facilitates penetration of the peritrophic membrane by degrading mucin (Derksen, 1988; Gallo *et al.*, 1991; Wang *et al.*, 1994; Gijzen *et al.*, 1995; Lepore *et al.*, 1996; Bischoff and Slavicek, 1997; Wang and Granados, 1997, 1998; Popham *et al.*, 2001). The chitin-binding agent calcofluor (M2R) inhibits formation of the peritrophic membrane (Wang and Granados, 2000) and increases the susceptibility of larvae to baculovirus infection. Calcofluor also the enhances the retention of infected midgut cells (Washburn *et al.*, 1998) and the relative contributions of these two effects to calcofluor-enhanced susceptibility of the host insect are unclear (Washburn *et al.*, 1998; Wang and Granados, 2001). It is also unclear how viruses that lack enhancin penetrate the peritrophic membrane. Possibilities include that virus infection occurs before the peritrophic membrane is fully formed, particularly in insects that produce the peritrophic membrane in response to feeding (Tellam, 1996), or through variation in peritrophic membrane structure in different species of Lepidoptera (Hopkins and Harper, 2001). Alternatively, there may be other virus proteins with peritrophic membrane-degrading activity.

Virions cross the peritrophic membrane and bind to the brush border microvilli of epithelial cells (**Figure 9**). ODV are highly infectious to midgut epithelial cells and less infectious to other tissues (Volkman and Summers, 1977). The primary target cells are the columnar cells of the midgut epithelium (Granados and Williams, 1986). ODV enter the cells by direct fusion of the viral and cellular membranes (Granados and Lawler, 1981), and the entry is likely

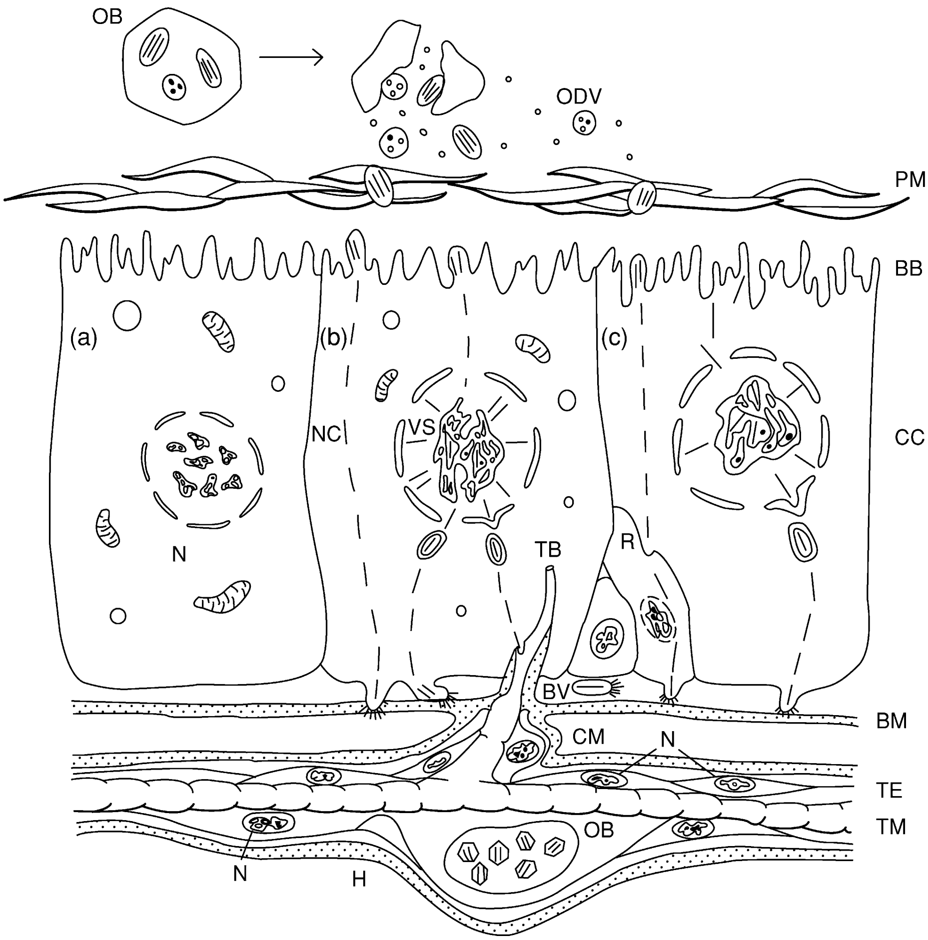

Figure 9 Infection of the midgut epithelium of the host insect by MNPV. Occlusion bodies (OB) dissolve in the midgut releasing ODV, which move through the peritrophic membrane (PM). (a) Uninfected columnar cell (CC) showing the normal distribution of heterochromatin in the nucleus (N); (b) columnar cell showing entry of virus at the brush boarder membrane (BB). Some nucleocapsids (NC) move to the nucleus, while other nucleocapsids undergo trancytosis. Infection of tracheoblasts (TB) closely associated with the midgut epithelium and subsequent infection of the tracheal epithelium (TE), as indicated by the presence of OB, is also shown. (c) Direct infection of regenerative cells (R), by transcytosis as for *Spodoptera exigua*, in addition to infection of columnar cell (CC). Budded virus acquires an envelope as it buds through the virus-modified plasma membrane. BV may enter the hemocoel (H) by budding through the basement membrane (BM) or via the tracheal epithelium (TE). Enlargement of the nucleus on infection of the cell is shown in (b) and (c). VS, virogenic stroma; CM, circular muscle; TM, tracheal matrix.

to involve a highly abundant or relatively non-specific receptor site (Horton and Burand, 1993). ODV entry is insensitive to inhibitors of adsorptive endocytosis.

Nucleocapsids move to the nucleus and uncoat, or may pass directly through the cell to infect other cells, or enter the hemocoel (Granados and Lawler, 1981; Keddie *et al.*, 1989) (**Figure 9**). The mechanism for movement of nucleocapsids within microvilli is unknown in the absence of microtubules (Volkman, 1997). BV bud from the basal side of the midgut epithelium and infectious virus can be detected in the hemolymph a few hours after infection (Granados and Lawler, 1981). When multiple nucleocapsids infect a single columnar epithelial cell, some nucleocapsids derived from ODV can be converted directly into BV without replication in the nucleus, taking advantage of GP64 that is expressed as an early gene on entry of other nucleocapsids into the nucleus (Washburn *et al.*, 2003a). Infection with the M or S phenotype of NPV results in infection of primary tissues with multiple or single nucleocapsids, respectively. Infection of secondary tissues is more rapid for the M phenotype supporting the hypothesis that ODV nucleocapsids can be repackaged as budded virus, while systemic infections of the S phenotype require virus replication in the primary target cells (Washburn *et al.*, 2003a). Direct acquisition of the envelope protein GP64 by ODV-derived nucleocapsids of the M phenotype allows

rapid movement of the virus through the midgut epithelial cells for further dissemination within the host insect (Washburn *et al*., 2003b). In the case of *Spodoptera exigua*, ODV-derived nucleocapsids of AcMNPV infect both the columnar cells and the underlying regenerative cells (Flipsen *et al*., 1995b) (**Figure 9**). Some lepidopteran larvae clear AcMNPV-infected cells from the midgut with almost full recovery of the tissue by 60 h p.i. (Keddie *et al*., 1989; Washburn *et al*., 2003b). The direct movement of virus through the midgut cells would provide an advantage to the virus in larvae that shed infected midgut epithelial cells and may have provided the driving force for evolution of the MNPV from the SNPV. The clearing of infected cells from the midgut may benefit MNPV by allowing the host insect to continue to feed (Volkman and Keddie, 1990).

Infection results in rapid formation of filamentous actin (F-actin) bundles, which may facilitate transport of nucleocapsids to the nucleus (Charlton and Volkman, 1993; Lanier and Volkman, 1998). Nucleocapids migrate to the nucleus and uncoat at the nuclear pore complex (GV) or just inside the nuclear membrane (Bilimoria, 1991). A capsid-associated protein kinase associated with NPV and GV virions may function in unpackaging of the viral genome by phosphorylation of the basic core protein P6.9 (Miller *et al*., 1983; Wilson and Consigli, 1985; Funk and Consigli, 1993). Transcription of immediate early genes rapidly follows with virus-specific RNA detectable within 30 min of infection (Chisholm and Henner, 1988). At this stage, F-actin aggregates form at the plasma membrane mediated by an early viral gene product, actin rearrangement-inducing factor-1 (ARIF-1) which colocalizes with the F-actin aggregates (Dreschers *et al*., 2001).

Numerous morphological changes occur in the cell and the nucleus during the course of infection. Within the cytoplasm, there are alterations to the cytoskeleton and endomembrane systems, and large fibrillar structures develop. Within the first hour after infection, thick microfilament cables form from nucleocapsid-induced rearrangement of cellular actin (Charlton and Volkman, 1991). These cables, which are associated with nucleocapsids prior to viral gene expression, are only present at 1–4 h p.i. The capsid proteins P39 and P78/83 appear to interact with actin and induce actin polymerization, thereby enabling movement of nucleocapsids to and/or into the nucleus (Lanier and Volkman, 1998). Within the first 6–8 h p.i., the nucleus swells, the cell becomes rounded, and the distribution of heterochromatin and morphology of the nucleolus change. Rounding of the cell appears to be the result of virus-mediated rearrangement of the microtubules and is the first cytopathic effect seen by light microscopy following infection (Volkman and Zaal, 1990) (**Figure 10**). Heterochromatin becomes marginated along the inner nuclear membrane. The transition from early to late gene expression marks the onset of viral replication, and at this time the virogenic stroma, or viral replication center, is produced in the nucleus (Knudson and Harrap, 1976; Young *et al*., 1993). The virogenic stroma is electron dense, contains intrastromal spaces, and has a convoluted periphery (**Figure 3**). Formation of the virogenic stroma is dependent on viral DNA synthesis and late gene expression (Carstens *et al*., 1994). During the late phase, F-actin appears in the virogenic stroma and in the surrounding ring zone next to the inner nuclear membrane (Charlton and Volkman, 1991) (**Figure 11**), associated with P78/83 and VP39 (Charlton and Volkman, 1991; Lanier and Volkman, 1998). Nuclear F-actin is required for production of nucleocapsids (Ohkawa and Volkman, 1999). Six early viral genes, including *ie-1*, have been implicated

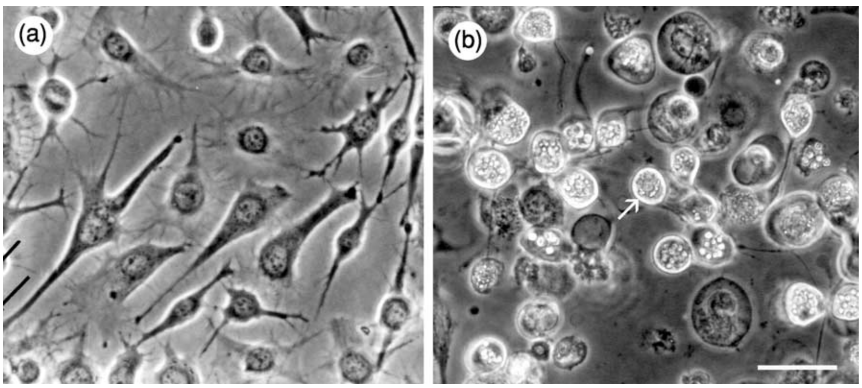

Figure 10 Cells of the *Manduca sexta* cell line GV1 illustrating (a) the normal fibroblast-like morphology with elongate extensions, and (b) rounding of cells on infection with AcMNPV. Refractile polyhedra are apparent within the distended nuclei by 3 days post infection (arrow). Rounding of the cells is the first response to baculovirus infection as seen by light microscopy. Photographs were taken under phase contrast. Scale bar = 50 μm.

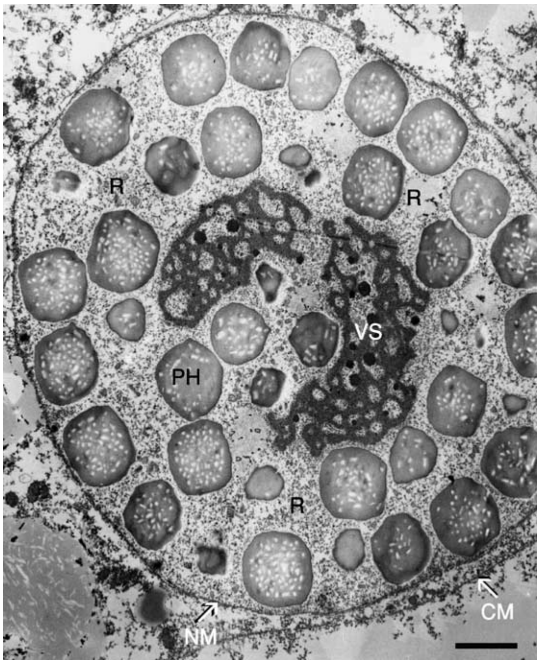

Figure 11 Hemocyte of *Agrotis ipsilon* infected with *Agrotis ipsilon* MNPV. The nucleus of the cell is shown with multiple polyhedra (PH) and the central, electron dense virogenic stroma (VS). The ring zone (R), nuclear membrane (NM), and cell membrane (CM) are indicated. Scale bar = 2 μm.

in recruitment of the monomeric G-actin to the nucleus (Ohkawa *et al.*, 2002). Progeny nucleocapsids appear within the virogenic stroma at about 10 h p.i. and synthesis of viral DNA continues for at least 12 h. As the virogenic stroma matures, the ring zone, a peristromal compartment of nucleoplasm appears (Figure 11). Intranuclear envelopment of virions and OB formation occurs in this compartment. Budded virus is produced during the late phase, and occluded virus is produced during the very late phase of virus infection (Table 1). The diameter of the nuclei of infected cells increases to five to ten times that of the nucleus of an uninfected cell (Federici, 1997). Baculovirus infection results in arrest of the cell cycle at the G_2/M phase, a phenomenon that may be mediated by viral proteins (Braunagel *et al.*, 1998).

Progeny nucleocapsids produced within the virogenic stroma initially bud through the plasma membrane modified by the virus-encoded protein GP64, to acquire a BV envelope (see Section 6.8.2.2). Later in infection nucleocapsids are enveloped and incorporated into the matrix of OB (see Section 6.8.2.3), while BV production is curtailed. Mature OB are released when the infected cell lyses. Large cytoplasmic vacuoles associate with both the nuclear and the outer plasma membranes and the nucleus disintegrates (van Oers *et al.*, 1993; Williams and Faulkner, 1997). The P10 protein, cellular microfilaments and virus-produced cathepsin and chitinase are required for OB release from the host insect (Williams *et al.*, 1989; Hawtin *et al.*, 1997; Thomas *et al.*, 2000).

Production of occlusion bodies in the midgut epithelial cells does not occur for most lepidopteran insects. The high levels of actin associated with the microvilli of the columnar epithelial cells may have an inhibitory effect on the production of occluded virus (Volkman *et al.*, 1996). The infected cells are sloughed off when the larva molts and the midgut epithelium is regenerated (Flipsen *et al.*, 1993).

6.8.3.2. Dissemination within the Host

With the exception of lepidopteran NPVs and an NPV of the cranefly *Tipula paludosa*, all other NPVs infect only the midgut epithelium (Federici, 1993). In contrast, lepidopteran NPVs transiently infect the midgut and then spread to virtually all other tissues. With the exception of the GV of *H. brillians*, which is restricted to the midgut, all other GVs transiently infect the midgut before invading other tissues. For lepidopteran NPVs, systemic spread may occur through direct penetration of the basement membrane into the hemocoel (Granados and Lawler,

1981; Flipsen *et al.*, 1995b; Federici, 1997) and via the tracheal system (Engelhard *et al.*, 1994) although there is debate over whether one route predominates the other (Federici, 1997). Following infection of the midgut epithelial cells, viruses infect the tracheolar cells that service the midgut (Washburn *et al.*, 2001). The tracheoles often penetrate the basement membrane to supply tissues with oxygen, and thereby provide a means for the virus to bypass the basement membrane barrier. However, because tracheolar cells also are covered by basement membrane, it is not clear how BV would then enter the hemocoel without crossing a basement membrane. Given that the pores in the basement membrane are too small to allow physical passage of BV (Reddy and Locke, 1990), penetration of the basement membrane by BV may be an enzymatic process or may be possible when the basement membrane is thin, in early instars and surrounding tracheoles that are suspended in the hemolymph (Federici, 1997; Volkman, 1997). Because the midgut epithelial cells contribute to production of the overlying basement membrane, it is also possible that infection of these cells disrupts maintenance of the basement membrane (Knebel-Mörsdorf *et al.*, 1996), or that enlargement of infected cells alters basement membrane structure thereby allowing passage of budded virus. Following infection of *Heliothis virescens* and *Helicoverpa zea* with AcMNPV, infection of tracheal cells occurred 6–10 h prior to the appearance of BV in the hemolymph, suggesting that BV entering the hemocoel may be derived from the tracheal cells (Trudeau *et al.*, 2001).

BV enter cells by adsorptive endocytosis (Volkman and Goldsmith, 1985; Blissard and Wenz, 1992) and are transported in clathrin-coated vesicles to the endosome where they fuse with the endosome membrane thereby releasing nucleocapsids into the cytoplasm (Blissard, 1996). Fusion is mediated by GP64, the major envelope glycoprotein as the endosomal pH decreases (Monsma and Blissard, 1995).

The infection spreads within a tissue by cell-to-cell transmission. The tissue tropism varies from mono-organotrophic (e.g., *Neodiprion sertifer* NPV and *Culex nigripalpus* NPV that infect only the midgut epithelium) to polyorganotrophic with infection of most tissues (Granados and Williams, 1986; Moser *et al.*, 2001). Once the tracheal matrix and hemocytes become infected in susceptible polyorganotrophic hosts, infection spreads rapidly to the epithelial and fat body tissues (Keddie *et al.*, 1989; Engelhard *et al.*, 1994; Flipsen *et al.*, 1995b). Infection then proceeds to nerve, muscle, pericardial cells, and reproductive and glandular tissues. Some tissues such as the Malpighian tubules and salivary glands are not well infected with only immediate early genes expressed suggesting that tissue tropism may be restricted by the availability of appropriate host factors to support virus replication (Knebel-Mörsdorf *et al.*, 1996).

The ability of the hemocytes of a host to support virus replication appears to be a key factor determining the susceptibility of some species to virus infection, through both virus amplification within the hemocoel, and the ability of the hemocytes to encapsulate sites of infection. In permissive hosts such as *H. virescens* and *T. ni*, the hemocytes play a primary role in amplification of virus in the hemocoel for initiation of new sites of infection. In some semipermissive hosts such as *H. zea*, although nucleocapsids of AcMNPV reach the nuclei of hemocytes, these cells do not support virus replication, and hence effectively remove virus from the hemocoel. The hemocytes of *H. zea* and *Manduca sexta* also appear to block virus dissemination by encapsulating infected tracheal elements possibly in response to ruptured basement membrane (Washburn *et al.*, 1996, 2000). Infection of hemocytes of the permissive host *H. virescens* compromises their ability to encapsulate (Trudeau *et al.*, 2001). There are contradictory reports on the role of hemocytes in virus dissemination within *Spodoptera frugiperda*, which is semipermissive to infection by AcMNPV. Clarke and Clem (2002) found lack of infection of hemocytes in this species, suggesting that the tracheal system may serve as the primary conduit for virus dissemination within this host. In contrast, Haas-Stapleton *et al.* (2003) found that hemocytes were infected by BV within the hemocoel. The opposing conclusions of these two studies may result from differential dispersal of virus from the sites of BV injection, between the first and second abdominal segment such that virus was injected to the rear of the abdomen (Clarke and Clem, 2002), versus through the planta of one of the prolegs (Haas-Stapleton *et al.*, 2003).

The response of the host insect to baculovirus infection varies dramatically according to the host–virus combination, which larval instar becomes infected, the virus dose acquired, and environmental conditions. As an example, about 4 days after infection of third instar *H. virescens* (a permissive host) with AcMNPV, host larvae become less responsive with reduced feeding activity (**Figure 12**). The cuticle becomes swollen and glossy in appearance as a result of hypertrophy of infected cells and tissues. In species that are lightly pigmented, the larvae take on a whitish coloration resulting from the polyhedra in the nuclei of fat body and epidermal cells. The baculovirus gene *ctl* encodes a small peptide with sequence similar to the conotoxins of predatory

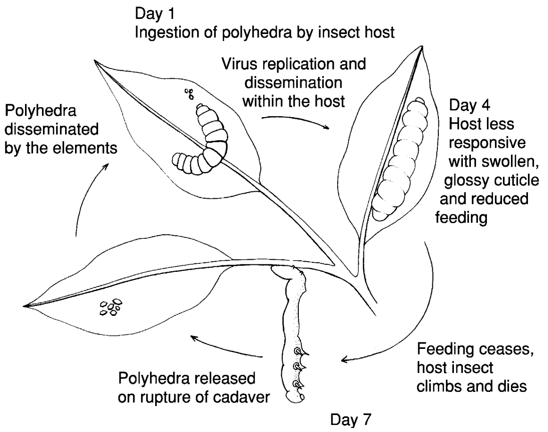

Figure 12 Effects of baculovirus infection on a susceptible host insect. The timing of the various stages varies according to the virus dose, larval instar, and environmental conditions. The timing of events would be typical for AcMNPV infection of third instar larvae of *Heliothis virescens*.

marine snails and aptotoxins of spiders (Eldridge *et al.*, 1992; Skinner *et al.*, 1992) (see **Chapter** 5.7). Conotoxins are calcium channel antagonists, while the aptotoxins are insecticidal causing rapid paralysis and death (Skinner *et al.*, 1992). While the function of baculovirus CTL remains to be determined, it may function to paralyze the insect during late stages of infection thereby promoting viral use of diminishing host resources (Eldridge *et al.*, 1992).

6.8.3.3. Dissemination from the Host

By 6–7 days after infection, feeding ceases. OB are released on lysis of infected cells. As the cells lyse, millions of polyhedra accumulate and the basement membrane degrades. Prior to death, many species exhibit negative geotropism and climb to the top of the vegetation, thereby facilitating broad dispersal of progeny virus. The cuticle becomes fragile and the dead insect liquefies. The baculovirus chitinase (*chiA*) and cathepsin (*v-cath*) genes, which are present in members of both NPV and GV, act in concert to facilitate release of occlusion bodies from the insect cadaver by degrading the cuticle and internal tissues (Hawtin *et al.*, 1995, 1997; Slack *et al.*, 1995; Kang *et al.*, 1998).

The chitinase of AcMNPV has both exo- and endo-chitinase activity against a range of substrates and is active from pH 3 to 10 (Hawtin *et al.*, 1995; Thomas *et al.*, 2000). It accumulates within the endoplasmic reticulum as a result of a C-terminal ER retention motif (KDEL). The chitinase is released as infected cells lyse (Thomas *et al.*, 1998). Removal of the ER retention motif and consequent secretion of the enzyme results in more rapid host liquefaction (Saville *et al.*, 2002). V-Cath is a cysteine protease that accumulates in the cell as an inactive proenzyme, proV-Cath (Bromme and Okamoto, 1995; Hom *et al.*, 2002). The viral cathepsin, which has a pH optimum of 5.0–5.5 is also active at pH 7 (Ohkawa *et al.*, 1994). ProV-Cath activation occurs on death of the infected cell possibly as a result of lysosomal protease release, and appears to contribute to death of the cell (Hom *et al.*, 2002). ChiA is required for the processing of V-Cath (Hom and Volkman, 2000).

A single dead insect may release as many as 10^{10} polyhedra (Entwistle and Evans, 1985) with the fat body, epidermis, and tracheal matrix producing the largest quantities of polyhedra (Aizawa, 1963). The amount of virus produced depends in part on the speed of kill of the host insect. In theory, the longer the insect survives, the more time the virus has for replication and production of progeny. For example, infection of the semipermissive host *Mamestra brassicae* with AcMNPV resulted in a higher virus yield than infection of the permissive host *T. ni* that succumbed more rapidly to infection (Hernandez-Crespo *et al.*, 2001). However, the yield of polyhedra may vary with species according to the physiological bases for the semipermissive character.

Liquefaction of the host cadaver increases transmission of the virus to conspecifics and facilitates dissemination in the environment. Polyhedra can survive outside the host in soil, in crevices of plants, or other refugia for years (Jaques, 1975), and are ubiquitous. Hence, in contrast to other viruses for which death of the host represents an evolutionary dead end, death of the baculovirus-infected host represents a successful replication strategy.

Predatory arthropods, scavengers, and parasitoids feeding on, or parasitizing baculovirus-infected lepidopteran larvae may become contaminated with virus and play an important role in dissemination of baculoviruses under field conditions (Ruberson *et al.*, 1991; Fuxa *et al.*, 1993; Chittihunsa and Sikorowski, 1995; Sait *et al.*, 1996; Vasconcelos *et al.*, 1996). Grazing mammals and birds also contribute to baculovirus dissemination (Entwistle and Evans, 1985; Fuxa, 1991).

The most common route for baculovirus transmission between the infected and healthy individuals is via horizontal transmission when a larva ingests occlusion bodies from the environment. Vertical transmission (from parent to offspring) is common for nucleopolyhedroviruses (Smits and Vlak, 1988; Kukan, 1999; Fuxa *et al.*, 2002). Artificial selection resulted in an increased rate of vertical transmission of *S. frugiperda* NPV suggesting a genetic basis for this characteristic (Fuxa and

Richter, 1991). Vertical transmission of baculoviruses may be important for species such as *S. frugiperda* that disperse or migrate such that successive generations are located at different geographic locations.

6.8.4. Virus Replication

Regulation of more than 100 baculovirus genes is complex and requires coordinated expression of temporally regulated early, late, and very late genes (Rohel and Faulkner, 1984). Each stage of virus replication is dependent on expression of genes in the preceding stage. Baculovirus gene expression appears to be regulated at the level of transcription, and includes a unique switch from transcription of early genes by host RNA polymerase II, to late and very late genes by a virus-encoded RNA polymerase (Fuchs *et al*., 1983; Guarino *et al*., 1998a, 1998b). *Trans*-acting protein factors (IE0, IE1, IE2, and PE38) interact with *cis*-acting DNA elements (upstream activation regions or homologous regions) in the virus genome to initiate early gene expression (Friesen, 1997).

6.8.4.1. Early Gene Expression

Early genes (transcribed before initiation of virus DNA replication) are distributed throughout the genome and transcription often results in overlapping RNAs that differ at the 5′ end. RNA transcripts are detectable within the first 15 min indicating that transcription likely begins on uncoating of the DNA in the nucleus. Early gene transcription peaks at 6–12 h p.i. in *S. frugiperda* cells. Downregulation of early gene transcription may result from expression of late genes or viral DNA replication. The expression of some early genes, such as *p35*, *gp64*, *39K*, and *ie1*, continues into the late phase as a result of the presence of both early and late promoter motifs. The early promoters, which are responsive to the host RNA polymerase II and host transcription factors, are readily distinguished from late promoters on the basis of nucleotide sequence. The early promoters consist of core transcription elements and *cis*-acting elements either in close proximity or within transcriptional enhancers. Most early promoters are TATA-containing (TATA+), initiator-containing (INR+), or composite (TATA+, INR+). The TATA element regulates the rate of transcription initiation and defines the start site for transcription. The INR motif (e.g., ATCA(G/T)T(C/T)) overlaps the RNA start site, contributes to basal promoter activity, and determines the start site in the absence of the TATA motif. The tetranucleotide CATG is the most conserved of the INR-like motifs of baculovirus early genes and is also prevalent in the promoters of arthropod genes (Cherbas and Cherbas, 1993). Both INR and TATA bind specific factors that recruit the TFIID transcription complex at the promoter. The presence of both motifs may enhance recruitment of the required factors to ensure adequate expression of early genes, and use of universal host transcription factors may facilitate gene expression in a broad range of tissue types. An upstream activation region (UAR), often present for early baculovirus promoters, potentiates transcription from the early promoter. The activity of the UAR may vary in a host-specific manner, which is consistent with the hypothesis that host transcription factors act via the UAR to potentiate basal promoter activity. Transient expression assays suggest that other early baculovirus genes including *dnapol* that do not have the conventional INR or TATA promoter motifs may be more dependent on virus-encoded transactivators (Ohresser *et al*., 1994). Downstream activating region (DAR) motifs contribute to basal promoter activity and are likely to stabilize protein interactions at the INR.

The homologous regions (*hrs*) are repetitive and highly conserved sequences that occur in multiple copies in the baculovirus genome. They are also unique to baculovirus genomes. *hrs* consist of repeated sequences encompassing direct repeats of imperfect palindromic sequences. These elements function as transcriptional enhancers of *cis*-linked early viral genes, and experimental data also indicate that they serve as origins of virus replication (Pearson *et al*., 1992; Rodems and Friesen, 1993). *hrs* may also contribute to late gene transcription (Lu and Miller, 1995b). Enhancement of transcription is most likely through enhancement of transcription initiation. The *hrs* vary in size according to the number of palindromic repeats and in the number of copies in different baculovirus genomes. Although host factors can mediate *hr*-stimulated transcription from viral promoters in the absence of viral proteins, *hr*-mediated enhancement of transcription is dramatically increased by IE1, which binds as a dimer directly or indirectly to the *hr* (Friesen, 1997). *hrs* also function as origins of DNA replication in transient replication assays (Ahrens *et al*., 1995b; Kool *et al*., 1995).

On initial infection when DNA template concentrations are low, baculoviruses express transregulatory proteins that stimulate early gene expression. The immediate early transregulator IE1 plays a key role in regulation of gene expression. IE1 activates expression of early genes (*p35*, *gp64*, 39K, *p143*, *dnapol*, *pe38*, *lef-1*, *lef-2*, *lef-3*, and *ie1*) and is

required for DNA replication and transcription of late genes. IE1 dramatically enhances expression of genes that are *cis*-linked to *hr* enhancers. IE1 down-regulates transcription of *pe38* and *ie2*. The *ie1* promoter along with associated upstream sequences is active in uninfected cells, and can be used to direct foreign gene expression in transformed lepidopteran cells (Jarvis *et al*., 1990). The steady state level of IE1 increases during infection although the function of this protein during virus replication remains to be determined.

IE0 is an immediate early transregulator identical to IE1 except for an additional 54 N-terminal residues. IE0 results from splicing of the upstream *ie0* exon and fusion to the *ie1* exon. RNA splicing is a rare event in baculovirus gene expression and probably only occurs during the early stages of infection (Kovacs *et al*., 1991). IE0 transactivates the *hr*-linked promoters of *ie-1* and *39K*. IE2 stimulates transcription of several promoters, but to a lesser extent than IE1. IE2 and PE38 contain motifs typical of transcription regulators, including a leucine zipper and a RING finger. PE38 stimulates expression from the *p143* helicase promoter.

6.8.4.2. DNA Replication

For *S. frugiperda* cells infected by AcMNPV, viral DNA replication occurs from 6 to 18 h p.i., and then declines. Viral DNA synthesis is dependent on production of early viral proteins. *Cis*-acting elements that may be involved in initiation of viral DNA synthesis have been identified by analysis of defective virus particles generated on repeated passage of AcMNPV in cell culture. These defective viruses lack large regions of the AcMNPV genome with four regions that become amplified. Two of these regions contain *hrs*, and both the *hr* and non-*hr* regions can support transient replication of plasmids (Kool *et al*., 1993b, 1994a). The efficiency of replication decreases with reduction of the number of palindromes present in the *hr* (Leisy *et al*., 1995). The presence of multiple *hrs* dispersed throughout the genome may provide redundancy in the event that an *hr* is deleted. Loss of a single *hr* element from *Bombyx mori* NPV or AcMNPV has no impact on virus replication (Majima *et al*., 1993; Rodems and Friesen, 1993). However, demonstration that *hrs* function *in vivo* as origins of replication is lacking. Non-*hr* origins of replication have been identified in AcMNPV and OpMNPV (Kool *et al*., 1993a; Pearson *et al*., 1993).

The isolation of conditional-lethal mutants that are defective in DNA replication has facilitated identification of virus genes that are involved in virus DNA replication (Lee and Miller, 1978; Brown *et al*., 1979; Gordon, 1984; Lu and Carstens, 1991; Ribeiro *et al*., 1994). Transient replication assays were used to identify regions of the baculovirus genome that are able to support replication of cotransfected origin-containing plasmid DNA (Kool *et al*., 1994a, 1994b; Ahrens *et al*., 1995a; Ahrens and Rohrmann, 1995a, 1995b; Lu and Miller, 1995b). Five genes were classified as essential (*p143*, *ie1*, *lef-1*, *lef-2*, and *lef-3*) and five as stimulatory (*dnapol*, *p35*, *ie-2*, *lef-7*, and *pe38*) for replication of AcMNPV DNA (Kool *et al*., 1994b; Lu and Miller, 1995b). The *p143* gene encodes a helicase, which acts as a host range determinant. Incorporation of a fragment of *B. mori* NPV (BmNPV) helicase into AcMNPV (with few amino acids differing between the AcMNPV and BmNPV sequences) allowed AcMNPV to infect *B. mori* cells and larvae (Maeda *et al*., 1993; Croizier *et al*., 1994; Argaud *et al*., 1998). *lef-1* is an early gene important for late and very late gene expression (Passarelli and Miller, 1993), and essential for DNA replication (Lu and Miller, 1995b). Conserved domains indicate that Lef-1 may be a baculovirus primase (Barrett *et al*., 1996). Lef-2 is required for late gene expression and DNA replication. Lef-2 interacts with Lef-1 suggesting that these two proteins may function in replication as a heterodimer (Evans *et al*., 1997). Lef-3 is a single-stranded DNA binding protein that is essential for DNA replication (Hang *et al*., 1995). Although Lu and Miller (1995b) classified *dnapol* as stimulatory in transient assays, other reports have shown that *dnapol* is essential for virus replication (Pearson *et al*., 1993; Kool *et al*., 1994a, 1994b; Ahrens and Rohrmann, 1995a). The host DNA polymerase, in conjunction with virus genes essential for replication, may be able to replicate viral DNA at a suboptimal level. P35 is an apoptotic suppressor of *S. frugiperda* cells infected with AcMNPV (Clem *et al*., 1991), and stimulates DNA replication by preventing apoptosis possibly induced by expression of late gene products or DNA replication (Clem and Miller, 1994). Under some circumstances IE1 has been reported to trigger apoptosis (Prikhod'ko and Miller, 1996). However, IE1 also induces expression of P35. The genes *ie-2* and *pe38* function as stimulators of DNA replication probably through activation of genes involved in replication. Both genes encode transactivators of early gene expression (Carson *et al*., 1988; Lu and Carstens, 1993). PE38 activates *p143*, the baculovirus helicase homolog, while IE-2 stimulates production of PE38 and IE1. The effects of IE-2 are cell line specific (Lu and Miller, 1995a). Lef-7 is a putative single-stranded DNA binding protein and, along with Hcf-1, is a cell line-specific regulator of

DNA replication (Lu and Miller, 1995a, 1996). In addition to the genes identified as being required for replication by transient replication assays, Lin and Blissard (2002b) found that *lef-11* is necessary for viral DNA replication in the context of virus infection.

Because alteration of only one residue in AcMNPV helicase enables this virus to replicate in the otherwise nonpermissive BmN cell line, it is likely that a host protein interacts with the viral helicase, and that this interaction has virus and cell line specificity. Hence, host factors may be involved in replication of baculovirus DNA in addition to the viral genes described here. The host cell topoisomerase would also be required to relieve torsional stress as the duplex DNA is unwound by P143.

Given that infection-dependent replication of origin-containing plasmids results in production of concatemers of plasmid DNA, baculovirus DNA may be amplified by a rolling circle mode of replication. The detection of multiple unit-length genome fragments from replicating viral DNA also supports this hypothesis (Leisy and Rohrmann, 1993; Oppenheimer and Volkman, 1997). The mechanism for production of unit length genomes *in vivo* however remains to be established. Alternatively, replication may involve the theta mechanism initially, rolling circle synthesis, and recombination at the late stage, as for herpesviruses (Mikhailov, 2003).

6.8.4.3. Late and Very Late Gene Expression

Expression of late and very late genes begins following initiation of viral DNA replication, and is dependent on viral DNA replication. The late phase genes, which are transcribed at about 6–24 h p.i., include those encoding the structural proteins of the nucleocapsid, such as the major capsid protein VP39 and the basic core protein P6.9. The very late genes, transcribed at 18–72 h p.i., encode polyhedrin or granulin. The P10 protein, which affects disintegration of the nucleus, is expressed during the very late phase (Roelvink *et al*., 1992). Production of the late and very late viral genes coincides with a dramatic decline in the host RNAs (6–18 h p.i.) (Ooi and Miller, 1988; Okano *et al*., 2001) and host protein synthesis (Carstens *et al*., 1979). The decline in host RNAs appears to result from one or more late viral genes and is concurrent with margination of host cell chromatin (Ooi and Miller, 1988). However, the amount of host TATA-binding protein (TBP), a transcription factor that localizes to sites of viral DNA replication, increases, possibly as a result of viral disruption of TBP turnover (Quadt *et al*., 2002). Transcription of mitochondrial encoded genes is also unaffected by baculovirus infection (Okano *et al*., 2001).

A unique four-subunit RNA polymerase is responsible for the switch from early to late and very late gene expression (Beniya *et al*., 1996). All four subunits are encoded by the viral genome, specifically by *lef-4*, *lef-8*, *lef-9*, and *p47* (Guarino *et al*., 1998a). Lef-4 is hypothesized to provide a capping function for RNA transcribed by the polymerase (Jin *et al*., 1998). Two separate enzyme activities can be distinguished that differ in their ability to transcribe the very late genes (Xu *et al*., 1995). This α-amanitin resistant polymerase requires the promoter element TAAG. Late promoters initiate from (A/G/T)TAAG, while the motif (T/A)ATAAGNA (T/A/C)T(T/A)T is conserved for promoters of *polyhedrin (polh)*, *granulin*, and *p10* genes (Rohrmann, 1986). The late and very late genes are distinguished by an additional promoter element, the burst element, in the untranslated leader of very late genes (Ooi *et al*., 1989).

Nineteen AcMNPV genes, referred to as late expression factor (LEF) genes, are required for optimal expression of late and very late proteins in transient expression assays (Lu and Miller, 1995b; Todd *et al*., 1995, 1996; Rapp *et al*., 1998; Li *et al*., 1999; Lin and Blissard, 2002a) (**Table 2**). A subset of these genes is required for the viral DNA replication (Kool *et al*., 1994a; Lu and Miller, 1995b; Lin *et al*., 2001; Guarino *et al*., 2002b; Lin and Blissard, 2002b) (**Table 2**). Among the LEF genes are *ie-1* and *ie-2*, which transactivate early gene expression and may

transactivate other *lefs* including the replication-associated *lefs* such as *dnapol*, *lef-3*, and *p143*. Many of the LEF genes are expressed during the early phase of gene expression. LEFs include the four genes *lef-4*, *lef-8*, *lef-9*, and *p47*, which encode subunits of the virus-encoded RNA polymerase (Lu and Miller, 1997; Gross and Shuman, 1998; Guarino *et al*., 1998a, 1998b). Lef-5 is an initiation factor and increases transcription from both late and very late promoters (Guarino *et al*., 2002a). Very late expression factor-1 (Vlf-1) appears to regulate transcription of very late genes (McLachlin and Miller, 1994). Vlf-1 has sequence similarity to integrase/resolvases and DNA-binding activity without integrase activity (McLachlin and Miller, 1994). It interacts with the burst element of very late gene promoters, thereby directing the viral-specific RNA polymerase to these sites (Yang and Miller, 1999). No other genes that regulate very late gene expression have been identified (Todd *et al*., 1996).

Expression of late and very late genes is regulated primarily at the level of transcription. Many late transcripts have mini-open reading frames, or are di- or polycistronic, which may provide mechanisms for translational regulation of downstream ORFs. There is also evidence of *cis*-acting transcriptional regulation of flanking genes, which may be common given that genes of different temporal classes are dispersed throughout the genome (Ooi and Miller, 1990; Gross and Rohrmann, 1993).

6.8.5. Effects on the Host

6.8.5.1. Virulence

Virulence is defined as the relative ability of a microorganism to overcome host defenses, or the degree of pathogenicity within a group or species (Poulin and Combes, 1999). Insect species are classified as permissive, semipermissive, or nonpermissive to virus infection, according to the degree of susceptibility (Bishop *et al*., 1995). Enhanced virulence against semipermissive species will result in host range expansion, and hence virulence and host range are intrinsically linked. The LD_{50} of a virus in a given host (the dose of virus required to kill 50% of the population) provides an indicator of the efficiency with which the baculovirus can lethally infect that host, and hence provides a measure of adaptation to the host. Various studies have been conducted to select for increased baculovirus virulence against a particular species under laboratory conditions (**Table 3**). The protocol typically involves repeated passaging of a baculovirus through the insect host. The mechanistic bases for the increased virulence in such cases remain to be determined however.

For fatal infection to occur, the baculovirus must overcome a number of barriers or defenses (that are distinct from mechanisms of resistance) (see Section 6.8.5.5) that may be presented by the host insect. The first potential barrier to baculovirus infection is the requirement for an alkaline environment in the midgut for dissolution of OB and release of ODV. The high alkalinity within the midgut of some Lepidoptera is hypothesized to protect larvae from toxic tannins in the diet (Berenbaum, 1980). Organisms without this characteristic would not be exposed to ODV, which are required for infection of the midgut epithelium. ODV must then negotiate the peritrophic membrane, a process that is poorly understood and likely varies with species according to temporal and structural properties of the peritrophic membrane (Tellam, 1996). Having negotiated the peritrophic membrane, various mechanisms may prevent virus replication within the cell, such as requirements for viral attachment, fusion and entry into the cell, apoptosis (Clem and Miller, 1993), shut down of protein synthesis (Du and Thiem, 1997), and incompatibility between the host cell and virus replication machinery (Croizier *et al*., 1994). Most viruses would not replicate in nonpermissive organisms because of restrictions at the molecular level. Studies on infection of cell lines with

BV show that most semi- and nonpermissive insect cells support expression from baculovirus early gene promoters, but not from late or very late promoters (Morris and Miller, 1992, 1993; Liu and Carstens, 1993). Expression from late promoters in some cases suggests that the block likely occurs during or after viral DNA replication. Interestingly, baculoviruses are able to enter mammalian cells and mammalian promoters are used to drive gene expression for gene therapy purposes (Van Loo *et al*., 2001; Ghosh *et al*., 2002; Kost and Condreay, 2002; Huser and Hofmann, 2003). Baculoviruses do not replicate in mammalian cell lines.

Even if the baculovirus is able to replicate in the midgut cells, Lepidopteran larvae are able to slough midgut cells that are infected by ODV (Briese, 1986b; Engelhard and Volkman, 1995; Washburn *et al*., 1995, 1998). Infected midgut epithelial cells are also shed during molting. Evasion of the shedding of infected cells is hypothesized to have led to evolution of the M phenotype of NPV, and the ability of ODV-derived nucleocapsids to cross the midgut epithelial cells and rapidly produce budded virus (Granados and Lawler, 1981; Washburn *et al*., 1999, 2003a) (see Section 6.8.3.1 and **Figure 9**).

Baculoviruses encounter developmental resistance, with infection of later instars requiring a higher viral inoculum. Larvae also become increasingly resistant to fatal baculovirus infection as they age within each instar (Evans, 1986; Teakle *et al*., 1986). In addition, baculovirus infection of some semipermissive species is curtailed by the inability of hemocytes to support virus replication, and by melanization of infected tissues (Trudeau *et al*., 2001).

The arms race between the host defenses and evolution of baculoviruses to counter those defenses contributes to the virulence of a baculovirus against a specific host. Genes encoding enhancin for degradation of the peritrophic membrane, ecdysteroid UDP-glucosyl transferase for inactivation of ecdysteroids, and suppressors of apoptosis provide particularly nice examples of baculovirus weapons in this arms race. Understanding of the barriers to baculovirus infection will facilitate genetic manipulation to enhance the virulence of baculovirus insecticides.

6.8.5.2. Host Range

NPVs have been isolated from more than 500 insect species in several orders (Lepidoptera, Hymenoptera, Diptera, Coleoptera, Thysanura, Trichoptera). GVs have only been identified from lepidopteran hosts and have been isolated from more than 100 species. The NPVs tend to infect only members of the genus, or in some cases the family of the host insect species from which the virus was originally isolated. Few detailed studies of baculovirus host range have been conducted, and there is a wide variation in bioassay methodology, which makes comparison between studies difficult. One potential shortcoming of laboratory-based host range studies is that the heterogeneity observed in baculoviruses isolated from the field (Lee and Miller, 1978; Smith and Summers, 1979) may be more representative for studies of host range than laboratory clones, and indeed may be important for virus survival (Weitzmann *et al*., 1992).

Lymantriid NPVs such as those from *Lymantria dispar* and *Orgyia antiqua* tend to have a narrow host range (Barber *et al*., 1993). Some viruses of noctuid species infect few species, while other viruses isolated from noctuids, such as *A. californica*, *A. falcifera*, and *M. brassicae* (Payne, 1986; Doyle *et al*., 1990; Hostetter and Puttler, 1991), infect 30–40 species from multiple families. AcMNPV infects 43 species of Lepidoptera within 11 families (Payne, 1986). The GVs and hymenopteran NPVs appear to have narrower host ranges than the lepidopteran NPVs.

Current research on baculovirus host range is driven in part by the requirement for assessment of baculovirus host range for registration of baculovirus insecticides. This task has become more important with the registration of recombinant baculovirus insecticides for assessment of potential risks from recombinant baculoviruses to nontarget organisms. Understanding the genetic bases for host range may allow manipulation of baculovirus host range characteristics for pest management purposes.

6.8.5.2.1. Host range genes There are eight baculovirus genes that are known to encode host range determinants (Miller and Lu, 1997) (**Table 4**), most of which have been identified by analysis of restriction of baculovirus replication to specific cell lines. Insertion or alteration of a single viral gene can influence host range. Alteration of a single residue in the *p143* gene, which encodes a DNA helicase homolog, was sufficient to enable AcMNPV to infect cell lines of *B. mori*, while alteration of two residues allowed AcMNPV to infect and kill larvae of *B. mori* (Croizier *et al*., 1994; Kamita and Maeda, 1997; Argaud *et al*., 1998).

Although TnGV and AcMNPV both replicate in *T. ni*, the DNA helicase of TnGV could not substitute for that of AcMNPV. This result suggests that specific protein–protein or protein–DNA interactions are necessary for a functional replication complex (Bideshi and Federici, 2000). Introduction of the host range factor 1 (*hrf-1*) gene of LdMNPV into AcMNPV enabled AcMNPV to infect *L. dispar* cell

Table 4 Nucleopolyhedrovirus genes implicated in host range or virulence

				Effect on replication of AcMNPV in:				
Gene	*Origin of gene*	*Function*	Manipulation	Bombyx mori	Trichoplusia ni	Spodoptera spp.	Lymantria dispar	*Reference*

lines and larvae. The presence of *hrf*-1 in the AcMNPV genome resulted in a slight enhancement of AcMNPV virulence against *H. zea* (Chen *et al.*, 1998). Hrf-1 overcomes an apparent inhibition of tRNA synthesis in *L. dispar* cells infected with AcMNPV (Mazzacano *et al.*, 1999). Host cell-specific factor 1 (*hcf-1*) is required for replication of AcMNPV in *T. ni* cell lines but not for replication of AcMNPV in a *S. frugiperda* cell line (Lu and Miller, 1996). Hcf-1 was necessary for infection of *T. ni* larvae by injection, and disruption of *hcf-1* resulted in a 20–30% increase in time taken by the virus to kill the host insect following oral infection. The effect of *hcf-1* on virulence of AcMNPV in *T. ni* larvae would confer a significant advantage in the field. AcMNPV *lef-7* (late expression factor 7) is required for efficient infection of a *S. frugiperda* and a *S. exigua* cell line, but not a *T. ni* cell line (Chen and Thiem, 1997). AcMNPV ORF 603 is important for infection of *S. frugiperda* larvae but not for infection of *T. ni* larvae (Popham *et al.*, 1998). Disruption of expression of IE0, and concomitant increased expression of the apoptosis suppressor P35, enables AcMNPV to replicate in *S. littoralis* cells that undergo apoptosis on infection with wild-type AcMNPV (Lu *et al.*, 2003). The baculovirus antiapoptotic gene *p35* allows AcMNPV to replicate in a *S. frugiperda* cell line and in larvae, but is not required for replication in *T. ni* cells and larvae (Clem *et al.*, 1991, 1994; Clem and Miller, 1993). The presence in AcMNPV of at least one gene that specifically facilitates replication in *T. ni* larvae (*hcf-1*) and at least one gene that specifically facilitates replication in *S. frugiperda* larvae (*lef-7*) indicates that the ability to infect multiple species provides a selective advantage to the virus.

A DNA microarray of the AcMNPV genome has been used to identify six AcMNPV genes (*orf150*, *p10*, *pk2*, *lef-3*, *p35*, and *lef-6*) that are differentially regulated in cell lines derived from *S. frugiperda* (Sf9) and *T. ni* (High Five®) (Yamagishi *et al.*, 2003). Although the functional significance of these genes (with the exception of *p35*) in the two cell lines is unclear, these results are indicative of host cell-specific regulation of AcMNPV genes, suggesting differential viral gene expression for optimal replication in different cell types.

6.8.5.2.2. Antiapoptotic genes P35 is a 35 kDa suppressor of apoptosis that inhibits CED-3/ICE-like proteases produced in response to virus infection and involved in apoptosis of infected insect cells (Clem, 1997). Viruses lacking a functional *p35* gene induce apoptosis of the infected cell, with characteristic blebbing of the plasma membrane, nuclear condensation, and intranucleosomal cleavage of cellular DNA. Baculovirus-induced apoptosis is correlated with reduced infectivity, replication, and dissemination within the host insect (Zhang *et al.*, 2002; Clarke and Clem, 2003). P35 is expressed

during the early and late stages of infection to suppress apoptosis that occurs during the transition from the early to the late stage of infection. A reduction in OB production and lack of liquefaction of cadavers is observed in larvae of *T. ni* infected with *p35* mutants (Herschberger *et al.*, 1992; Clem *et al.*, 1994). P35 is the most broadly acting antiapoptotic protein known and is able to block apoptosis in a wide range of organisms. Hence it is of interest that P35 does not prevent apoptosis in cell lines from *S. littoralis* and *Choristoneura fumiferana* (Chejanovsky and Gershburg, 1995; Palli *et al.*, 1996).

A second family of baculovirus antiapoptotic genes, called *iap* (inhibitor of apoptosis) has been found in all baculoviruses except CuniNPV (Hughes, 2002). There are three *iap* genes in baculoviruses, but only EppoMNPV and OpMNPV have all three. AcMNPV has *iap1* and *iap2* in addition to *p35*, but the function of AcMNPV *iap* genes has not yet been demonstrated (Clem and Miller, 1994; Griffiths *et al.*, 1999). These Iap proteins may serve an auxiliary role in antiapoptotic activity (Viliplana and O'Reilly, 2003), act by blocking signal transduction pathways stimulated by various death stimuli (Clem, 1997), or may only function as inhibitors of apoptosis in certain hosts.

The protein P94 may induce apoptosis in tissues that are important for oral infection (Clem *et al.*, 1994). P35 is not required to inhibit apoptosis if P94 is not expressed (Kamita *et al.*, 1993; Clem, 1997). P94 is not required for infection of larvae of *S. frugiperda* or *T. ni*, but may be important for other species. If P94 induces apoptosis, there would be strong selection to acquire both of these genes. In line with this hypothesis, P35 in BmNPV is not required for infection of *B. mori* and most of the *p94* gene in this virus has been deleted (Kamita *et al.*, 1993; Clem, 1997).

6.8.5.3. Survival Time and Yield

The amount of time taken by the virus to kill the host varies widely, according to the host–virus combination, virus dose, larval instar, and environmental conditions, temperature in particular. In general, an increase in the dose of virus ingested results in a decrease in the survival time of the host insect (van Beek *et al.*, 1988). The survival time of 50% of the infected population (ST_{50}) and the LD_{50} both provide measures of pathogen virulence. The survival time of the host is also linked to the virus yield, with longer survival times allowing for additional rounds of virus replication, resources permitting. To promote increased survival time and virus yield, baculoviruses have acquired a gene that encodes ecdysteroid UDP-glucosyltransferase (*egt*).

Expression of the baculovirus *egt* gene has a complex effect on the host larva. By inactivating ecdysteroids, Egt allows the insect to live longer and grow larger thereby allowing increased production of virus. *egt* is expressed during the early phase of infection, and is secreted from infected cells rather than being retained in the endoplasmic reticulum as in the case of related mammalian proteins (O'Reilly, 1995). Egt catalyzes the conjugation of ecdysteroids with UDP-glucose or UDP-galactose and is specific for ecdysteroids (O'Reilly and Miller, 1989; O'Reilly *et al.*, 1992; Kelly *et al.*, 1995; Clark *et al.*, 1996). This sugar conjugation and inactivation of ecdysteroids suppresses host molting, prevents pupation, and prevents the conversion of permissive larvae into nonpermissive hosts. A critical level of Egt is required for the arrest of host development and hence the timing of arrest depends on the dose of virus received and also the timing of infection during the larval instar (O'Reilly, 1997). Suppression of molting causes infected larvae to continue to feed when they would otherwise cease feeding in preparation for the molt, and the yield of OB is increased (O'Reilly and Miller, 1991). Deletion of the *egt* gene from the AcMNPV genome results in a 20–30% reduction in the time taken by the virus to kill the host and an associated reduction in virus yield (O'Reilly and Miller, 1991). In *S. exigua*, Egt did not arrest development but Egt served to maintain the integrity of the Malpighian tubules of infected larvae (Flipsen *et al.*, 1995a). Hence, the role of Egt may not be dependent solely on inhibition of molting. Other evidence suggests that high titers of ecdysteroids are detrimental to virus replication and Egt may serve to mitigate these effects (O'Reilly *et al.*, 1995; O'Reilly, 1997).

6.8.5.4. Sublethal Effects and Latent Infections

The impact of baculoviruses on host populations extends beyond mortality of infected larvae, because of physiological effects that result from infection at sublethal doses of virus. Effects typical of sublethal infections include change in development time and sex ratio, and reduced fecundity and egg viability (Rothman and Myers, 1996a). The mechanisms of sublethal effects are poorly understood. Virus-induced alteration of hormonal and enzyme levels may affect host development or production of viable eggs or sperm (Subrahmanyam and Ramakrishnan, 1980; O'Reilly and Miller, 1989; Burand and Park, 1992). Latent viruses do not induce symptoms until activated by various stressors (Hughes *et al.*, 1993, 1997). Host insects that harbor latent viruses do not transmit virus horizontally, but can transmit virus vertically.

6.8.5.5. Resistance

Resistance is defined as physiological alteration in response to selection pressure from exposure to baculoviruses, resulting in decreased susceptibility of the host insect to the baculovirus. This is distinct from developmental resistance described above (see Section 6.8.5.1).

The development of resistance to baculoviruses is a key issue for use of baculoviruses in pest management but has received relatively little attention (Briese, 1986a, 1986b; Fuxa, 1993). Insects of the same species collected from different locations often vary in their susceptibility to a particular baculovirus, presumably because prior exposure in some localities has been selected for resistant populations (Fuxa, 1987). Resistance to and virulence of baculoviruses are likely to vary geographically according to frequency and levels of exposure. In Brazil, the resistance of the velvet bean caterpillar to *Anticarsia gemmatalis* MNPV increased according to the number of years of treatment at different sites (Abot *et al*., 1995). Several studies have shown that it is possible to select for resistant hosts under selection pressure from different baculoviruses, although not for all virus–host combinations (Kaomini and Roush, 1988). The cabbage looper, *T. ni*, has been shown to evolve up to 22-fold resistance to the virus TnSNPV (Milks and Myers, 2000), which was not associated with a detectable fitness cost and was stable in the absence of virus exposure (Milks *et al*., 2002). In contrast, resistance to other NPVs or a GV was associated with reduced pupal weight, developmental time, and/or egg production or hatch in *A. gemmatalis* (Fuxa and Richter, 1998), *S. frugiperda* (Fuxa *et al*., 1988), and *Plodia interpunctella* (Boots and Begon, 1993). *Spodoptera frugiperda* acquired 4.5-fold resistance to SfNPV following selection for seven generations (Fuxa *et al*., 1988); *P. interpunctella* acquired twofold resistance following exposure to *P. interpunctella* GV for 2 years (Boots and Begon, 1993); *A. gemmatalis* acquired fivefold resistance in eight generations in the laboratory, and >1000-fold resistance in 13 generations in the field in Brazil (Fuxa and Richter, 1998). As expected for resistance associated with fitness cost, resistance was rapidly lost on removal of virus selection from *S. frugiperda* and *A. gemmatalis* (Fuxa and Richter, 1989, 1998). There is also evidence that resistance to *S. frugiperda* NPV confers cross-resistance to other baculoviruses (Fuxa and Richter, 1990).

The mechanistic bases for resistance to baculoviruses have not been addressed. An additional complexity is that sublethal infection can cause the same effects as resistance such as altered development time and reduced fecundity. Assessment of field populations of the Western tent caterpillar *Malacosoma californicum pluviale*, for example, showed that effects were more consistent with sublethal infection than disease-induced resistance (Rothman and Myers, 1996b).

6.8.6. Baculovirus Genomics

6.8.6.1. General Properties of Baculovirus Genomes

At the time of writing, the genomes of 19 baculoviruses have been sequenced (**Table 5**). The sizes of the genomes range from approximately 80 to 180 kbp, due to the presence of unique genes, and gene duplications including the "baculovirus repeat ORFs" or *bro* genes (Gomi *et al*., 1999; Hayakawa *et al*., 1999; Kang *et al*., 2003). The genomes vary as a result of deletions, gene insertions, inversions, and duplications. Transposable elements have contributed to some of these modifications (Friesen, 1993; Jehle, 1996; Jehle *et al*., 1997). The organization of genes in NPV genomes is highly conserved, with rearrangements of genomic segments and presence or absence of auxiliary genes contributing to their diversity. The G+C content is highly variable, ranging from 28% to 59% of the genome.

In addition to the essential genes that are required for virus propagation (including genes required for virus gene expression, replication, virus assembly, and transmission), the large size of baculovirus genomes allows for inclusion of a second class of genes, the auxiliary genes (**Table 6**). These genes are not essential but confer some selective advantage to the virus, and may act at the cellular or organismal level (O'Reilly, 1997). These genes include *ubi*, *egt*, and *ctl*. Many baculovirus genes have yet to be characterized and the functions of many genes that have been studied remain unknown. Extensive analysis of 13 baculovirus genomes revealed a core of 30 common genes, including 10 of unknown function, and an additional 32 genes that are present in all of the lepidopteran baculoviruses (Herniou *et al*., 2003). In addition, 27 genes are specific to GVs and 14 to lepidopteran NPVs suggesting a role for these genes in the differences in the biology of these two groups. There are 17 genes that are specific to group I NPVs, including *gp64*.

There are numerous examples of baculovirus genes with homology to genes from eukaryotic or prokaryotic organisms (Possee and Rohrmann, 1997) (**Table 6**). The high frequency of homologous recombination during viral replication, combined with movement of genetic material by transposable

[a,b]Viruses with the same superscript letter are considered to be variants of the same virus (Blissard *et al.*, 2000).

elements (Miller and Miller, 1982; Fraser *et al.*, 1983; Friesen, 1993), provide possible mechanisms for genetic exchange between disparate organisms. Some of the genes such as *egt*, the ecdysteroid UDP-glucosyl transferase gene, and *sod*, the superoxide dismutase gene homolog, are most likely of insect origin. Indeed, a genome-wide survey revealed six genes likely to have been horizontally transferred into baculoviruses, namely *DNA ligase*, *rr1*, *gta*, *iap*, *chi*, and *egt*, of which *egt* and *iap* are derived from insects (Hughes, 2002; Hughes and Friedman, 2003). The AcMNPV chitinase gene *chiA* has the highest similarity to bacterial chitinase (Hawtin *et al.*, 1995). The higher G+C content of this gene is also more typical of the bacterial gene than other baculovirus genes. The F protein genes are also likely to have been acquired from insect hosts (Malik *et al.*, 2000; Rohrmann and Karplus, 2001).

The sequencing of multiple baculovirus genomes has allowed inference of baculovirus evolution and genetic diversity (Herniou *et al.*, 2003), horizontal gene transfer (Hughes and Friedman, 2003), identification of genes that have evolved in response to changing selection pressures (Harrison and Bonning, 2003, 2004), and identification of genes involved in virus–host insect interactions (Dall *et al.*, 2001).

6.8.6.2. Baculovirus Evolution

Comprehensive phylogenetic analyses of 30 genes common to 13 baculovirus genomes highlighted the division of baculoviruses into four groups: GVs, group I NPVs, group II NPVs, and the dipteran NPV CuniNPV (Herniou *et al.*, 2003). Phylogenetic analysis of *dnapol* from NPV and GV provides an example of this division (**Figure 13**). It is likely that the Baculoviridae will be reclassified to accommodate CuniNPV, which clearly does not belong with the lepidopteran NPVs.

Gene content mapping highlighted the fluid nature of baculovirus genomes including examples of repeated gene acquisitions and losses. Thirty-three genes were identified that have been acquired separately on two or even three occasions (Herniou *et al.*, 2003; Hughes and Friedman, 2003). Baculoviruses have sufficient flexibility with incorporation of additional genetic material to allow "sampling" for beneficial genes from the environment (Herniou *et al.*, 2001). Recombination between baculoviruses may occur when different baculoviruses infect the same cell. This is most likely to occur in the field between related viruses that share common hosts (Smith and Summers, 1980; Croizier and Ribeiro, 1992). Gene loss and acquisition may also result from the activity of transposable elements, several of which have been observed on culture of baculoviruses in cell lines. Sites favored by transposons include the *fp25K* gene resulting in several mutant viruses with the few polyhedra (FP) phenotype. *Trichoplusia ni* cell-derived transposable elements include IFP2 ("piggyBac") (Cary *et al.*, 1989), TFP3 ("tagalong") (Wang *et al.*, 1989), *hitchhiker* (Bauser *et al.*, 1996), and TED (Miller and Miller, 1982). For Sf cells, the elements IFP1.6 and IFP2.2 have been characterized (Beames and Summers, 1988, 1990), and a Tc1-like transposon has been identified in the genome of CpGV (Jehle *et al.*, 1995, 1997, 1998).

Shared protein phylogenetic profiles indicate the presence of viral proteins specific for infection of lymandtriid hosts. Only OpMNPV and LdMNPV that infect the lymantriids *L. dispar* and *Orygia pseudotsugata* encode *hrf1*, *ctl1*, and *ctl2*. Other baculoviruses encode one or other of the *ctl* genes,

Table 6 Baculovirus genes with homologs in other organisms

Gene	*Homolog*	*Other locations*
Virus propagation[a]		
iap	Inhibitor of apoptosis	Mammals, insects
fgf	Fibroblast growth factor	Mammals
gta	General transcription activator	Mammals
dnapol	DNA polymerase	Eukaryotes, prokaryotes, other virus families
vlf-1	Integrase/resolvase	Yeast, prokaryotes
pnk/pnl	Polynucleotide kinase and ligase	Phage, yeast, plants
alk-exo	Alkaline exonuclease	Eukaryotes, prokaryotes
gp64	Viral glycoprotein	Thogoto virus
gp37	Spindlin	Entomopoxviruses
dUTPase	dUTPase	Eukaryotes, prokaryotes, other virus families
rr 1, 2	Ribonucleotide reductase subunits	Eukaryotes, prokaryotes, other virus families
f	Envelope fusion protein	*Drosophila melanogaster*
Auxiliary genes[b]		
ptp	Protein tyrosine phosphatase	Eukaryotes, prokaryotes, poxviruses
ctl	Conotoxin	Cone snails, spiders
egt	Ecdysteroid UDP-glucosyl transferase	Eukaryotes, prokaryotes
pk1	Protein kinase	Eukaryotes, prokaryotes, other virus families
pk2	Protein kinase, eiF2-α-like	Eukaryotes
pcna	Proliferating cell nuclear antigen	Eukaryotes
sod	Superoxide dismutase	Eukaryotes, prokaryotes, poxviruses
ubi	Ubiquitin	Eukaryotes, prokaryotes
chiA	Chitinase	Eukaryotes, prokaryotes
cath	Cathepsin	Eukaryotes
p10	Filament-associated late protein	Entomopoxviruses

[a]Genes required for virus propagation including those encoding structural proteins, those required for virus gene expression, replication, production of progeny virus.
[b]Genes not required for virus replication but providing some selective advantage.
After Possee and Rohrmann (1997).

but not both, and *hrf1* is only found in OpMNPV and LdMNPV. The link between the presence of all three genes and infection of a particular lepidopteran family suggests that these proteins may function in specific interactions with this host family (Herniou *et al*., 2003).

6.8.6.3. Identification of Genes Involved in Virus–Insect Interactions

Dall *et al*. compared the genes of representative viruses from three different families that include viruses that infect insects, namely the Poxviridae, Baculoviridae, and Iridoviridae (Dall *et al*., 2001). Six groups of genes were identified that were present in all three families, present in viruses with insect hosts, and absent in members with vertebrate hosts. Four of the six groups of genes are found in baculoviruses, and include the fusolin/gp37 group, which encodes proteins that facilitate infection (Xu and Hukuhara, 1992; Mitsuhashi *et al*., 1998; Hukuhara *et al*., 1999). Analysis of the other three groups found in baculoviruses may provide leads for genetic improvement of baculovirus insecticides by modification of host range or virulence.

6.8.6.4. Identification of Genes that Have Undergone Adaptive Molecular Evolution

An alternative approach for identifying genes underlying host range or virulence is to compare the genomes of closely related baculoviruses that exhibit differential virulence to host species. The closely related viruses *Rachiplusia ou* MNPV (*A. falcifera* MNPV) (Harrison and Bonning, 1999) and AcMNPV have broad, overlapping host ranges but there are significant differences in the ability of these two viruses to infect at least six species. These species include the corn earworm *H. zea*, the European corn borer *Ostrinia nubilalis*, and the navel orangeworm *Amyelois transitella* (Lewis and Johnson, 1982; Hostetter and Puttler, 1991; Vail *et al*., 1993; Cardenas *et al*., 1997; Harrison and Bonning, 1999). On comparison of the genomes of these two viruses, it was found that the *hrs* of RoMNPV contain fewer palindromic repeats than in AcMNPV, homologs of five AcMNPV genes including *ctl* are missing from RoMNPV, and the composition of promoter motifs differed in 23 cases (Harrison and Bonning, 2003). On the basis that the primary selection pressure on a virus comes from its

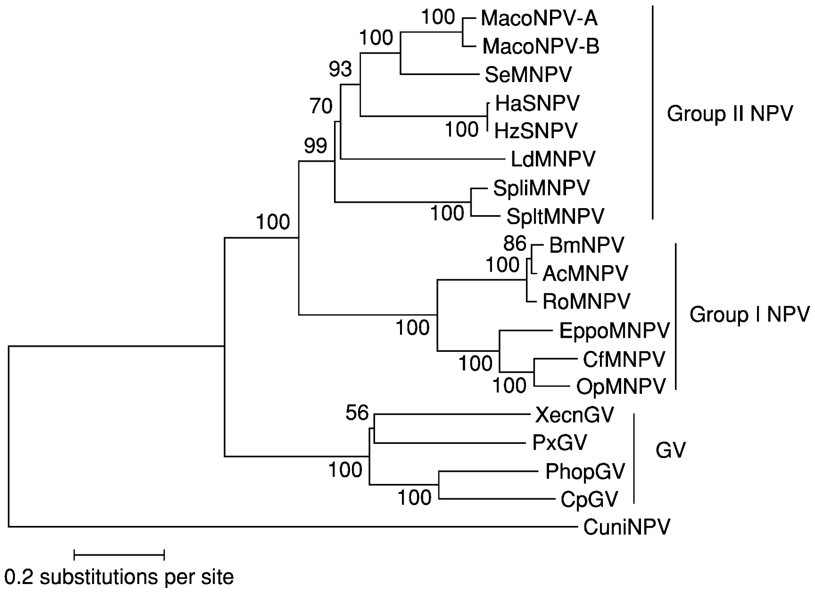

Figure 13 Phylogenetic analysis of predicted amino acid sequences of *dnapol* illustrating the separation of groups I and II NPVs from GVs and from the dipteran NPV derived from *Culex nigripalpus*. Phylogram produced by minimum evolution (ME) analysis of baculovirus DNA polymerase predicted amino acid sequences. Bootstrap values >50% (*n* = 1000 replicates) are shown at interior branches where they occur. The Group I and Group II NPV clades are indicated. AcMNPV, *Autographa californica* multiple nucleopolyhedrovirus (Ayres *et al.*, 1994); BmNPV, *Bombyx mori* nucleopolyhedovirus (Gomi *et al.*, 1999); CfMNPV, *Choristoneura fumiferana* multiple nucleopolyhedrovirus (Liu and Carstens, 1995); CpGV, *Cydia pomonella* granulovirus (Luque *et al.*, 2001); CuniNPV, *Culex nigripalpus* nucleopolyhedrovirus (Afonso *et al.*, 2001); EppoMNPV, *Epiphyas postvittana* multiple nucleopolyhedrovirus (Hyink *et al.*, 2002); HaSNPV, *Helicoverpa armigera* single nucleopolyhedrovirus (Chen *et al.*, 2001); HzSNPV, *Helicoverpa zea* single nucleopolyhedrovirus (Chen *et al.*, 2002); LdMNPV, *Lymantria dispar* multiple nucleopolyhedrovirus (Kuzio *et al.*, 1999); MacoNPV-A, *Mamestra configurata* nucleopolyhedrovirus strain 90/2 (Li *et al.*, 2002b); MacoNPV-B, *Mamestra configurata* nucleopolyhedrovirus strain 96B (Li *et al.*, 2002a); OpMNPV, *Orgyia pseudotsugata* multiple nucleopolyhedrovirus (Ahrens *et al.*, 1997); PxGV, *Plutella xylostella* granulovirus (Hashimoto *et al.*, 2000); PhopGV, *Phthorimaea operculella* granulovirus (accession number NC_004062); *Rachiplusia ou* multiple nucleopolyhedrovirus (Harrison and Bonning, 2003); SeMNPV, *Spodoptera exigua* multiple nucleopolyhedrovirus (Ijkel *et al.*, 1999); SpliMNPV, *Spodoptera littoralis* multiple nucleopolyhedrovirus (accession number AF215639); SpltMNPV, *Spodoptera litura* multiple nucleopolyhedrovirus (Pang *et al.*, 2001); XecnGV, *Xestia c-nigrum* granulovirus (Hayakawa *et al.*, 1999).

host, and that genes that have adaptively evolved may be involved in virulence, positive selection analysis was conducted on the genes of AcMNPV and RoMNPV (Yang *et al.*, 2000; Harrison and Bonning, 2003). Genes in which nonsynonymous (amino acid changing) substitutions are fixed at a higher rate than synonymous (silent) substitutions are identified as having undergone adaptive molecular evolution, or positive selection. This maximum likelihood analysis resulted in the identification of two genes, *arif-1* and *odv-e18*, predicted to have undergone positive selection. Odv-E18 is present in the envelope of occlusion-derived virus (Braunagel *et al.*, 1996b) and hence in an ideal location as a host range determinant for initial infection of midgut cells of the host insect. Arif-1 (actin-rearrangement-inducing factor) is involved with dissociation of the actin network of the host cell and the actin cables that form early during virus infection, and in production of actin aggregates at the plasma membrane (Dreschers *et al.*, 2001).

The strength of the positive selection analysis increases with increasing number of data sets. The positive selection analyses have been extended to include genes from multiple NPV genomes, and from this analysis nine genes predicted to have undergone positive selection have been identified (Harrison and Bonning, 2004). Alignments of 83 group I NPV genes were fitted to models of codon substitution that allow for varying selection intensity among codon sites. Genes predicted to have undergone positive selection include *ac38*, *lef-10*, *lef-12*, *odv-e18*, and *odv-e56*. NPV genes that have undergone positive selection may modulate the ability of different NPVs to replicate efficiently in cells (*lef-10*, *lef-12*) or establish primary infection of the midgut (*odv-e18*, *odv-e56*) of different host species.

6.8.7. Conclusion

Baculoviruses will continue to play an important role in the management of insect pests, as model

systems for studies of fundamental biological processes, as tools for recombinant protein expression, and as candidate vectors for gene therapy. The potential of mosquito baculoviruses such as CuniNPV for management of mosquito-borne disease will also be of particular interest. Sequencing of additional baculovirus genomes and comparative genomics will provide further insights into baculovirus biology and evolution. Data acquired from the comparative genomics studies such as identification of baculovirus genes that have undergone adaptive molecular evolution (Harrison and Bonning, 2003) and those potentially involved in interaction with the insect host (Dall *et al*., 2001) provide particularly useful leads for elucidation of how baculoviruses have evolved with their hosts. DNA microarrays of baculovirus genomes (Yamagishi *et al*., 2003), expressed sequence tag (EST) libraries (Okano *et al*., 2001), and RNA interference (Means *et al*., 2003) will be valuable tools for future study of baculovirus gene expression and virus–host cell interactions. Increased understanding of baculovirus biology will facilitate further optimization of baculovirus-related technologies.

6.9 Genetically Modified Baculoviruses for Pest Insect Control

S G Kamita, K-D Kang, and B D Hammock,
University of California, Davis, CA, USA
A B Inceoglu, Ankara University, Ankara, Turkey

6.9.1. Introduction

There are presently more than 20 known groups of insect pathogenic viruses, which are classified into 12 viral families (Tanada and Kaya, 1993; Blissard *et al.*, 2000). Among insect pathogenic viruses, members of the family Baculoviridae are the most commonly found and most widely studied. Baculoviruses are rod shaped, enveloped viruses with large, covalently closed, double-stranded DNA (dsDNA) genomes. Baculoviruses are made up of two genera: nucleopolyhedrovirus (NPV) and granulovirus (GV). The NPVs can be further divided into two groups (I and II) on the basis of the phylogenic relationships of 20 distinguishing genes (Herniou *et al.*, 2001). Baculoviruses produce two phenotypes, the budded virus (BV) and the occluded virus (OV), during their life cycles (Granados and Federici, 1986; Miller, 1997). BVs are predominantly produced during an early phase of infection and acquire their envelopes as they bud through the plasma membrane. BVs are responsible for the systemic or cell-to-cell spread of the virus within an infected insect. Continuous cell lines that support high-level production of BVs are available for NPVs, but not for GVs. The availability of these cell lines has been critical for the development of genetically modified NPVs. OVs are produced during a late phase of infection and are involved in the horizontal or larva-to-larva transmission of the virus. The OV of the NPV is known as a polyhedron (plural polyhedra) or polyhedral inclusion body, and that of the GV is known as a granule. Within the proteinaceous crystal matrix of the OV are embedded virions termed the occlusion derived virions (ODVs). Each ODV is formed by single or multiple nucleocapsids surrounded by an envelope. In the field, the polyhedron or granule structure protects the embedded ODV(s) from the environment. The morphology and biological properties of baculoviruses are reviewed in detail in **Chapter 6.8**.

Owing to their inherent insecticidal activities, natural baculoviruses have been used as safe and effective biopesticides for the protection of field and orchard crops, and forest in the Americas,

Europe, and Asia (Black *et al*., 1997; Hunter-Fujita *et al*., 1998; Vail *et al*., 1999; Moscardi, 1999; Copping and Menn, 2000; Lacey *et al*., 2001; see **Chapter 6.8**). Both NPVs and GVs have been successfully registered for use as microbial pesticides by commercial companies and government agencies. NPVs of the velvetbean caterpillar *Anticarsia gemmatalis* (AgMNPV) and *Helicoverpa armigera* (HaSNPV) are being used with particular success for the protection of soybean in Brazil (Moscardi, 1999) and cotton in China (Sun *et al*., 2002), respectively. Natural baculoviruses, however, are slower acting and more target specific (i.e., their host specificity is narrow) compared to synthetic chemical pesticides such as the pyrethroids. The general use of natural baculoviruses in developed countries has been limited except against forest pests primarily due to their slow speed of insect killing compared to chemical insecticides, and partially due to their relatively narrow host specificity, low field stability, and cost of production. As a natural control agent the "slow kill" characteristic allows the virus to replicate to tremendous numbers while allowing its host to feed for several days. Although an attribute in a natural control strategy, this trait is a severe limitation in modern agriculture. This trait and others such as narrow host specificity can and have been addressed by genetically modifying the baculovirus using recombinant DNA technology.

During the 1980s, the birth of genetically modified (GM) baculoviruses came along with exciting new research in the laboratories of Summers (Summers and Smith, 1987) and Miller (1988). They simultaneously exploited a combination of unique characteristics of NPVs to establish the baculovirus expression vector systems (BEVS) that are now in common use for basic research and commercial applications. These characteristics include: (1) the availability of the exceptionally strong polyhedrin gene (*polh*) promoter to drive foreign gene expression; (2) a selection system based upon the visualization of the nonessential (in cultured cells) gene product of the polyhedrin gene; (3) a dsDNA genome that can be easily modified; (4) a rod-shaped capsid that can extend to package additional DNA; and (5) a eukaryotic cell line that supports virus replication at high levels. *Autographa californica* multicapsid NPV (AcMNPV), originally isolated from the alfalfa looper *A. californica* (Vail *et al*., 1973, 1999), is the baculovirus type species. AcMNPV was used by the Summers and Miller laboratories as the parental baculovirus for BEVS. Another baculovirus, *Bombyx mori* NPV (BmNPV), isolated from the silk moth *B. mori*, was used by Maeda (1989a) as the parental baculovirus in an alternative BEVS that used larvae of *B. mori* for *in vivo* expression. The methodologies for the construction and use of recombinant AcMNPVs and BmNPVs for the expression of heterologous genes have been thoroughly described (Summers and Smith, 1987; O'Reilly *et al*., 1992; Richardson, 1995; Merrington *et al*., 1999). These methodologies, with slight modifications, have also been used for the construction of GM baculovirus pesticides.

The studies to date indicate that GM baculoviruses can easily become an integral part of pest insect control, especially in developing countries and for the control of insects that have become resistant to synthetic chemical pesticides (reviews: Hammock *et al*., 1993; McCutchen and Hammock, 1994; Miller, 1995; Bonning and Hammock, 1996; Wood, 1996; Harrison and Bonning, 2000a; Inceoglu *et al*., 2001a; Bonning *et al*., 2002). Several innovative and successful approaches have been taken to improve the speed of kill of a baculovirus by genetic modification. These approaches include: (1) insertion of a foreign gene into the baculovirus genome whose product alters the physiology of the target host insect or is toxic towards the target host; (2) deletion of an endogenous gene from the baculovirus genome; and (3) incorporation of active toxin into the OV. Combinations of these approaches have also been successful in terms of decreasing the time required to kill the host or more importantly the time required to stop host feeding. Safe and effective protection of the crop from feeding damage should be the goal of a GM baculovirus pesticide. Baculoviruses have been transformed from natural disease agents to efficient pesticides through the above-mentioned discoveries and innovative approaches. Here, numerous innovations that have been used to improve the efficacy of baculoviruses for crop protection are discussed. Additionally, studies that have addressed the safety of natural and GM baculoviruses, especially in terms of risk to humans, the environment, and nontarget beneficial insects are also covered. The individual sections of this chapter provide a detailed and comprehensive summary of the field, especially in terms of improving the insecticidal activity of GM baculoviruses. In Section 6.9.7, the reader will also find a discussion of the reasons why GM baculoviruses do not receive the interest that they deserve. The authors hope that after reading this review, the reader will be convinced that the currently available GM baculovirus pesticides are effective and safe, and should be used as biological pesticides.

6.9.2. Insertion of Hormone and Enzyme Genes

6.9.2.1. Hormones

Keeley and Hayes (1987) were two of the first to suggest the use of an insect neurohormone gene to increase the insecticidal activity of the baculovirus. They wrote:

> use of an insect baculovirus as an expression vector for neurohormone genes has several advantages as a pest control strategy. (1) Insect viruses are genera- or species-specific so that the virus has a limited host range and would not affect nontarget insects. (2) The natural hormone would be produced at continuous, high levels by the viral expression vector. (3) The combination of natural insect hormones with insect-specific viruses constitutes an ideal insect pest control agent from the environmental standpoint.

Menn and Bořkovec (1989) further suggested "a neuropeptide gene placed behind a strong non-essential viral promoter is capable of turning an infected cell into a neuropeptide factory within the insect..." Maeda (1989b) pioneered the field by being the first to put these concepts into practice by generating a recombinant BmNPV expressing a diuretic hormone gene that disrupted the normal physiology of larvae of the silkworm *B. mori*. Subsequently, at least four biologically active peptide hormones have been expressed using recombinant baculoviruses: eclosion hormone (Eldridge *et al.*, 1991), prothoracicotropic hormone (O'Reilly *et al.*, 1995), pheromone biosynthesis activating neuropeptide (Vakharia *et al.*, 1995; Ma *et al.*, 1998), and neuroparsin (Girardie *et al.*, 2001). Unfortunately, expression of a biologically active hormone by the recombinant baculovirus has only been modestly successful or unsuccessful (**Figure 1**) in terms of improving the speed of kill of the baculovirus. In hindsight, this lack of success is not completely unexpected since critical events in the insect's physiology and life cycle are often protected by sequestration (by physical means or through time) or by overlapping systems. As we learn more about the regulatory mechanisms and timing of the hormonal control systems of insects, we should be able to develop more refined approaches to the use of hormone genes to improve the baculovirus as a pesticide.

6.9.2.1.1. Diuretic hormone Diuretic and anti-diuretic hormones play critical roles in the excretion and retention of water by insects in response to changes in their environment (Holman *et al.*, 1990; Coast *et al.*, 2002; Gade, 2004). The tobacco hornworm *Manduca sexta* encodes a neuropeptide hormone consisting of 41 amino acid residues that stimulates diuresis (Kataoka *et al.*, 1989). Because of the relatively short length of this peptide hormone, Maeda (1989b) was able to generate a synthetic gene encoding the peptide and attempted to express this gene in fifth instar larvae of *B. mori* using BmNPV. The synthetic diuretic hormone (DH) gene was designed on the basis of the codon usage of the polyhedrin gene of BmNPV and the gene structure of an amidated peptide from the giant silk moth *Hyalophora cecropia*. The DH gene construct also included a signal sequence for secretion from a cuticle protein (CPII) of *Drosophila melanogaster* (Meigan) (Snyder *et al.*, 1982) and a glycine residue at the C-terminus for amidation. The recombinant BmNPV (BmDH5) carrying the synthetic DH gene killed fifth instar larvae about 1 day faster than the wild-type BmNPV (Maeda, 1989b). This corresponded to a roughly 20% improvement in speed of kill in comparison to the wild-type BmNPV. BmDH5 also caused a 30% reduction in hemolymph volume, which was hypothesized to be due to the excretion of water into the Malpighian tubules, and subsequently hindgut and outside (Maeda, 1989b). Biologically active DH, however, was not detected in the circulating hemolymph of these animals (D.A. Schooley, unpublished data). The 20% improvement in speed of kill is modest in comparison to more recent GM baculovirus constructs, and the bioassays were based on injection of BV rather than oral infection with polyhedra (the normal mode of baculovirus infection in the field). Nevertheless, these experiments generated a lot of excitement in the study of genetically modified baculoviruses as pesticides and established some of the groundwork for subsequent GM baculovirus pesticide constructs.

6.9.2.1.2. Eclosion hormone Eclosion hormones (EH) are neuropeptides that influence several aspects of pupal–adult ecdysis (i.e., eclosion) as well as larval–larval ecdyses (Holman *et al.*, 1990; Nijhout, 1994). The release of EH from the brain is controlled by a circadian clock within the brain and declining ecdysteroid titers. The overexpression of EH by a recombinant baculovirus has been hypothesized to induce the premature onset of eclosion behavior and molting. A cDNA encoding EH of *M. sexta* has been inserted into recombinant AcMNPVs and shown to express high levels of biologically active and secreted EH (Eldridge *et al.*, 1991, 1992b). Time-mortality bioassays in fifth or sixth instar larvae of *Spodoptera frugiperda* injected with vEHEGTD (a recombinant AcMNPV carrying the EH encoding cDNA at the ecdysteroid

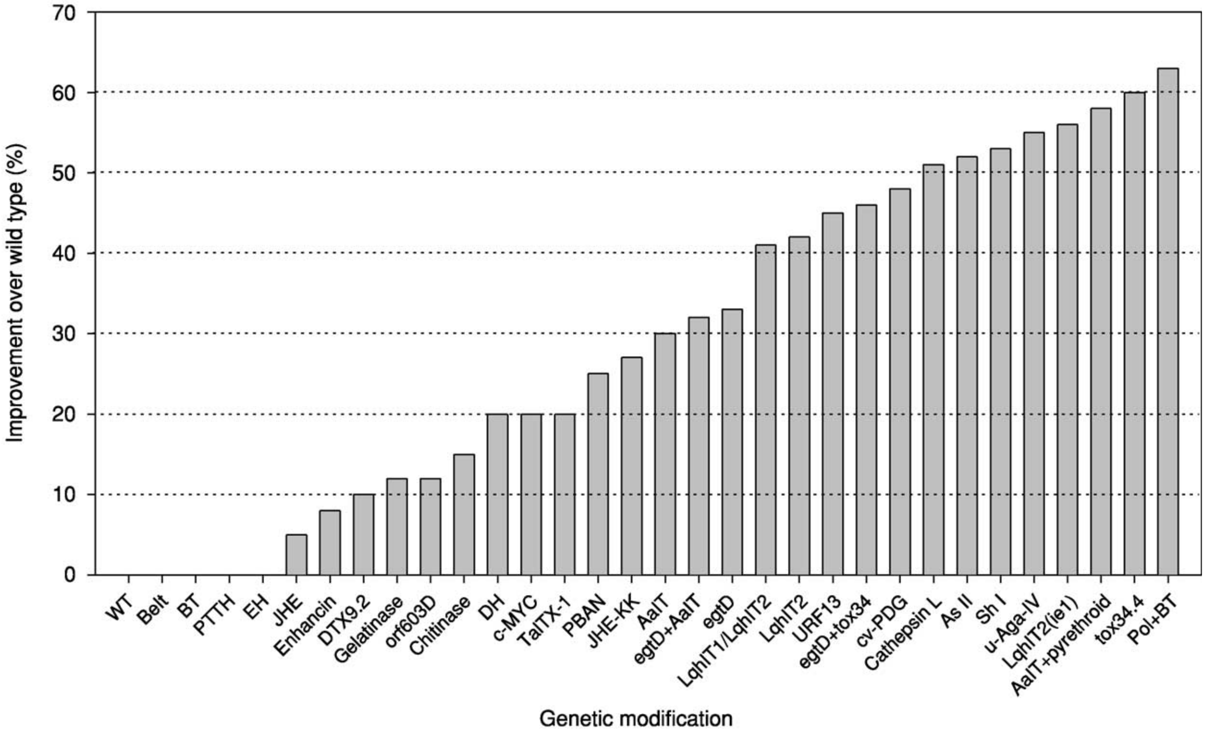

Figure 1 The speed of kill of the wild-type baculovirus can be dramatically improved by genetic modification. The genetic modification (insertion of a foreign gene or deletion of an endogenous gene) and percent improvement in speed of kill (or paralysis) relative to the wild-type virus or control virus is given. Because of differences in the parent virus, promoter, secretion signal, host strain and age, virus dose, and inoculation methods that were used, comparison between the different virus constructs is not possible. Abbreviations and reference(s): WT, wild type; Belt, insectotoxin-1 (Carbonell *et al.*, 1988); BT, *Bacillus thuringiensis* endotoxin (Merryweather *et al.*, 1990); PTTH, prothoracicotropic hormone (O'Reilly, D.R., **1995**. Baculovirus-encoded ecdysteroid UDP-glucosyltransferases. *Insect Biochem. Mol. Biol. 25*, 541–550); EH, eclosion hormone (Eldridge *et al.*, 1992b); JHE, juvenile hormone esterase (Hammock *et al.*, 1990a); enhancin, MacoNPV enhancin (Li *et al.*, 2003); DTX9.2, spider toxin (Hughes *et al.*, 1997); gelatinase, human gelatinase A (Harrison and Bonning, 2001); orf603D, deletion of AcMNPV *orf603* (Popham *et al.*, 1998a); chitinase (Gopalakrishnan *et al.*, 1995); DH, diuretic hormone (Maeda, 1989b); c-MYC, transcription factor (Lee *et al.*, 1997); TalTX-1, spider toxin (Hughes *et al.*, 1997); PBAN, pheromone biosynthesis activating neuropeptide (Ma *et al.*, 1998); JHE-KK, stabilized JHE (Bonning *et al.*, 1997b); AaIT, scorpion *Androctonus australis* insect toxin (McCutchen *et al.*, 1991; Stewart *et al.*, 1991); egtD + AaIT, insertion of *aait* at the *egt* gene locus (Chen *et al.*, 2000); egtD, deletion of ecdysteroid UDP-glucosyltransferase (*egt*) gene (O'Reilly and Miller, 1991); LqhIT1/LqhIT2, simultaneous expression of LqhIT1 and LqhIT2 (Regev *et al.*, 2003); LqhIT2, scorpion *Leiurus quinquestriatus* insect toxin 2 (Froy *et al.*, 2000); URF13, maize pore forming protein (Korth and Levings, 1993); egtD + tox34, insertion of *tox34* under the early *DA26* promoter at the *egt* gene locus (Popham *et al.*, 1997); cv-PDG, glycosylase (Petrik *et al.*, 2003); cathepsin L (Harrison and Bonning, 2001); As II, sea anemone toxin (Prikhod'ko *et al.*, 1996); Sh I, sea anemone toxin (Prikhod'ko *et al.*, 1996); μ-Aga-IV, spider toxin (Prikhod'ko *et al.*, 1996); LqhIT2(ie1), LqhIT2 under the early *ie1* promoter (Harrison and Bonning, 2000b); AaIT + pyrethroid, co-application of low doses of AcAaIT and pyrethroid (McCutchen *et al.*, 1997); tox34.4, mite toxin (Tomalski *et al.*, 1988; Burden *et al.*, 2000); Pol + BT, double expression of authentic polyhedrin and polyhedrin-BT-GFP fusion proteins (Chang *et al.*, 2003).

UDP-glucosyltransferase (*egt*) gene locus) showed that the median survival times (ST_{50}s) were reduced by approximately 29% (83 versus 117 h) and 17% (100 versus 120 h), respectively, in comparison to control larvae injected with wild-type AcMNPV. However, in comparison to control larvae injected with vEGTDEL (a control virus in which the *egt* gene was deleted), the ST_{50}s were not significantly different. Similar results were generated by time-mortality bioassays in neonate *S. frugiperda* that were orally inoculated with vEHEGTD, vEGTDEL, or AcMNPV. These findings indicated that deletion of the *egt* gene (rather than expression of EH) was responsible for the reduction in the ST_{50}. Eldridge *et al.* (1992b) thus concluded that EH expression does not provide enhanced biological control properties to AcMNPV. The role of the *egt* gene in improving speed of kill is discussed later in this chapter.

6.9.2.1.3. Prothoracicotropic hormone Prothoracicotropic hormones (PTTHs) or "brain hormones" are neurosecretory polypeptides that stimulate the

secretion of ecdysteroids from the prothoracic glands (Holman *et al*., 1990; Nijhout, 1994). The overexpression of PTTH by a recombinant baculovirus has been hypothesized to artificially elevate ecdysteroid levels resulting in the premature induction of molting, which in turn could disrupt insect feeding behavior (Menn and Borkovec, 1989; O'Reilly *et al*., 1995; Black *et al*., 1997). O'Reilly *et al.* (1995) have constructed a recombinant AcMNPV expressing the mature PTTH of *B. mori* (fused to a secretion signal sequence of sarcotoxin 1A of the flesh fly). This virus expressed PTTH in larvae of *S. frugiperda* resulting in the induction of higher than normal levels of hemolymph ecdysteroids. However, the expressed PTTH produced no observable effects on the development of *S. frugiperda* and, furthermore, inhibited the pathogenicity of the virus. In the same study, O'Reilly *et al.* (1995) expressed the mature PTTH-signal sequence construct using a mutant AcMNPV in which the AcMNPV encoded *egt* gene was knocked out. This virus apparently generated an even higher level of peak hemolymph ecdysteroid titer (1162 ± 476 versus $724 \pm 194\,\mathrm{pg}\,\mu\mathrm{l}^{-1}$) in comparison to a control virus that expressed PTTH but retained a normal *egt* gene. This higher ecdysteroid peak, however, was delayed by about 48 h (i.e., the peak occurred at 96 versus 48 h postinfection (p.i.)). These findings suggest that higher levels of hemolymph ecdysteroids are detrimental to the pathogenicity of the virus. In contrast, other studies (as will be discussed later) show that inactivation of the *egt* gene (putatively resulting in higher ecdysteroid levels) results in improved pathogenicity.

6.9.2.1.4. Pheromone biosynthesis activating neuropeptide Pheromone biosynthesis activating neuropeptide (PBAN) is a neurosecretory peptide (33–34 amino acid residues) of the brain that appears to be essential for pheromone biosynthesis and release in some lepidopterans (Holman *et al*., 1990; Nijhout, 1994). PBAN stimulates pheromone biosynthesis in conjunction with nervous stimuli during the dark phase of the photoperiod. Ma *et al.* (1998) expressed a PBAN of the corn earworm *Helicoverpa zea* (Hez-PBAN) fused to the bombyxin (an insect neurohormone) signal sequence for secretion using a recombinant AcMNPV (AcBX-PBAN). AcBX-PBAN expressed biologically active PBAN in cultured cells and larvae of *Trichoplusia ni*. In droplet feeding assays using preoccluded virus, neonate and third instar larvae of *T. ni* infected with AcBX-PBAN showed ST_{50}s that were reduced by 26% (58.3 versus 79.1 h) and 19% (70.2 versus 87.0 h), respectively, in comparison to larvae infected with a control virus. Although the mechanism for the improved speed of kill is unknown, Ma *et al.* (1998) did not observe any morphological differences between larvae that were infected with AcBX-PBAN or the control virus.

6.9.2.2. Juvenile Hormone Esterase

Wigglesworth (1935, 1936) was the first to identify a "juvenile factor" produced by the corpora allata that keeps larval insects in the juvenile state. Subsequently, Röller *et al.* (1967) and Meyer *et al.* (1970) showed the chemical structure of "juvenile hormone (JH)." Six JHs (JH-0, JH-I, JH-II, JH-III, 4-methyl JH-1, and JHB_3) have been identified to date, all of which are terpenoids derived from farnesenic acid (or its homologs) with an epoxide group at the 10, 11 position of one end and a conjugated methyl ester at the other end (Nijhout, 1994; Cusson and Palli, 2000). JH-III appears to be the most common of the JHs being found in all of the insect orders examined to date. In addition to their function as a "juvenile factor," JHs and/or their metabolites are involved in a diverse array of other functionalities including roles in development, metamorphosis, reproduction, diapause, migration, polyphenism, and metabolism (Riddiford, 1994; Gilbert *et al*., 2000; Truman and Riddiford, 2002). These diverse functionalities clearly indicate that the biosynthesis, transport, sequestration, and degradation of JH and/or its metabolites must be carefully regulated. Conversely, this careful regulation of JH titer opens a window of attack where a recombinant baculovirus expressing an appropriate protein(s) could disrupt the fine balance in JH titer and consequently the insect life cycle. Two pathways for the degradation of JH have been intensively studied in insects (Hammock, 1985; Roe and Venkatesh, 1990; de Kort and Granger, 1996). One involves a soluble esterase, JH esterase (JHE), that hydrolyzes the methyl ester moiety at one end of the JH molecule resulting in a carboxylic acid moiety (Kamita *et al*., 2003a). The other involves a microsomal epoxide hydrolase, JH epoxide hydrolase (JHEH) that hydrolyzes an epoxide moiety at the other end of the JH molecule to produce a diol.

Hammock *et al.* (1990a) first hypothesized that the natural insecticidal activity of the baculovirus AcMNPV could be improved by expression of a gene encoding JHE. The rationale behind this was that the recombinant AcMNPV would be ingested by early larval instars, and subsequently JHE would be produced at a point in development that is inappropriate for the insect. The observed result was that infected larvae reduced feeding and weight gain, and subsequently died slightly more quickly in

comparison to the wild-type AcMNPV (Hammock *et al.*, 1990a, 1990b; Eldridge *et al.*, 1992a). Two approaches to improve this technology have included: (1) improving the *in vivo* stability (i.e., reducing removal from the hemolymph and/or degradation) of the JHE enzyme by genetic modification of the JHE gene; and (2) increasing or altering the timing of gene expression by using alternative promoters to drive JHE expression. Recombinant baculoviruses expressing JHE have also been used as tools for hypothesis testing with regard to the biological activity of JHE within the insect host (van Meer *et al.*, 2000). JHE proteins from at least five different insect species including *Heliothis virescens* (Hammock *et al.*, 1990a; Bonning *et al.*, 1992), *Choristoneura fumiferana* (Feng *et al.*, 1999), *B. mori* (Hirai *et al.*, 2002), *M. sexta* (Hinton and Hammock, 2003a), and *T. molitor* (Hinton and Hammock, 2003b) have been expressed using recombinant AcMNPVs.

6.9.2.2.1. Increase in *in vivo* stability Studies have shown that recombinant JHE from *H. virescens*, when injected into larvae of *M. sexta*, is rapidly recognized and taken up into the pericardial cells from the hemolymph (Booth *et al.*, 1992; Ichinose *et al.*, 1992b, 1992a). This removal of JHE from the hemolymph occurs by a receptor mediated, endocytotic, saturable mechanism that does not involve passive filtration (Ichinose *et al.*, 1992a, 1992b; Bonning *et al.*, 1997a). The JHE is presumed to be degraded in lysosomes (Booth *et al.*, 1992). At least two putative JHE binding proteins may be involved in transport and/or degradation of JHE in the pericardial cells, including a putative heatshock cognate protein (HSP) (Bonning *et al.*, 1997a) and P29 (Shanmugavelu *et al.*, 2000, 2001). Receptor mediated endocytosis of JHE has been demonstrated in early and late larval instars of *M. sexta* (Ichinose *et al.*, 1992a). Although JHE is normally stable in hemolymph, the half-life of JHE injected into the hemolymph can be as little as 20 min under conditions where endogenous and exogenous proteins including bovine serum albumin, ovalbumin, and hemolymph JH binding protein have half-lives of days (Ichinose *et al.*, 1992a). Thus, the mechanism by which JHE is specifically recognized and removed by the pericardial cells could be a very important target for increasing the half-life of JHE in the hemolymph. There are three ways in which the uptake and degradation of JHE can be disrupted: (1) prevention of receptor mediated uptake by the pericardial cells; (2) disruption of transport to the lysosomes; and (3) prevention of lysosomal degradation.

Bonning *et al.* (1997b) identified two lysine residues that are likely to be on the surface of the JHE protein of *H. virescens* and potentially involved in uptake or degradation of JHE. These lysine residues are Lys-29 near the N-terminus, which is potentially involved in ubiquitin conjugation, and Lys-524, which is located within a putative lysosome targeting sequence. A mutated JHE protein (JHE-KK) in which both of these lysine residues were mutated to arginine residues showed decreased efficiency of lysosomal targeting (Bonning *et al.*, 1997b), and binds to the putative JHE binding protein (P29) with significantly less affinity than authentic JHE (Shanmugavelu *et al.*, 2000). However, JHE-KK as well as mutant JHEs in which only one of the lysine residues was mutated to an arginine residue showed similar catalytic activities and removal rates of JH from the hemolymph as the authentic JHE. A high-resolution crystal structure should assist with determining the basis of the interaction of JHE and the putative JHE binding protein P29 described by Shanmugavelu *et al.* (2000). These researchers hypothesize that P29 interacts with JHE of *H. virescens* and facilitates targeting of JHE to lysosomes within pericardial cells. Other putative JHE binding proteins have been identified in *M. sexta*, and their possible roles in the degradation of JHE remain to be elucidated (Shanmugavelu *et al.*, 2001). First instar larvae of *H. virescens* that were infected with a recombinant AcMNPV expressing JHE-KK (AcJHE-KK) under a very late viral promoter died approximately 22% faster (ST_{50} of 90 versus 116 h) than control larvae infected with a recombinant AcMNPV expressing the authentic JHE (AcJHE) (Bonning *et al.*, 1999). In similar experiments, first instar *T. ni* that were infected with AcJHE-KK died approximately 27% faster (ST_{50} of 83 versus 113 h) compared to control larvae infected with AcJHE. Kunimi *et al.* (1996) have analyzed the survival times of third to fifth instar *T. ni* that were infected with AcJHE-KK. In these older insects, they found that the ST_{50}s of AcJHE-KK infected third, fourth, and fifth larvae were reduced by roughly 4% (124.8 versus 130.2 h), 9% (126.6 versus 138.6 h), and 8% (135.0 versus 147.0 h), respectively, in comparison to control AcMNPV infected larvae. In similar bioassays of second to fifth instars of the soybean looper *Pseudoplusia includens*, AcJHE-KK infected larvae did not show a reduced survival time in comparison to AcMNPV infected control larvae (Kunimi *et al.*, 1997). The reasons for these differences in the survival times between species and instars are unknown, however, Bonning *et al.* (1999) speculated that host and/or age specific effects may be involved.

6.9.2.2.2. Gene silencing and RNA interference AcPR1 is a recombinant AcMNPV that produces biologically active JHE of *H. virescens* (Hanzlik *et al.*, 1989) under the very late baculoviral *p10* gene promoter (Roelvink *et al.*, 1992). AcPR2 is a recombinant AcMNPV in which the same JHE gene is placed under the *p10* promoter in the antisense direction. Transcription of this gene generates mRNAs that are antisense to the JHE mRNAs generated by AcPR1. These antisense JHE mRNAs are able to reduce the JHE activity produced by AcPR1 when AcPR1 and AcPR2 are coinfected into *Spodoptera frugiperda* (Roelvink *et al.*, 1992). By injection of AcPR2 into fifth instar *H. virescens*, Hajos *et al.* (1999) showed that AcPR2 downregulates JHE activity in more than 95% of the injected larvae. This effect was putatively due to direct RNA–RNA interaction between sense and antisense JHE RNAs. Although 95% of the infected larvae showed a reduction in JHE activity, only 25% of these larvae showed morphogenic alterations (Hajos *et al.*, 1999). These alterations were similar to those induced by the exogenous application of JH (Cymborowski and Zimowska, 1984) or JHE inhibitors (Hammock *et al.*, 1984) to the larvae. On the basis of the effectiveness of this baculovirus mediated gene silencing approach, Hajos *et al.* (1999) suggest that the identification of other host gene targets could greatly reduce lethal times or feeding damage of a GM baculovirus pesticide.

RNA interference (RNAi) is a sequence specific mechanism by which a targeted gene is silenced by the introduction of double-stranded RNA (dsRNA) that is homologous to the targeted gene (Hutvagner and Zamore, 2002; Denli and Hannon, 2003). Mechanistically, it is likely that the antisense RNA mediated gene silencing described by Hajos *et al.* (1999) involves the RNAi pathway. RNAi has been demonstrated in a diverse range of organisms including plants, fungi, arthropods, and mammals. One biological function of RNAi appears to be as a defense mechanism against RNA viruses in plants and other organisms. Recently, RNAi has been shown to be effective in lepidopteran cell lines (Means *et al.*, 2003; Valdes *et al.*, 2003) and larvae such as the giant silk moth, *H. cecropia* (Bettencourt *et al.*, 2002) and cabbage looper *T. ni* (Kramer and Bentley, 2003). Our laboratory has explored the use of RNAi to block the activity and effects of JHE in cultured *S. frugiperda* cells and larvae of *H. virescens*. In the larval experiments, a 0.5 kb dsRNA fragment that corresponds to the 5′-coding sequence of the JHE gene of *H. virescens* (Hanzlik *et al.*, 1989) was generated. Neonate *H. virescens* that ingested these dsRNAs within 6 h of hatching showed a statistically significant (two-sided Mann-Whitney test with an error type I of 99%) increase in weight (in comparison to control larvae) by the second and third days of the fifth larval instar. Additionally, injection of the same 0.5 kb dsRNAs into the larvae of *H. virescens* on the first day of the fifth instar resulted in a 16 h delay in the median time to pupation in comparison to water injected or untreated controls (**Figure 2**). Treatments were compared with Wilcoxon (Gehan) statistics on a 99% error type I. These comparisons indicated that RNAi against the JHE of *H. virescens* is effective at prolonging the juvenile state. The authors are currently in the process of constructing recombinant AcMNPVs carrying JHE gene derived sequences in a “head-to-head” manner such that the expressed RNAs will form a hairpin loop structure. Such a

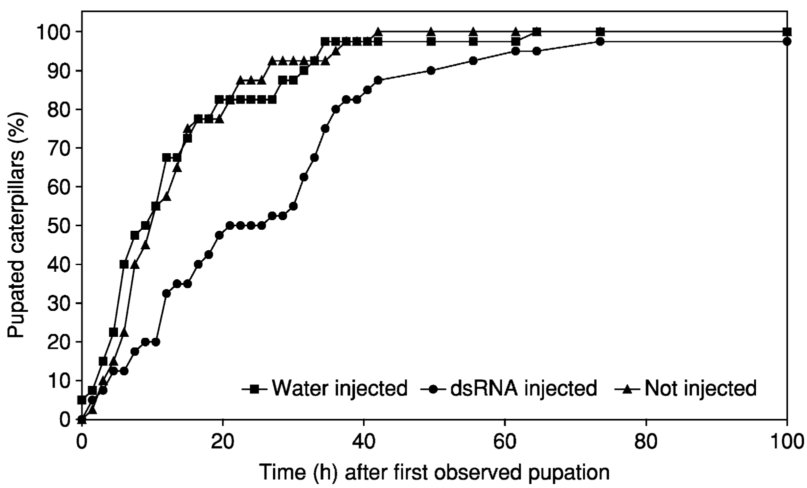

Figure 2 Percentage of larvae that pupate over time following treatment with double-stranded RNA (dsRNA), double-distilled water, or untreated. Pupation was scored on the basis of head capsule slippage at 1.5 h or longer intervals.

recombinant AcMNPV may be able to induce the RNAi response more efficiently. Of course, a recombinant virus that is effective at prolonging the juvenile state would be a disaster as a biological insecticide. However, these experiments are important in that they demonstrate the effectiveness of an RNAi approach in the regulation of insect neuroendocrinology and the results should be easily transferred to other significant physiological effectors.

The use of an authentic, insect-derived protein to combat the insect is conceptually elegant and potentially safer because one is only trying to express an endogenous protein at an inappropriate time or at higher levels in order to alter the physiology of the insect. Additionally, there is a perception that expressing the insect's own protein at an inappropriate time in development offers public relations advantages over the expression of toxins or proteases as will be discussed below. In practice, however, overexpression of an insect hormone or protein involved in hormone metabolism has not been dramatically effective. For example, the limited number of JHEs tested to date not enhance the speed of kill as well as scorpion toxins or proteases. However, with JHE there is a clear mechanism of action and an obvious path toward generating improved viruses by engineering the protein for greater stability in the insect. The recent homology model of Thomas *et al.* (1999) and crystal structure of the protein will greatly enhance these efforts.

6.9.2.3. Proteases

In order to better understand the rationale behind the use of protease encoding genes for improving speed of kill, a brief review of the midgut barriers faced by the baculovirus is given. The first barrier that the ODV encounters in the midgut is the fluid within the lumen. The high pH (8–11) and endogenous proteases found in the lumen are initially required to release ODVs from the polyhedra or granules. However, digestive enzymes or other factors within the lumen could also lead to the inactivation of the released ODV, if the ODVs do not quickly initiate infection. One such factor is a lipase, Bmlipase-1, isolated from the digestive juice of *B. mori* that shows antiviral activity against BmNPV (Ponnuvel *et al.*, 2003). The peritrophic membrane (PM; or peritrophic envelope) is the first physical barrier that the ODV faces (Richards and Richards, 1977; Brandt *et al.*, 1978; Tellam, 1996). The PM is composed of chitin fibrils in a protein–carbohydrate matrix. The specific composition and layout of the PM differs in different lepidopteran species and at different larval instars. The manner in which the ODVs pass this barrier is still not well understood. The second physical barrier that the virus faces is the midgut epithelium. The midgut epithelium is primarily composed of a single layer of columnar cells. The columnar cells show directionality (polarity) in which the luminal border is formed by microvilli (brush border membrane) and the hemocoelic border shows characteristic infolding with large numbers of mitochondria associated with the infolds. Regenerative and endocrine cells are also part of the midgut epithelium. Several pathways have been proposed for how the nucleocapsids pass through the midgut epithelium barrier following the fusion of ODVs with the microvillar membrane (Federici, 1997). One pathway involves entry of the nucleocapsid into the columnar cells, translocation through the cytoplasm, and budding through the hemocoelic border of the same cell without any viral replication. The other pathways involve the generation of progeny nucleocapsids within the columnar cells that can bud (1) through the hemocoelic border, (2) into the tracheal matrix via tracheoblasts, or (3) into regenerative cells. Once in the regenerative cells, the nucleocapsids may translocate through the cell without replication and through the hemocoelic border or virus replication may occur in these cells as well. Washburn *et al.* (2003) have proposed a "hybrid" pathway in which some nucleocapsids of MNPVs uncoat and start replication whereas others pass directly through the columnar cells. The third midgut associated barrier to systemic infection is the basement membrane (or basal lamina). The basement membrane (BM) is a fibrous matrix composed primarily of glycoproteins, type IV collagen, and laminin, which are secreted by the epithelial cells (Ryerse, 1998). The BM functions in several roles including structural support of the epithelium or surrounding tissues, filtration, and differentiation (Yurchenco and O'Rear, 1993).

6.9.2.3.1. Enhancins Enhancins are baculovirus encoded proteins that can enhance the oral infectivity of a heterologous or homologous baculovirus. Enhancin, also known as synergistic factor (SF) or virus enhancing factor (VEF), was first described by Tanada as a lipoprotein of 93–126 kDa found within the capsule of the GV of the armyworm *Pseudaletia unipuncta* (Yamamoto and Tanada, 1978a, 1978b) that enhances the infection of baculoviruses in lepidopteran larvae (Tanada, 1959). The enhancin of the GV of *T. ni* (TnGV) has been shown to possess metalloprotease activity (Lepore *et al.*, 1996; Wang and Granados, 1997). Tanada first suggested

that this factor is virus encoded (Tanada and Hukuhara, 1968) and Hashimoto *et al.* (1991) confirmed this by cloning and sequencing the *vef* gene from TnGV. Subsequently, enhancin gene homologs have been sequenced from the GVs of *H. armigera* and *P. unipuncta* (Roelvink *et al.*, 1995) and *Xestia c-nigrum* (four homologs; Hayakawa *et al.*, 1999). Enhancin gene homologs have also been identified in two NPVs, *Lymantria dispar* NPV (two homologs, E1 (Bischoff and Slavicek, 1997) and E2 (Popham *et al.*, 2001)) and *Mamestra configurata* NPV (Li *et al.*, 2003). Disruption of the E1 enhancin gene homolog of LdMNPV reduces viral potency from 1.4- to 4-fold in comparison to the wild-type LdMNPV but does not affect the killing speed of the virus (Bischoff and Slavicek, 1997). Enhancins appear to enhance virus infection by: (1) degrading high molecular weight proteins such as mucin (Wang and Granados, 1997), which are found in the PM (Derksen and Granados, 1988; Gallo *et al.*, 1991; Lepore *et al.*, 1996; Wang and Granados, 1997); and/or (2) enhancing fusion of the virus to the midgut epithelium cells (Ohba and Tanada, 1984; Kozuma and Hukuhara, 1994; Wang *et al.*, 1994).

Enhancin genes have been expressed by recombinant AcMNPVs in order to improve the ability of the virus to gain access to the midgut epithelium cells. A recombinant AcMNPV, AcMNPV-enMP2, carrying the enhancin gene of *M. configurata* NPV under its authentic promoter has been constructed (Popham *et al.*, 2001; Li *et al.*, 2003). In dose-mortality studies, AcMNPV-enMP2 shows a 4.4-fold lower median lethal dose ($LD_{50} = 2.8$ versus 12.4 polyhedra per larva) in second instar larvae of *T. ni* in comparison to the wild-type virus (Li *et al.*, 2003). In time-mortality studies, the ST_{50} of AcMNPV-enMP2 infected larvae was not significantly different from that of wild-type AcMNPV infected larvae when the larvae were inoculated at biologically equivalent doses (i.e., at an LD_{90} dose). However, when the larvae were inoculated with the same number (i.e., 32 polyhedra per larva) of AcMNPV-enMP2 or wild-type AcMNPV, the AcMNPV-enMP2 inoculated larvae showed an approximately 8% faster ST_{50} (130 versus 141 h). Li *et al.* (2003) suggest that this enhancement in speed of kill may be the result of increasing the number of initial infection foci in the host insect midgut rather than increasing the speed of the spread of the virus infection.

Hayakawa *et al.* (2000b) have generated a recombinant AcMNPV (AcEnh26) expressing the enhancin gene from *T. ni* granulovirus. In bioassays in which third instar larvae of *S. exigua* were fed a mixture of AcEnh26 infected Sf-9 cells and AcMNPV polyhedra, the LD_{50} of AcMNPV was 21-fold lower in comparison to feeding with a mixture of control virus infected Sf-9 cells and AcMNPV (2.69×10^3 versus 5.75×10^4 polyhedra per larva). In similar experiments, the LD_{50} of another baculovirus, *Spodoptera exigua* NPV (SeNPV), was ninefold lower (19.1 versus 162 polyhedra per larva) when coinfected with AcEnh26 infected Sf-9 cells. In an interesting twist to these experiments, Hayakawa *et al.* (2000b) engineered the enhancin gene from *T. ni* into tobacco plants and used a mixture of AcMNPV and lyophilized transgenic tobacco leaves for bioassay. They found a tenfold reduction in the LD_{50} of AcMNPV when the enhancin expressing tobacco was added to the bioassay. These findings suggest that expression of the enhancin gene in plants (Granados *et al.*, 2001; Cao *et al.*, 2002) or mixing enhancin expressing plant material in baculovirus pesticide formulations may be an effective method for improving the speed of kill of natural and recombinant baculoviruses.

6.9.2.3.2. Basement membrane degrading proteases As mentioned above, the basement membrane is the last midgut-associated barrier that the baculovirus virion must cross prior to the initiation of systemic infection. Harrison and Bonning (2001) have constructed recombinant AcMNPVs expressing three different proteases (rat stromelysin-1, human gelatinase A, and cathepsin L from the flesh fly *Sarcophaga peregrina*) that are known to digest BM proteins. Of these recombinant AcMNPVs, AcMLF9.ScathL expressing cathepsin L under the late baculovirus *p6.9* gene promoter generated a 51% faster speed of kill (ST_{50} of 48 versus 98 h) in comparison to wild-type AcMNPV in neonate larvae of *H. virescens*. Expression of gelatinase under the p6.9 promoter also improved speed of kill by approximately 12% (ST_{50} of 86.5 versus 98 h) in comparison to wild-type AcMNPV. On the basis of lethal concentration bioassays, there were no statistically significant differences in the virulence (i.e., LD_{50}) of these viruses in comparison to the wild-type AcMNPV. In bioassays to determine feeding damage, AcMLF9.ScathL infected larvae consumed approximately 27- and 5-fold less lettuce (29.27 and 5.21 cm^2, respectively) in comparison to mock or AcMNPV infected (1.1 cm^2) second instars of *H. virescens*, respectively. Although the mechanism of this improvement in speed of kill has yet to be determined, Harrison and Bonning (2001) speculated that digestion of BM proteins by the cathepsin L may: (1) hasten the spread of infection through the BM; (2) inappropriately

activate prophenoloxidase, a key enzyme involved in the formation of melanin during wound healing and the immune response in insects; and/or (3) cause BM damage that results in deregulation of ionic and molecular traffic between the hemocoel and the tissues. Harrison and Bonning (2001) also expressed cathepsin L under the baculovirus early *ie1* promoter using the recombinant baculovirus AcIE1TV3.ScathL. This virus, however, did not show any improvement in speed of kill. They speculated that expression under the early promoter did not produce sufficient cathepsin L to have an effect on the infected host. The effectiveness of protein expression using early, late, and/or constitutively expressed promoters will be further discussed later.

6.9.2.4. Other Enzymes and Factors

Chitin is an insoluble structural polysaccharide that is found in the exoskeleton and gut linings of insects (Cohen, 1987). Chitinases are enzymes that can degrade chitin into low molecular weight, soluble, and insoluble oligosaccharides (Kramer and Muthukrishnan, 1997). Genes encoding chitinases have been identified in several lepidopteran insects including *M. sexta* (Gopalakrishnan *et al.*, 1993), *B. mori* (Kim *et al.*, 1998; Daimon *et al.*, 2003), *Hyphantria cunea* (Kim *et al.*, 1998), *S. litura* (Shinoda *et al.*, 2001), and *C. fumiferana* (Zheng *et al.*, 2002). The genome of *B. mori* appears to encode multiple, potentially five different, chitinase genes (Daimon *et al.*, 2003). Chitinase and cysteine protease genes are also found in the genomes of NPVs and GVs (Ohkawa *et al.*, 1994; Hawtin *et al.*, 1995; Slack *et al.*, 1995; Kang *et al.*, 1998; Gong *et al.*, 2000). Baculovirus encoded chitinases and proteases (V-CATH) are thought to be involved in the degradation of the chitinous and proteinaceous components, respectively, of the host cadaver in order to induce liquefaction (O'Reilly, 1997; Hom and Volkman, 2000). Hom and Volkman (2000) have suggested another role of the baculovirus encoded chitinase, namely, proper folding of the nascent V-CATH polypeptides in the endoplasmic reticulum (ER). A recombinant AcMNPV, vAcMNPV· chi, has been generated that expresses the chitinase gene of *M. sexta* (Gopalakrishnan *et al.*, 1995). When fourth instar *S. frugiperda* were injected with vAcMNPV·chi, larval death occurred nearly 1 day earlier than those infected with the wild-type virus AcMNPV.

Carbohydrates are the major source of energy that powers insect metabolism and form the material basis of chitin in the cuticle of insects (Cohen, 1987). Thus, the availability of sugars is essential for normal growth and development. Trehalose, a disaccharide composed of two glucose molecules, is the major carbohydrate in the hemolymph of most insects (Friedman, 1978). Sato *et al.* (1997) have generated two recombinant AcMNPVs, vTREVL, and vERTVL, expressing a trehalase cDNA from the mealworm beetle *T. molitor* in the sense and antisense directions, respectively. In Sf-9 cell cultures and larvae of the cabbage armyworm *Mamestra brassicae* that were infected with vTREVL, biologically active trehalase was secreted into the supernatant and found in the hemolymph, respectively. The survival time of fifth instar larvae of *M. brassicae* that were infected with vTREVL was longer than control larvae infected with the wild-type AcMNPV. Interestingly, the vTREVL infected larvae showed considerably reduced melting in comparison to the AcMNPV infected larvae. The survival time of larvae infected with vERTVL was also slightly longer than that of control larvae infected with AcMNPV, but less than that of vTREVL.

URF13 is a mitochondrially encoded protein of maize that forms pores in the inner mitochondrial membrane (Korth *et al.*, 1991). Korth and Levings (1993) have generated recombinant, occlusion-negative AcMNPVs expressing authentic (BV13T) or mutated (BV13.3940) URF13 encoding genes under the *polh* promoter. When third to fourth instar larvae of *T. ni* were injected with BV13T or BV13.3940, 100% died by 60 h post injection. Control larvae that were injected with wild-type AcMNPV or a control β-galactosidase expressing AcMNPV lived up to 106 and 100 h p.i., respectively. The median lethal time (LT_{50}) of BV13T or BV13.3940 appeared reduced by about 45% (50 versus 94 h) in comparison to control virus infected larvae (estimate based on mortality graph). Although the mechanism of this toxicity was not determined, Korth and Levings (1993) showed that baculovirus expressed URF13 is localized in the membranes of cells of Sf-9 cultures and larvae of *T. ni*. They suggested that this membrane localization interferes with normal cellular functions. The URF13 induced cytotoxicity, however, appeared to be unrelated to pore formation, because the mutated URF13 expressed by BV13.3940 is unable to form membrane pores (Braun *et al.*, 1989), but the toxicity of BV13.3940 was the same as that of BV13T.

c-MYC is a transcription factor that is involved in various physiological processes including cell growth, proliferation, loss of differentiation, and

apoptosis in a variety of organisms (Pelengaris and Khan, 2003). Lee *et al.* (1997) have generated a recombinant AcMNPV carrying a 754 bp-long fragment of human *c-myc* exon II in the antisense direction under the *polh* promoter. When third or fourth instar *S. frugiperda* are injected with this virus at an average dose of 3500 plaque forming units (pfu) per mg of body weight, 75% of the larvae stop feeding by 3 days postinfection. This is roughly a twofold reduction in feeding in comparison to wild-type AcMNPV injected larvae, in which about 35% of the larvae stop feeding. This feeding cessation occurs roughly 2 days before death of the larva. Furthermore, the average survival time of the larvae is reduced by approximately 1 day. Lee *et al.* (1997) indicate two important advantages to this antisense strategy. First, this strategy does not require protein synthesis and also avoids any potential problems associated with posttranslational modifications or secretion. Second, since no foreign protein is produced the likelihood of insect resistance will be reduced.

Sunlight (i.e., UV radiation) is a major factor in the inactivation of baculoviruses in the field (Ignoffo and Garcia, 1992; Dougherty *et al.*, 1996; Black *et al.*, 1997; Ignoffo *et al.*, 1997). In an attempt to reduce UV inactivation, Petrik *et al.* (2003) have generated a recombinant AcMNPV that expresses an algal virus pyrimidine dimer specific glycosylase, cv-PDG (Furuta *et al.*, 1997), which is involved in the first steps of the repair of UV damaged DNA. The recombinant AcMNPV (vHSA50L) expresses the cv-PDG encoding the *A50L* gene under the *hsp70* promoter of *D. melanogaster*. Polyhedra of vHSA50L were not more resistant to UV inactivation than the wild-type AcMNPV, however, BV of vHSA50L were threefold more resistant to UV inactivation. In dose-mortality bioassays in neonate *T. ni*, the median lethal concentrations (LC_{50}s) of vHSA50L and AcMNPV were not significantly different. In neonates of *S. frugiperda*, however, the LC_{50} of vHSA50L was reduced by approximately 16-fold (7.1×10^5 versus 1.15×10^7 polyhedra per ml). Surprisingly, time-mortality bioassays (at an LC_{90} dose) in vHSA50L infected neonates of *S. frugiperda* indicated that the LT_{50} of vHSA50L was reduced by approximately 41% (73.6 versus 124.4 h). This reduction in LT_{50} was even greater (48%, 65.0 versus 124.4 h) for a construct (vHSA50-LORF) that carried *A50L* excluding the 5′-untrans--untranslated region under the *hsp70* promoter. In contrast to the neonate *S. frugiperda*, significant differences were not found in the LT_{50}s of neonate *T. ni* that were infected with vHSA50L or vHSA50LORF.

6.9.3. Insertion of Insect Selective Toxin Genes

Arthropods that feed on or parasitize other arthropods possess potent venoms that rapidly immobilize their prey. The venoms of arthropods such as scorpions, spiders, and parasitic wasps are composed of a mixture of salts, small molecules, proteins, and peptides (Zlotkin *et al.*, 1978, 1985; Zlotkin, 1991; Loret and Hammock, 1993; Gordon *et al.*, 1998; Possani *et al.*, 1999). Peptide toxins that are specifically active against invertebrates, vertebrates, or both invertebrates and vertebrates have been identified in these venoms. These peptide toxins generally target major ion channels such as the Na^+, K^+, Ca^{2+}, and Cl^- channels although there are several examples of peptides with unusual targets such as the intracellular calcium activated ryanodine channel (Fajloun *et al.*, 2000). Kinin-like peptides that interfere with physiological events have also been identified in venom (Inceoglu and Hammock, unpublished data). Arthropod venoms have been utilized as highly useful sources for the mining of highly potent and selective peptide toxins that selectively paralyze insects. Several of these peptides have been expressed by recombinant baculoviruses for the purpose of improving their speed of kill and insecticidal activity.

6.9.3.1. Scorpion Toxins

On average scorpion venom contains from 200 to 500 different peptides. It is conservatively assumed that about 10% of these peptides are insect selective toxins. Considering that there are roughly 1250 identified species of scorpion, this represents an enormous diversity (25 000 to 62 500) of potent and selective insecticidal peptides for pest control using baculovirus expression. Scorpion toxins are classified on the basis of size and pharmacological target site into two main groups: long and short chain neurotoxins (Zlotkin *et al.*, 1978; Loret and Hammock, 1993; see **Chapter 5.6**). Toxins with selective activity against insects are found in both the long and short chain groups. Long chain neurotoxins are polypeptides of 58–70 amino acid residues, cross-linked by four disulfide bonds, which mainly target voltage gated sodium channels and to some degree calcium channels (Zlotkin, 1991; Loret and Hammock, 1993; Gordon *et al.*, 1998). Short chain neurotoxins are peptides of 31–37 amino acid residues, cross-linked by three or four disulfide bonds, which mainly target potassium and chloride channels (Loret and Hammock, 1993). The long chain neurotoxins, the better studied of the two

main groups, are further classified into mammal or insect selective toxins, with the insect selective toxins being further classified on the basis of their mode of action into three subgroups: alpha insect toxins, excitatory toxins, and depressant toxins (Zlotkin *et al.*, 1995; Gordon *et al.*, 1998; Inceoglu *et al.*, 2001b). Each of these subgroups target different molecular sites and produce distinct effects upon the voltage gated sodium channel of the insect (Cestele and Catterall, 2000). In addition, when injected into larvae of the blowfly *S. falculata*, toxins in each of these subgroups display unique symptoms. Alpha insect toxins cause contractive paralysis that is delayed and sustained (Eitan *et al.*, 1990). Excitatory toxins, such as AaIT from the North African scorpion *Androctonus australis*, cause paralysis that is immediate and contractive (Zlotkin *et al.*, 1971, 1985; Zlotkin, 1991). In contrast, depressant toxins, such as LqhIT2 from the yellow Israeli scorpion *Leiurus quinquestriatus hebraeus*, cause transient (until 5 min post injection) contractive paralysis, followed by sustained, flaccid paralysis (Zlotkin *et al.*, 1985; Zlotkin, 1991).

Carbonell *et al.* (1988) were the first to attempt to express biologically active scorpion toxin, insectotoxin-1 of *Buthus eupeus* (*BeIt*), under control of the very late polyhedrin promoter using recombinant AcMNPV constructs (vBeIt-1, vBeIt-2, and vBeIt-3). The vBeIt-1 construct carried the 112 nucleotide-long *BeIt* gene 6 nucleotides downstream of the last nucleotide of the polyhedrin leader. The vBeIt-2 construct carried the *BeIt* gene fused to a 21 amino acid-long signal sequence for secretion of human β-interferon (Ohno and Taniguchi, 1981) 18 nucleotides downstream of the polyhedrin leader. The vBeIt-3 construct expressed *BeIt* as a fusion with the N-terminal 58 codons of the polyhedrin gene. All three constructs produced similar, high levels of *BeIt* specific transcripts from the polyhedrin promoter. The vBeIt-1 and vBeIt-2 constructs produced exceptionally low levels of the 4 kDa BeIt peptide, whereas the vBeIt-3 construct produced significant amounts of a 13–14 kDa polyhedrin-BeIt fusion peptide. Toxin specific biological activity, however, was not observed by bioassay in larvae of *T. ni*, *Galleria mellonella*, and *Sarcophaga*. Carbonell *et al.* (1988) speculated that this was the result of: (1) toxin instability; (2) a low sensitivity threshold of the toxin bioassay; and/or (3) inability of the polyhedrin-BeIt fusion to properly fold.

6.9.3.1.1. AaIT The insect-selective neurotoxin AaIT (*Androctonus australis* insect toxin 1), found in the venom of the scorpion *A. australis*, was the first scorpion toxin to be expressed by recombinant baculoviruses that showed biological activity (Maeda *et al.*, 1991; McCutchen *et al.*, 1991; Stewart *et al.*, 1991). AaIT is composed of a single polypeptide chain of 70 amino acid residues cross-linked by four disulfide bonds and is highly specific for the voltage gated sodium channel of insects (Zlotkin *et al.*, 2000; see **Chapter 5.6**). The toxin induces a neurological response similar to that evoked by the pyrethroid insecticides, but apparently acts at a different site within the sodium channel (see discussion below regarding toxin interactions with chemical pesticides). Maeda *et al.* (1991) constructed a recombinant BmNPV carrying a synthetic AaIT gene (Darbon *et al.*, 1982) that was linked to a signal sequence for secretion of bombyxin and driven by the very late polyhedrin (*polh*) gene promoter. The recombinant virus, BmAaIT, expressed biologically active AaIT that was secreted into the hemolymph of BmAaIT infected silkworm larvae. The BmAaIT infected larvae (second to fifth instar *B. mori*) displayed symptoms that were consistent with sodium channel binding by AaIT including body tremors, dorsal arching, feeding cessation, and paralysis beginning at 40 h p.i. Death occurred by 60 h p.i. This corresponded to an improvement in speed of kill of approximately 40% in comparison to control larvae infected with the wild-type BmNPV.

In related experiments, McCutchen *et al.* (1991) and Stewart *et al.* (1991) independently generated recombinant AcMNPVs expressing AaIT under the very late baculoviral *p10* promoter. The Stewart *et al.* construct, AcST-3, expressed AaIT as a fusion protein with the signal sequence of the baculoviral GP67 protein. The McCutchen *et al.* construct, AcAaIT, expressed AaIT as a fusion protein with the bombyxin signal sequence. Bioassays using orally inoculated, second instar larvae of *T. ni* indicated that the median lethal dose (LD_{50}) of AcST-3 was reduced by about 30% (44 versus 31 polyhedra per larva) in comparison to the wild-type AcMNPV. The median survival time (ST_{50}) of AcST-3 infected larvae (infected with approximately 17.4 polyhedra per larva) was reduced by about 25% (85.8 versus 113.1 h) in comparison to control larvae infected with AcMNPV. Third instar *T. ni* that are infected with a dose of AcST-3 that resulted in 100% mortality showed a 50% reduction in feeding damage in comparison to AcMNPV infected control larvae. The McCutchen *et al.* construct, AcAaIT, showed similar results by bioassay using second instar larvae of *H. virescens*. The LD_{50} of AcAaIT was reduced by about 39% (13.3 versus 21.9 polyhedra per larva) in comparison to AcMNPV. The ST_{50} of AcAaIT infected larvae (infected with 250 polyhedra per larva) was reduced by about 30% (88.0 versus

125 h) in comparison to control larvae infected with AcMNPV. By droplet feeding assays of neonate *H. virescens*, the ST_{50} of AcAaIT infected larvae was reduced by up to 46% (Inceoglu and Hammock, unpublished data). McCutchen *et al.* conducted additional experiments in which third instar larvae of *M. sexta* (an unnatural host of AcMNPV) were injected with AcAaIT (5 μl containing 1×10^6 pfu). They detected AaIT specific symptoms as early as 72 h post injection and found a 29% decrease (120 versus 168 h) in the speed of kill. Additional observations made during this study showed that larvae infected with AcAaIT typically were paralyzed and stopped feeding several hours prior to death. Furthermore, the yields of progeny viruses (polyhedra per cadaver) in AcAaIT infected larvae (third, fourth, or fifth instar *T. ni*) were only 20–32% of those of control larvae infected with AcMNPV (Kunimi *et al.*, 1996; Fuxa *et al.*, 1998). This suggested that the recombinant virus will be quickly outcompeted in the field by the wild-type virus (see below).

Hoover *et al.* (1995) have further characterized the paralytic effect of AaIT by bioassay using third instar *H. virescens* that were inoculated with either AcAaIT or AcMNPV. When the AcAaIT or AcMNPV infected larvae were placed on greenhouse cultivated cotton plants, it was found that the AcAaIT infected larvae fell off the plants approximately 5–11 h before death. This "knock-off" effect occurred before the induction of feeding cessation. As a consequence, the amount of leaf area consumed by the AcAaIT infected larvae was up to 62% and 72% less than that consumed by the AcMNPV and mock infected larvae, respectively (**Figure 3**). Knock-off effects have also been observed in field trials (on cotton) to assess the efficacy of recombinant AcMNPV (Cory *et al.*, 1994) or HaSNPV (Sun *et al.*, 2004) expressing AaIT. On the basis of this knock-off effect, Hoover *et al.* (1995) suggested that median survival time is not necessarily predictive of the reduction in the amount of feeding damage that results from the application of a recombinant baculovirus. Cory *et al.* (1994) and Hoover *et al.* (1995) also emphasized that the knock-off effect should reduce foliage contamination because unlike AcAaIT infected larvae that fall off the plant, wild-type virus infected larvae tend to die on the plant. Consequently, they suggested that the reduction in virus inoculum on the foliage should decrease the spread and recycling of the recombinant virus in comparison to the wild-type virus. A discussion of the fitness of a recombinant virus in comparison to the wild-type parent is given later in this chapter.

The AaIT gene has been expressed using other baculovirus vectors, for example, the NPVs of the mint looper *Rachiplusia ou* (RoMNPV; Harrison and Bonning, 2000b) and cotton bollworms *Helicoverpa zea* (HzNPV; Treacy *et al.*, 2000) and *H. armigera* (HaSNPV; Chen *et al.*, 2000; Sun

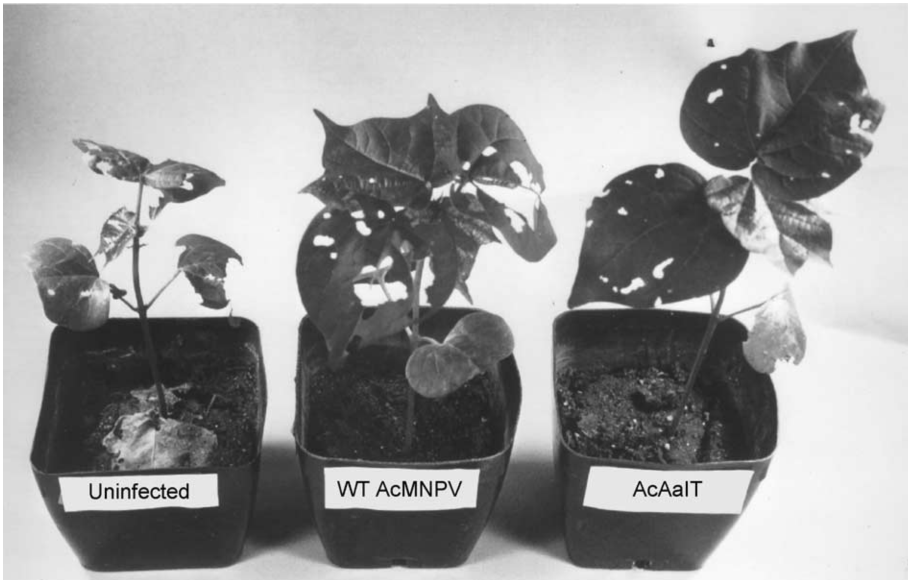

Figure 3 Damage to cotton plants by third instar larvae of *Heliothis virescens* that were inoculated with an LD_{99} dose of AcMNPV or AcAaIT or mock infected. On average, the leaf damage caused by AcAaIT infected larvae was reduced by 62% in comparison to AcMNPV infected larvae and 71.7% in comparison to mock infected larvae (Hoover *et al.*, 1995). (Reprinted with permission from Hoover, K., Schultz, C.M., Lane, S.S., Bonning, B.C., Duffey, S.S., *et al.*, **1995**. Reduction in damage to cotton plants by a recombinant baculovirus that knocks moribund larvae of *Heliothis virescens* off the plant. *Biol. Control* 5, 419–426; © Elsevier.)

et al., 2002, 2004). RoMNPV is also known as *Anagrapha falcifera* Kirby MNPV (Harrison and Bonning, 1999). Harrison and Bonning (2000b) have generated recombinant RoMNPVs (Ro6.9AaIT) expressing AaIT fused to the bombyxin signal sequence under the late *p6.9* promoter of AcMNPV. The *p6.9* promoter, like the very late promoters, requires the products of viral early genes and the initiation of viral DNA replication for its activation (Lu and Miller, 1997). However, it is activated earlier and drives higher levels of expression than the *p10* or *polh* promoters in tissue culture (Hill-Perkins and Possee, 1990; Bonning *et al.*, 1994). In dose-mortality bioassays (droplet feeding), there were no significant differences between the LC_{50}s of Ro6.9AaIT and the wild-type RoMNPV in neonate European corn borer *Ostrinia nubilalis* (8.1×10^6 and 1.0×10^7 polyhedra per ml, respectively) or *H. zea* (9.5×10^4 and 5.4×10^4 polyhedra per ml, respectively). The LC_{50}s, however, were significantly different in neonate *H. virescens* (1.67×10^5 and 8.4×10^4 polyhedra per ml, respectively). Survival-time bioassays (at an LC_{99} dose) of neonates of *O. nubilalis*, *H. zea*, and *H. virescens* infected with Ro6.9AaIT generated ST_{50}s that were reduced by approximately 34% (120 versus 181 h), 37% (81 versus 128 h), and 19% (72.5 versus 89.5 h), respectively, in comparison to control larvae infected with RoMNPV. Later in this chapter, recombinant HzNPV and HaSNPV constructs in which the AaIT gene was placed under a very late promoter or other alternative promoter (e.g., early, chimeric, or constitutive) and inserted at the *egt* gene locus of the virus are discussed.

6.9.3.1.2. Lqh and Lqq A series of highly potent insecticidal toxins have been identified and characterized from the venom of yellow Israeli scorpions, *L. quinquestriatus hebraeus* and *L. quinquestriatus quinquestriatus*. Both excitatory (e.g., LqqIT1, LqhIT1, and LqhIT5) and depressant (e.g., LqhIT2 and LqqIT2) insect selective toxins have been isolated from these scorpions (Zlotkin *et al.*, 1985, 1993; Kopeyan *et al.*, 1990; Zlotkin, 1991; Moskowitz *et al.*, 1998; see **Chapter 5.6**). Gershburg *et al.* (1998) have generated recombinant AcMNPVs expressing the excitatory LqhIT1 toxin under the very late *p10* (AcLIT1.p10) and early *p35* (AcLIT1.p35) gene promoters, and the depressant LqhIT2 toxin under the very late *polh* gene promoter (AcLIT2.pol). These constructs expressed LqhIT1 and LqhIT2 that were secreted to the outside of the cell under endogenous secretion signals. On the basis of time-mortality bioassays using neonate *H. armigera*, they found that the median effective times (ET_{50}s) for paralysis and/or death of AcLIT1.p10 and AcLIT2.pol were 66 and 59 h. This was an improvement of roughly 24% and 32%, respectively, in comparison to the wild-type AcMNPV (ET_{50} of 87 h). The ET_{50} was also reduced by about 16% (to 73 h) when LqhIT1 was expressed under the early promoter by AcLIT1.p35, although not as dramatically in comparison to AcLIT1.p10. Imai *et al.* (2000) have generated a recombinant BmNPV (BmLqhIT2) expressing LqhIT2 fused to a bombyxin signal sequence under the *polh* gene promoter. Fourth instar larvae of *B. mori* that were injected with BmLqhIT2 (2×10^5 pfu per larva) initially showed LqhIT2 specific symptoms at 48 h post injection and stopped feeding at roughly 82 h post injection. This was an improvement of roughly 35% in the ET_{50} in comparison to the wild-type BmNPV.

Harrison and Bonning (2000b) have generated recombinant AcMNPVs expressing LqhIT2 fused to a bombyxin signal sequence under the late *p6.9* (AcMLF9.LqhIT2) or very late *p10* (AcUW21.LqhIT2) gene promoters. Survival-time bioassays (at an LC_{99} dose) of neonate *H. virescens* infected with AcMLF9.LqhIT2 or AcUW21.LqhIT2 showed that the ST_{50}s (63.5 h) of larvae infected with these viruses were the same (Harrison and Bonning, 2000b). However, log-rank tests of the Kaplan-Meier survival curves of larvae infected by these viruses were significantly different ($P < 0.05$). In comparison to AcUW21.LqhIT2 infected neonate *H. virescens*, more of the AcMLF9.LqhIT2 infected neonates died at earlier times postinfection (Harrison and Bonning, personal communication). In comparison to control larvae infected with wild-type AcMNPV, AcMLF9.AaIT (recombinant AcMNPV expressing AaIT under the *p6.9* gene promoter), or AcAaIT, neonate *H. virescens* infected with AcMLF9.LqhIT2 or AcUW21.LqhIT2 showed reductions in median survival times of approximately 34% (63.5 versus 96.0 h), 10% (63.5 versus 71.0 h), and 10% (63.5 versus 70.5 h), respectively. Harrison and Bonning (2000b) have also generated recombinant RoMNPVs expressing LqhIT2 under the *p6.9* (Ro6.9LqhIT2) and *p10* (Ro10LqhIT2) promoters of AcMNPV. Ro10LqhIT2 produced visibly fewer polyhedra that potentially occluded fewer virions in Sf-9 cell cultures and thus were not used in bioassays. Survival-time bioassays (at an LC_{99} dose) in neonate larvae of the European corn borer *O. nubilalis* Hübner, *H. zea*, and *H. virescens* infected with Ro6.9LqhIT2 generated ST_{50}s that were approximately 41% (107 versus 181 h), 42% (74.5 versus 128 h), and 27% (65.5 versus 89.5 h) faster, respectively, than those generated in control neo-

nates infected with wild-type RoMNPV. The ST_{50}s of Ro6.9LqhIT2 infected neonate *H. zea* and *H. virescens* were also significantly lower than control neonates infected with a recombinant RoMNPV expressing AaIT under the *p6.9* promoter.

Chejanovsky *et al.* (1995) have generated a recombinant AcMNPV (AcLα22) that expresses the *L. quinquestriatus hebraeus* derived alpha toxin, LqhαIT (Eitan *et al.*, 1990). The LT_{50} of AcLα22 was roughly 35% faster (78 versus 120 h) than that of the wild-type AcMNPV in larvae of *H. armigera*. Since the LqhαIT toxin binds at a different site on the insect sodium channel from that of the excitatory toxins (Zlotkin *et al.*, 1978; Cestele and Catterall, 2000), Chejanovsky *et al.* (1995) suggested that a baculovirus expressing both alpha and excitatory toxins may yield a synergistic interaction between the toxins. However, they cautioned that LqhαIT toxin lacks absolute selectivity for insects (Eitan *et al.*, 1990); thus, a recombinant baculovirus expressing LqhαIT is not appropriate as a biological pesticide. The LqhαIT toxin, however, should be an effective tool to study the targeting of different types of toxins on the voltage gated sodium channel. The effectiveness of the use of multiple synergistic toxins is discussed below. Other examples of the expression of insect selective toxins from *L. quinquestriatus hebraeus* using alternative promoters, signal sequences for secretion, viral vectors, and/or insertion of the toxin gene at the *egt* gene locus are given later in this chapter.

6.9.3.2. Mite Toxins

The insect-predatory straw itch mite *Pyemotes tritici* encodes an insect paralytic neurotoxin TxP-I that induces rapid, muscle contracting paralysis in larvae of the greater wax moth *G. mellonella* (Tomalski *et al.*, 1988, 1989). TxP-I is encoded by the *tox34* gene as a precursor protein of 291 amino acid residues. The mature protein is secreted from the insect cell following cleavage of a 39 amino acid long signal sequence for secretion (Tomalski and Miller, 1991). The mode of action of TxP-I is unknown, however, it is highly toxic (even at a dose of $500\,\mu g\,kg^{-1}$) to lepidopteran larvae but not toxic to mice at a dose of $50\,mg\,kg^{-1}$. A recombinant, occlusion-negative AcMNPV (vEV-Tox34) expressing the *tox34* gene under a modified polyhedrin promoter (P_{LSXIV}; Ooi *et al.*, 1989) was shown to paralyze or kill fifth instar larvae of *T. ni* by 2 days post injection with 400 000 pfu of BV. In contrast, control larvae injected with BV of wild-type AcMNPV never showed symptoms of paralysis (Tomalski and Miller, 1991). Tomalski and Miller (1991, 1992) have constructed two other occlusion-negative AcMNPVs that express the *tox34* gene under early (vETL-Tox34) or hybrid late/very late (vCappolh-Tox34) gene promoters as well as an occlusion-positive AcMNPV (vSp-Tox34) expressing *tox34* under a different hybrid late/very late promoter. The activities of these constructs will be discussed later in this chapter. Lu *et al.* (1996) have constructed an occlusion-positive AcMNPV (vp6.9tox34) that utilizes the late *p6.9* promoter to drive expression of *tox34*. Use of this late promoter resulted in earlier, by at least 24 h, and higher level of TxP-I expression in comparison to TxP-I expression under a very late promoter. As discussed above, the *p6.9* gene promoter is not an early promoter, but is activated earlier and can drive higher levels of expression than very late promoters in tissue culture (Hill-Perkins and Possee, 1990; Bonning *et al.*, 1994). In time-mortality bioassays (at an LC_{95} dose), the median time to effect (ET_{50}) of vp6.9tox34 in neonate larvae of *S. frugiperda* and *T. ni* was reduced by approximately 56% (44.7 versus 101.3 h) and 58% (41.7 versus 99.0 h), respectively, in comparison to wild-type AcMNPV. In neonate *S. frugiperda* and *T. ni*, the earlier and higher level of TxP-I expression under the late promoter resulted in a 20–30% faster induction of effective paralysis or death in comparison to TxP-I expression under the very late gene promoter.

Burden *et al.* (2000) have constructed a slightly different TxP-I encoding gene (*tox34.4*) by RT-PCR of mRNAs purified from total RNA extracted from *P. tritici* using primers designed to amplify the *tox34* open reading of Tomalski and Miller (1991). A recombinant AcMNPV (AcTOX34.4) expressing TxP-I under the *p10* promoter has been generated. The LD_{50}s of AcTOX34.4 were not significantly different than those of the wild-type AcMNPV in dose-mortality bioassays of second (9.3 polyhedra per larva) and fourth (13.1 polyhedra per larva) instar larvae of *T. ni*. In time-mortality bioassays, second and fourth instar larvae of *T. ni* infected with AcTOX34.4 showed a 50–60% reduction (depending on virus dose and instar) in the mean time to death in comparison to control larvae infected with wild-type AcMNPV. There was also a dramatic reduction in the yield of progeny virus (number of polyhedra per μg of cadaver) at the time of death. Second and fourth instar larvae of *T. ni* that were infected with AcTOX34.4 produced roughly 85% and 95% lower yields of polyhedra per unit weight, respectively, in comparison to control larvae infected with AcMNPV. On the basis of pathogen–host model systems that describe how insect viruses may regulate host population density (as will be

discussed later in this chapter), Burden *et al.* (2000) suggested that the dramatic reduction in yield of AcTOX34.4 will cause it to be outcompeted by the wild-type AcMNPV.

6.9.3.3. Other Toxins

In addition to peptide toxins of scorpion and mite origin, insect-selective and highly potent toxins have been identified from other organisms including spiders, anemones, and bacteria. The spider *Agelenopsis aperta* and sea anemones *Anemonia sulcata* and *Stichadactyla helianthus* possess the insect selective toxins μ-Aga-IV, As II, and Sh I, respectively (Prikhod'ko *et al.*, 1996). Recombinant AcMNPVs carrying synthetic genes that express μ-Aga-IV (vMAg4p+), As II (vSAt2p+), or Sh I (vSSh1p+) under the very late P_{SynXIV} promoter have been constructed (Prikhod'ko *et al.*, 1996). The As II and Sh I toxins were each expressed as fusion peptides with a signal sequence derived from the flesh fly sarcotoxin IA, whereas μ-Aga-IV was expressed as a fusion peptide with the mellitin signal sequence of the honeybee, *Apis mellifera*. In neonate larvae of *T. ni*, the LC_{50} of vSSh1p+ was slightly lower than that of AcMNPV, but those of vMAg4p+ and vSAt2p+ were essentially identical. In contrast, in neonate larvae of *S. frugiperda* the LC_{50}s of all three viruses were increased by 3.75- to 5.25-fold in comparison to AcMNPV. In time-mortality bioassays, neonate larvae of *T. ni* and *S. frugiperda* infected (at an LC_{95} dose) with any of the recombinant viruses died more quickly than control larvae infected with AcMNPV. In neonate *T. ni* infected with vMAg4p+, vSAt2p+, and vSSh1p+, the ET_{50}s (median times to effectively paralyze or kill) were reduced by 17% (84.5 versus 102.0 h), 38% (62.8 versus 102.0 h), and 36% (65.3 versus 102.0 h), respectively. In neonate *S. frugiperda*, the ET_{50}s were reduced by 37% (65.7 versus 104.3 h), 31% (71.8 versus 104.3 h), and 35% (67.5 versus 104.3 h), respectively. Related constructs in which these toxins were expressed under a constitutive promoter or in tandem will be discussed below.

Hughes *et al.* (1997) have generated recombinant AcMNPVs expressing insect specific toxins DTX9.2 and TalTX-1 from the spiders *Diguetia canities* and *Tegenaria agrestis*, respectively. DTX9.2 was expressed by vAcDTX9.2 as a fusion protein with a signal sequence from the AJSP-1 gene of *T. ni* under the *polh* promoter. TalTX-1 (authentic signal sequence and mature protein) was expressed by vAcTalTX-1 under the *polh* promoter. In time-mortality bioassays, neonate larvae of *T. ni, S. exigua*, and *H. virescens* infected (at a less than LC_{50} dose) with vAcDTX9.2 generated ST_{50}s that were reduced by approximately 9% (62.6 versus 68.8 h), 9% (71.3 versus 78.5 h), and 10% (74.1 versus 81.9 h), respectively, in comparison to control larvae infected with a control virus (Ac-Bb1). Neonate *T. ni, S. exigua*, and *H. virescens* infected (at a less than LC_{50} dose) with vAcTalTX-1 generated ST_{50}s that were reduced by approximately 20% (55.5 versus 68.8 h), 18% (64.4 versus 78.5 h), and 19% (66.1 versus 81.9 h), respectively, in comparison to control larvae infected with Ac-Bb1. In all cases, larvae infected with the toxin expressing viruses stopped feeding prior to larvae infected with Ac-Bb1 or wild-type AcMNPV. Neonate *T. ni, S. exigua*, and *H. virescens* infected with vAcDTX9.2 showed FT_{50}s (median times to cessation of feeding) that were approximately 33, 28, and 42%, respectively, faster than control larvae infected with Ac-Bb1. Similarly, neonate *T. ni, S. exigua*, and *H. virescens* infected with vAcTalTX-1 showed FT_{50}s that were approximately 26, 17, and 37%, respectively, faster than control larvae. Interestingly, although the speed of kill of vAcTalTx-1 was faster, vAcDTX9.2 was able to stop feeding more quickly. Thus, Hughes *et al.* (1997) emphasized that enhanced speed of kill is not necessarily a reliable indicator of the enhanced speed with which feeding is stopped.

The genus *Bacillus* is composed of Gram-positive, endospore forming bacteria. During endospore formation, *Bacillus thuringiensis* (*Bt*) produces parasporal, proteinaceous, crystalline inclusion bodies that possess insecticidal properties. The biology and genetics of *Bt* and *Bt* toxins have been previously reviewed (Gill *et al.*, 1992; Schnepf *et al.*, 1998; Aronson and Shai, 2001). *Bt* encodes two major classes of lepidopteran-active toxins, cytolytic toxins and δ-endotoxins that are encoded by the *cyt* and *cry* genes, respectively. The δ-endotoxins of *Bt* are composed of large (>120 kDa) protoxin proteins that are solubilized in the alkaline conditions of the insect midgut and processed into the active toxin or toxins by proteases. The active toxins bind to specific receptors found on the insect's midgut epithelial cells and aggregate to form ion channels. Channel formation leads to disruption of the cell's transmembrane potential, which leads to osmotic cell lysis. Lethality is believed to be caused by (1) disruption of normal midgut function, which results in feeding cessation and starvation of young larvae, or (2) *Bt* septicemia.

Several studies have looked at the effectiveness of the expression of *Bt* toxin in terms of improving the insecticidal activity of the baculovirus. These studies have investigated the expression of full-length or truncated forms of *Bt* toxin genes

(e.g., *cryIAb*, *cryIAc*, etc.) that are placed under a very late promoter and expressed in AcMNPV (Martens *et al.*, 1990, 1995; Merryweather *et al.*, 1990; Ribeiro and Crook, 1993, 1998) or *Hyphantria cunea* NPV (Woo *et al.*, 1998). These studies showed that the *Bt* toxin is highly expressed by the baculovirus and subsequently processed into the biologically active form. However, *Bt* toxin expression did not improve the virulence of the virus (i.e., the LD_{50} of the recombinant virus is similar to or higher than the LD_{50} of the wild-type virus) or decrease the ST_{50} of larvae infected with the recombinant virus. These findings are not completely unexpected considering that the site of action of *Bt* toxins is the midgut epithelial cell, whereas the baculovirus expressed *Bt* protoxin is produced within the cytoplasm of cells within the insect body. Furthermore, the expressed protoxin (1) may not be digested to the active form because of the lack of appropriate proteases within the cytoplasm, (2) may be poorly secreted, or (3) the mature toxin may be cytotoxic to the cell (Martens *et al.*, 1995). In order to improve toxin secretion, several *Bt* toxin gene constructs have been generated in which a signal sequence of JHE of *H. virescens* was fused to the N-terminus of the toxin (Martens *et al.*, 1995). These toxins were translocated across the ER membrane, but they appeared to be retained within one of the ER or Golgi compartments. These findings suggest that the expression of the *Bt* toxin gene will have little or no effect in improving insecticidal activity once the virus crosses the midgut.

Chang *et al.* (2003) have taken a novel and apparently highly successful approach for the delivery of *Bt* toxin directly to the insect midgut epithelial cells using a recombinant baculovirus that occludes the toxin within its polyhedra. Their strategy was based upon the coexpression of (1) native polyhedrin and (2) a polyhedrin-foreign protein fusion from the same baculovirus (Je *et al.*, 2003). Chang *et al.* (2003) used this system to coexpress native polyhedrin and a polyhedrin-Cry1Ac-green fluorescent protein (GFP) fusion from the recombinant baculovirus ColorBtrus. ColorBtrus is a recombinant AcMNPV that produces apparently normal polyhedra that occlude *Bt* toxin and GFP. Although the Cry1Ac toxin was fused at both the N- and C-termini, this fusion protein could be digested by trypsin resulting in an immunoreactive protein that behaved identically to authentic Cry1Ac toxin. Chang *et al*. estimated that approximately 10 ng of Cry1Ac was contained in 1.5×10^6 ColorBtrus polyhedra. Furthermore, because of GFP incorporation, the ColorBtrus polyhedra fluoresced under UV light. This characteristic should allow the rapid monitoring and detection of ColorBtrus infected insects in the field (Chao *et al.*, 1996; Chang *et al.*, 2003). In dose-mortality bioassays using second or third instar larvae of the diamondback moth, *Plutella xylostella*, Chang *et al.* (2003) showed that the LD_{50} of ColorBtrus was reduced by roughly 100-fold in comparison to wild-type AcMNPV (28.3 versus 2798.3 polyhedra per larva, respectively). By time-mortality bioassays, the ST_{50} of larvae of *P. xylostella* infected with ColorBtrus was reduced by 63% (33.9 versus 92.8 h) in comparison to control larvae infected with wild-type AcMNPV when the larvae were inoculated at LD_{90} doses (i.e., 80 ColorBtrus or 10 240 AcMNPV polyhedra per larva). Chang *et al.* (2003) indicated that the ColorBtrus inoculated larvae displayed symptoms, such as feeding cessation, that were consistent with exposure to Cry1Ac. This suggested that feeding damage to the plant should cease very quickly after ingestion of ColorBtrus. Chang *et al.* (2003) further suggested that the "stacking" of multiple effectors (i.e., Cry1Ac toxicity and viral pathogenesis) by ColorBtrus should reduce the occurrence of resistance because the few individuals within the population that evolve resistance to the *Bt* toxin would also have to simultaneously evolve resistance to the baculovirus. Additionally, although the Cry1Ac toxin is highly toxic to a wide range of lepidopteran insects, it is not effective against *Spodoptera* species such as the beet armyworm *S. exigua* (Bai *et al.*, 1993). Since the beet armyworm is susceptible to AcMNPV, they suggested that this insect can be used for the efficient *in vivo* production of ColorBtrus or similar virus.

Besides the toxins mentioned here, new and interesting toxins are frequently being discovered. These novel insect specific toxins can potentially be expressed by baculoviruses. There is a great diversity of available toxins that can be expressed by GM baculoviruses either alone or in combination. We may have not yet reached the limits of improvement of the speed of kill of GM baculoviruses.

6.9.3.4. Improvement of Toxin Efficacy by Genetic Modifications

Thus far, the discussion on improving baculovirus pesticides has primarily focused on the expression of an insect selective toxin gene under late or very late baculoviral promoters. Here, the focus is on studies that have attempted to improve the efficacy of the toxin expressing constructs by (1) altering the timing and level of toxin expression, (2) improving folding and secretion efficiency of the toxin, and/or (3) expressing multiple toxins that target different

sites within the insect sodium channel. Related to this last point, studies on synergistic interactions between the expressed toxin and chemical pesticides are also discussed.

6.9.3.4.1. Alteration of the timing and level of expression In general, the first generation of recombinant baculovirus constructs used a single baculovirus derived very late (e.g., *polh* or *p10*) or late (e.g., *p6.9*) promoter to drive expression of the toxin gene (or other foreign gene). These promoters generally drive exceptionally high levels of protein expression (i.e., they are very strong promoters), but they require the products of viral early genes for activation. Thus, the very late/late promoters are not activated until a late stage of the baculovirus replication (Lu and Milller, 1997). At this late stage of infection, the translational machinery and processing pathways of the cell may be compromised (Jarvis *et al.*, 1990). Thus, a large amount of protein may be produced but not all of the protein will be functionally active due to poor folding or poor posttranslational modifications and the protein may also be retained within the cell due to poor secretion. Baculovirus early gene promoters, alternatively, are recognized by host transcription factors and are activated very soon after the viral DNA is uncoated in the nucleus. At this early stage of infection, the processing and secretory pathways of the cell should be in a less compromised state (in comparison to the late stage of infection). Thus, it is likely that a higher percentage of the expressed proteins will be properly folded, modified, and secreted. Earlier expression may be especially important for the proper folding of neurotoxins because they possess a relatively large number of disulfide bonds (e.g., the 70 amino acid-long AaIT peptide contains four disulfide bonds). Early gene promoters, however, generally drive very low levels of protein expression (i.e., they are weak promoters).

Several groups have attempted to circumvent the potential problems associated with protein expression under very late promoters using: (1) early gene promoters; (2) dual or chimeric promoters; and/or (3) constitutively expressed promoters to drive the expression of a foreign gene. Jarvis *et al.* (1996) have constructed a recombinant AcMNPV (*ie1*-AaIT) expressing the AaIT gene under the control of an immediate early gene (*ie1*) promoter of AcMNPV. In cultured Sf-9 cells infected with the *ie1*-AaIT construct, AaIT was detected as early as 4 h p.i. and continued to accumulate until at least 24 h p.i. At 24 h p.i., the amount of the expressed AaIT peaked and was about equal to that expressed by AcAaIT (AaIT expressed under the very late *p10* promoter). *In vitro* expression assays indicated that there was early and abundant expression of AaIT under the *ie1* promoter. These findings suggested that the *ie1*-AaIT construct should kill infected larvae more quickly than the AcAaIT construct. The results of the insect bioassays using neonate *H. virescens*, however, did not support this. Time-mortality bioassays showed that the *ie1*-AaIT virus killed neonate *H. virescens* only about 10% faster than the wild-type AcMNPV (LT_{50} of 87.0 versus 96.5 h). In comparison, AcAaIT killed the neonate *H. virescens* about 22% faster than AcMNPV (LT_{50} of 75.0 versus 96.5 h) in parallel experiments. Although Jarvis *et al.* (1996) were unclear as to the reason(s) for the slower speed of kill of *ie1*-AaIT in comparison to AcAaIT, they speculated that: (1) *ie1*-AaIT does not produce a threshold dose of AaIT that must be reached before kill rates can be enhanced; (2) duplication of the *ie1* promoter usurps limited cellular transcription factors needed by the endogenous *ie1* promoter for expression of the IE1 protein; (3) early expression of AaIT in midgut epithelial cells induces these cells to be shed thereby reducing the primary infection in these cells and/or dissemination of the virus into the hemocoel; and (4) the *ie1* promoter of AcMNPV has a narrower host range and/or tissue specificity in comparison to the virus as a whole. Interestingly, although *ie1*-AaIT infected larvae did not die as quickly as AcAaIT infected larvae, the relative growth rate of the *ie1*-AaIT infected larvae was about 13% lower (0.8 versus 0.92 mg per larva per day) than that of AcAaIT infected larvae. This suggested that even though they do not die as quickly, the *ie1*-AaIT infected larvae may consume less food.

van Beek *et al.* (2003) have compared the efficacy of recombinant AcMNPVs expressing either AaIT or LqhIT2 under various baculoviral early (*ie1* or *lef3*), early/late (*39K*), or very late (*p10*) gene promoters in larvae of *H. virescens, T. ni,* and *S. exigua*. The larvae were inoculated at both low (approximately LD_{50}) and high (approximately 100 times the LD_{50}) doses of each recombinant virus. By time-to-response bioassays using neonate and third instar *H. virescens* or *T. ni*, and second instar *S. exigua*, they found that the ET_{50} of the recombinant AcMNPV expressing AaIT under the early *hr5*/*ie1* promoter led in the majority of cases to a faster response, but a generalized pattern of response in terms of the effect of viral dose and instar was not found. The "*hr5*" designation indicates that the baculovirus *hr5* enhancer sequence was placed immediately upstream of the promoter sequence. By bioassays using third instar larvae of *H. virescens*, van Beek *et al.* found that there were no signifi-

cant differences in the ET_{50} of the recombinant AcMNPVs expressing LqhIT2 under an early (*hr5/ie1* or *hr5/lef3*) or early/late (*hr5/39K*) gene promoter. Furthermore, regardless of the larval instar or dose applied, when the early *hr5/ie1* promoter was used to drive the expression of LqhIT2 or AaIT, the ET_{50}s of the recombinant AcMNPV expressing LqhIT2 were consistently lower (by 8–32 h) in comparison to those of the recombinant AcMNPV expressing AaIT. This was putatively due to differences in the effectiveness of the two toxins.

As described above, Gershburg *et al.* (1998) have constructed recombinant AcMNPVs expressing the excitatory toxin LqhIT1 or depressant toxin LqhIT2 under either the early *p35* gene or very late *p10* gene promoters. They found that the recombinant AcMNPV expressing LqhIT1 under the *p35* promoter had a slightly slower ET_{50} (73 versus 66 h) in comparison to the recombinant AcMNPV expressing LqhIT1 under the *p10* promoter. However, they detected a clear paralytic effect when the *p35* promoter was used to express LqhIT1 even when they were unable to detect the LqhIT1 by immunochemical analysis. Thus, they suggested that baculovirus expression of toxin in cells that are adjacent to the target sites of the motor neural tissues overcomes the pharmacokinetic barriers that the toxin may face when, for example, purified toxin is injected to the insect. Consistent with this hypothesis, Elazar *et al.* (2001) have shown that the concentration of AaIT in the hemolymph of paralyzed *B. mori* larvae is approximately 50-fold lower when the paralyzing dose is delivered by a baculovirus (BmAaIT) rather than by the direct injection of purified AaIT. They hypothesized that baculovirus expression of AaIT provides a continuous, local supply of freshly produced toxin (via the tracheal system) to the neuronal receptors, thus providing access to critical target sites that are inaccessible to toxin that is injected. Therefore, a lower level of continuous expression under an early promoter may be sufficient to elicit a paralytic response.

As discussed above, Tomalski and Miller (1992) have constructed an occlusion-negative recombinant AcMNPV (vETL-Tox34) that expresses the *tox34* gene under the baculoviral early P_{ETL} promoter. In early fifth instar larvae of *T. ni*, this virus induced much slower paralysis (occurring after 48 h in 95% of larvae) in comparison to control larvae infected with recombinant AcMNPVs (vEV-Tox34, vCappolh-Tox34, or vSp-Tox34) expressing *tox34* under a very late or chimeric promoter (all larvae were paralyzed or dead by 48 h). Additionally, the average cumulative weight gain of vETL-Tox34 infected larvae at 24 h post injection was not significantly different to that of control larvae injected with AcMNPV or cell culture medium (mock infection). Lu *et al.* (1996) have also constructed a recombinant AcMNPV (vDA26tox34) expressing the *tox34* gene under the early *Da26* gene promoter. In comparison to vp6.9tox34 (*tox34* under a late promoter) or vSp-tox34 (*tox34* under a very late promoter) infected Sf-21 or TN-368 cells (derived from *S. frugiperda* and *T. ni*, respectively), TxP-I expression was detected at least 24 h earlier (but at dramatically lower levels) in Sf-21 and TN-368 cells infected with vDA26tox34. In time-mortality bioassays (at an LC_{95} dose), the ET_{50} of vDA26tox34 in neonate larvae of *S. frugiperda* and *T. ni* was reduced by approximately 39% (61.8 versus 101.3 h) and 28% (71.2 versus 99.0 h), respectively, in comparison to wild-type AcMNPV. However, this was 17.1 and 29.5 h slower, respectively, in comparison to neonate larvae of *S. frugiperda* and *T. ni* that were infected with vp6.9tox34 (ET_{50}s of 44.7 and 41.7 h, respectively). Even though the TxP-I is expressed significantly earlier under the early promoter, it is apparently not expressed in sufficient quantity, at least initially, to paralyze larvae of *S. frugiperda* or *T. ni*. Popham *et al.* (1997) have also expressed the *tox34* gene under the early *DA26* and late *p6.9* promoters (of AcMNPV) by recombinant HzSNPVs (HzEGTDA26tox34 and HzEGTp6.9tox34, respectively). They found that the ET_{50}s of HzEGTDA26tox34 and HzEGTp6.9tox34 in neonate larvae of *H. zea* were reduced by approximately 47% (35.4 versus 67.3 h) and 44% (38.0 versus 67.3 h), respectively, in comparison to a control virus. In contrast to the results of Lu *et al.* (1996), the early promoter was more effective in the case of HzSNPV and neonate *H. zea* suggesting that the effectiveness of a promoter will be virus and insect specific. With toxins of current potency, the use of early (and weak) promoters such as *ie1*, *lef3*, *p35, etl*, or *DA26* may or may not provide any benefit in terms of improved crop protection. However, if toxins that act at lower concentration (i.e., with much greater potency) are identified, the use of early promoters may offer a great advantage.

Tomalski and Miller (1992) have used a chimeric promoter ($P_{cap/polh}$) comprised of both the late capsid and very late polyhedrin promoter elements to drive the expression of the *tox34* gene in an occlusion-negative recombinant AcMNPV (vCappolh-Tox34). In Sf-21 cell cultures infected with vCappolh-Tox34, TxP-I is detected in the culture medium at 12 h p.i. at levels that are similar to those found in vEV-Tox34 (*tox34* under a very late promoter) infected Sf-21 cells at 24 h p.i. (i.e., high-

level expression occurred approximately 12 h earlier). When early fifth instar larvae of *T. ni* were injected with vCappolh-Tox34 approximately 50% of the insects were paralyzed by 24 h post injection. In comparison, only 10% or less of control virus (e.g., vEV-Tox34) infected larvae were paralyzed. Larvae infected with vCappolh-Tox34 also showed a significantly lower cumulative weight gain in comparison to control virus infected larvae. An occlusion-positive construct (vSp-Tox34) in which the *tox34* gene was placed under another hybrid late/very late promoter (P_{SynXIV}; Wang *et al.*, 1991) has also been constructed by Tomalski and Miller (1991, 1992). The induction of paralysis by vSp-Tox34 in fifth instar *T. ni* was slightly delayed, but all of the larvae were paralyzed or dead by 48 h post injection (as were vCappolh-Tox34 injected larvae; Tomalski and Miller, 1991, 1992). In time-mortality bioassays (at an LC_{95} dose), the ET_{50} of vSp-Tox34 in neonate larvae of *S. frugiperda* and *T. ni* was reduced by approximately 45% (55.4 versus 101.3 h) and 41% (58.5 versus 99.0 h), respectively, in comparison to control larvae infected with AcMNPV (Tomalski and Miller, 1992; Lu *et al.*, 1996). Furthermore, the yield (2.1×10^9 versus 3.5×10^9 polyhedra per larva) of vSP-Tox34 polyhedra from infected last instar larvae of *S. frugiperda* was reduced by approximately 40% in comparison to AcMNPV infected control larvae. Tomalski and Miller (1992) suggested that this reduction in yield will cripple the virus in terms of its ability to compete effectively with the wild-type virus in the environment.

Sun *et al.* (2004) have generated a recombinant HaSNPV (HaSNPV-AaIT) that expresses the AaIT gene under a chimeric promoter (ph-p69p) consisting of the late *p6.9* gene promoter inserted immediately downstream of the very late *polh* gene promoter in the same direction. The AaIT gene cassette was inserted at the *egt* gene locus of HaSNPV. Detailed dose-mortality bioassays indicated that the LD_{50}s of HaSNPV-AaIT was unchanged compared to wild-type (HaSNPV-WT) or *egt* gene-deleted (HaSNPV-EGTD) viruses in first to fifth instar larvae of the cotton bollworm, *H. armigera*. In time-mortality bioassays, first to fifth instar larvae of *H. armigera* infected with HaSNPV-AaIT showed reductions in the ST_{50}s of 10% (68.5 versus 76.5 h), of 20% (60.5 versus 75.5 h), 8% (71.0 versus 77.5 h), 4% (104.6 versus 109.0 h), and 10% (108.5 versus 121.0 h), respectively, in comparison to control larvae infected with HaSNPV-EGTD. In comparison to control (first to fifth instar) larvae infected with HaSNPV-WT, the corresponding reductions were 19, 28, 25, 21, and 18%, respectively. In third to fifth instar of *H. armigera* infected with HaSNPV-AaIT, the median times to feeding cessation (FT_{50}s) were reduced by 25% (51.5 versus 68.5 h), 22% (66.5 versus 85.0 h), and 12% (84.5 versus 96.5 h), respectively, in comparison to control larvae infected with HaSNPV-EGTD. In comparison to control larvae infected with HaSNPV-WT, the corresponding reductions in the FT_{50}s were 39%, 43%, and 30%, respectively. The role of the *egt* deletion in improving speed of kill is discussed further below. Sun *et al.* (2004) did not test constructs in which only the *polh* or *p6.9* gene promoter was used to drive expression of the AaIT gene, thus it was not possible to predict if expression under the dual promoter is more effective than expression under a single late or very late promoter.

The *hsp70* promoter of *D. melanogaster* (Snyder *et al.*, 1982) is constitutively active in insect cells (Vlak *et al.*, 1990; Zuidema *et al.*, 1990). Unlike very late or late gene promoters of the baculovirus, the *hsp70* promoter does not require the expression of baculovirus early gene products or the initiation of viral DNA synthesis for its activity. The *hsp70* promoter shows higher activity than early gene promoters, but it is not as active as baculoviral very late or late gene promoters (Morris and Miller, 1992, 1993). McNitt *et al.* (1995) have constructed occlusion-positive, recombinant AcMNPVs expressing AaIT (vHSP70AaIT) and TxP-I (vHSP70tox34) under the *hsp70* promoter. TxP-I was expressed at a significantly higher level under the *hsp70* promoter than under the early *DA26* promoter in both vHSP70tox34 infected Sf-21 and TN-368 cell cultures (McNitt *et al.*, 1995; Lu *et al.*, 1996). Additionally, TxP-I expression was detected as early as 6 and 12 h p.i., respectively, in the culture medium of vHSP70tox34 infected Sf-21 and TN-368 cells. Dose-mortality bioassays using neonate larvae of *S. frugiperda* or *T. ni* indicated that the LC_{50}s of vHSP70tox34 were unchanged from that of the AcMNPV. Time-mortality bioassays (at an LC_{95} dose) in neonate *S. frugiperda* and *T. ni* showed that the ET_{50}s of vHSP70tox34 were reduced by approximately 59% (41.8 versus 101.3 h) and 46% (53.8 versus 99.0 h), respectively, in comparison to control larvae infected with AcMNPV. In comparison to occlusion-positive, recombinant AcMNPVs expressing the *tox34* gene under very late (vSp-tox34) or late (vp6.9tox34) promoters, the ET_{50}s of vHSP70tox34 were faster than both vp6.9tox34 (44.7 h) and vSp-tox34 (55.4 h) in neonate *S. frugiperda*; and faster than vp6.9tox34 (41.7 h) and slower than vSp-tox34 (58.5 h) in neonate *T. ni*. This is surprising considering that the

overall level of TxP-I secretion under the *hsp70* promoter is substantially lower than that under the *p6.9* promoter (Lu *et al.*, 1996). On the basis of these findings Lu *et al.* (1996) suggested that expression from a relatively strong constitutive promoter such as *hsp70* is more effective, in some cases, than expression from a very strong late baculoviral promoter. Popham *et al.* (1997) have expressed the *tox34* gene under the *hsp70* promoter (HzEGT hsptox34) at the *egt* gene locus of a recombinant HzSNPV. Time-mortality bioassays (at an LC_{95} dose) in neonate *H. zea* showed that the ET_{50} of HzEGThsptox34 was reduced by 34% (44.1 versus 67.3 h) in comparison to control larvae infected with an *egt* deletion mutant of HzSNPV (HzEGT-del). In contrast to the results of Lu *et al.* (1996), however, expression of the *tox34* gene under the *hsp70* promoter was not as effective as expression under the early *Da26* (ET50 of 35.4 h) or late *p6.9* (ET_{50} of 38.0 h) promoters (both of these promoters were of AcMNPV origin).

The *hsp70* promoter has also been used to drive the expression of spider and sea anemone toxins. Prikhod'ko *et al.* (1998) have constructed recombinant AcMNPVs vhsMAg4p+, vhsSAt2p+, and vhsSSh1p+ that express the insect selective toxins μ-Aga-IV, As II, and Sh I, respectively, under the *hsp70* promoter. All of these constructs showed significantly reduced ET_{50}s (at an LD_{95} dose) in comparison to AcMNPV in neonate larvae of *S. frugiperda* and *T. ni*. In neonate *S. frugiperda* infected with vhsMAg4p+, vhsSAt2p+, or vhsSSh1p+, the ET_{50}s were reduced by approximately 55% (49.0 versus 110 h), 52% (52.5 versus 110 h), and 53% (51.9 versus 110 h), respectively. In neonate *T. ni*, the ET_{50}s were reduced by 42% (53.6 versus 99.7 h), 50% (49.0 versus 99.7 h), and 46% (52.9 versus 99.7 h), respectively. In both larval species, expression of μ-Aga-IV (*mag4* gene), As II (*sat2* gene), and Sh I (*ssh1* gene) under the *hsp70* promoter was more effective than expression under the very late P_{SynXIV} promoter (ET_{50}s of 60.0, 63.6, and 56.8 h, respectively, in *S. frugiperda*, and 84.4, 62.8, and 60.6 h, respectively, in *T. ni*).

Numerous studies (including several that are not included in our discussion above) have investigated the effectiveness of constitutive and baculoviral promoters (early, late, and very late) used either alone or in combination for the expression of the current generation of toxin genes. These studies, however, do not form a consensus opinion as to which promoter system is the most optimal in terms of improving insecticidal effectiveness of the toxin expressing baculovirus. The toxin gene, parental virus, and host-specific factors all appear to play important roles in determining the effectiveness of a particular promoter system. Given that an early or constitutive promoter does not provide a clear advantage (at least within the context of toxin genes of current potency), the use of a baculoviral late or very late promoter may provide a slight reduction in the risk that a toxin gene could be expressed in a nontarget insect. The argument here is that very late and late gene promoters are inactive in beneficial insects and other organisms (Heinz *et al.*, 1995; McNitt *et al.*, 1995) because the activation of these promoters requires (1) viral DNA replication and (2) late expression factors (LEF; Lu and Milller, 1997). In AcMNPV there are 18 *lef* genes that are required for optimal transactivation of expression from late and very late gene promoters. At least seven of the 18 *lef* genes appear to be involved in DNA replication and at least three *lef* gene products are part of a virus induced or virus encoded RNA polymerase. This RNA polymerase is required for transcription from late and very late genes. Thus, without viral DNA replication and the expression of essential *lef* genes, transcription from a late or very late gene promoter will not occur. In contrast, early and constitutive gene promoters can potentially be activated in nontarget insect cells (Morris and Miller, 1992, 1993; McNitt *et al.*, 1995). A discussion of the potential risks associated with gene transfer to nontarget insects and other organisms (e.g., mammals) is given below.

6.9.3.4.2. Better secretion and folding In order for a peptide or protein to be secreted to the outside of a eukaryotic cell, it must possess a signal sequence consisting of 15–30 hydrophobic amino acid residues at its N-terminal. Following the initiation of protein synthesis by ribosomes within the cytoplasm, the newly synthesized signal sequence is bound by a signal recognition particle (SRP). Subsequently, the SRP signal sequence–ribosome complex binds to a SRP receptor on the cytosolic surface of the rough ER membrane. The signal sequence peptide is then able to cross the ER membrane (and is generally cleaved off within the lumen of the ER) and the remainder of the protein is produced and secreted into the lumen of the ER. Once inside the ER lumen the peptide can undergo appropriate disulfide bond formation and folding. The mature protein then continues to the Golgi apparatus for subsequent release via secretory vesicles to the outside of the cell. In general, once inside the ER lumen, proteins are automatically transported through the Golgi apparatus and secreted (i.e., this is thought to be the default pathway) unless they possess a specific signal that directs them to another location.

Thus, the ability of the insect cell SRP to recognize the signal sequence on the baculovirus expressed protein is a key determinant for its eventual secretion to the outside of the cell. Signal sequences that originate from a variety of organisms (e.g., mammal, plant, yeast, insect, virus, etc.) are recognized by lepidopteran SRPs and can help direct baculovirus expressed proteins to the ER for subsequent processing and secretion from the cell (O'Reilly *et al.*, 1992). Signal sequences derived from proteins of insect origin, e.g., bombyxin from the silk moth *B. mori* (Adachi *et al.*, 1989), mellitin from the honeybee *A. mellifera* (Tessier *et al.*, 1991), and cuticle protein II (CPII) from *D. melanogaster* (Snyder *et al.*, 1982), have been shown to be functional when attached to a wide variety of proteins.

In order to improve processing, folding, and/or secretion of baculovirus expressed toxin, van Beek *et al.* (2003) have generated recombinant AcMNPVs expressing LqhIT2 (under the early *hr5/ie1* promoter) fused to various secretion signals of insect and noninsect origin. Signal sequences originating from bombyxin, CPII, adipokinetic hormone from *M. sexta* L. (Jaffe *et al.*, 1986), chymotrypsin of *Lucilia cuprina* (Weidemann) (Casu *et al.*, 1994), AcMNPV gp67 (Whitford *et al.*, 1989), and scorpion neurotoxins BjIT from *Hottentota judaicus* (Simon) (Zlotkin *et al.*, 1993), AaIT (Bougis *et al.*, 1989), and LqhIT2 (Zlotkin *et al.*, 1993) were tested. In time-mortality bioassays in third instar larvae of *H. virescens* (at a dose of polyhedra that was estimated to elicit a response in less than 50% of the larvae), they found that a recombinant AcMNPV expressing LqhIT2 fused to the bombyxin signal sequence elicited the fastest response time (ET_{50} of 62 h, estimate based on the graph). Recombinant AcMNPVs expressing LqhIT2 fused to the signal sequences of adipokinetic hormone (ET_{50} of 78 h), chymotrypsin (ET_{50} of 78 h), LqhIT2 (ET_{50} of 85 h), and gp67 (ET_{50} of 72 h) elicited intermediate response times. All of these viruses putatively expressed and secreted active toxin as evidenced by reduced survival times and the occurrence of paralysis. In contrast, recombinant AcMNPV expressing LqhIT2 fused to the signal sequences of CPII, BjIT, and AaIT appeared not to secrete active toxin because insects infected with these constructs exhibited symptomology that is typical of AcMNPV infection. In general, they found that the baculoviral gp67 or insect derived signal sequences (excluding CPII) worked better than the scorpion toxin derived signal sequences for the secretion of biologically active LqhIT2.

Lu *et al.* (1996) have constructed three recombinant AcMNPVs (vSp-BSigtox34, vSp-DCtox34, and vSp-tox21A/tox34) that express TxP-I (under the very late P_{SynXIV} promoter) fused to signal sequences originating from sarcotoxin IA of the flesh fly (Matsumoto *et al.*, 1986), CPII, and *tox21A* (a homolog of *tox34*) (Tomalski *et al.*, 1993), respectively. The levels of TxP-I secreted into the culture medium of Sf-21 cells infected with vSp-DCtox34 or vSp-tox21/tox34 were similar to control cells infected with vSp-tox34 (TxP-I fused to its own signal sequence). TxP-I secretion was undetectable on the basis of Western blotting in Sf-21 cell cultures infected with vSp-BSigtox34. By comparing the levels of TxP-I that were found within the cell (i.e., cell lysate) and in the culture medium (i.e., secreted), it appeared that the CPII secretion signal (vSp-DCtox34) was better than the *tox21A* signal sequence (vSp-tox21/tox34) in terms of being able to direct a higher percentage of the expressed TxP-I to the outside of the cell. TxP-I was only detected at very low levels within the cell lysates of Sf-21 cells infected with vSp-BSigtox34, thus it is difficult to determine whether the lack of TxP-I in the cell culture medium was the result of poor secretion or poor translation. In dose-mortality bioassays using neonate larvae of *T. ni*, the LC_{50}s of vSp-BSigtox34 and vSp-DCtox34 were similar to that of AcMNPV, whereas the LC_{50} of vSp-tox21A/tox34 was roughly double (5.3×10^4 versus 2.2×10^4 polyhedra per ml) that of AcMNPV. In time-mortality bioassays (at an LC_{95} dose) in neonate *T. ni*, the ET_{50}s of vSp-BSigtox34, vSp-DCtox34, and vSp-tox21A/tox34 were reduced by 26% (70.0 versus 94.6 h), 47% (49.9 versus 94.6 h), and 36% (60.8 versus 94.6 h), respectively, in comparison to control larvae infected with AcMNPV. However, in comparison to neonate *T. ni* infected with vSp-tox34 (a control virus expressing TxP-I fused to its authentic secretion signal, ET_{50} of 51.1 h), neonate *T. ni* infected with viruses expressing TxP-I fused to an alternative signal sequence did not show any improvements in ET_{50}. Additionally, although TxP-I secretion was undetected in Sf-21 cells infected with vSP-BSigtox34, neonate *T. ni* infected with this virus displayed paralysis indicating that the threshold level of toxin required for paralysis is low or that some cells within the larvae may more efficiently produce toxin. On the basis of these studies, Lu *et al.* (1996) suggested that the level of toxin secreted into the supernatant is generally diagnostic of how the virus will perform *in vivo*.

Chaperones found in the cytosol and ER (such as BiP, murine immunoglobulin heavy chain binding protein; Bole *et al.*, 1986) play key roles in protein folding, transport, and quality control in a wide

range of eukaryotic cells including insect cells (Ruddon and Bedows, 1997; Ailor and Betenbaugh, 1999; Trombetta and Parodi, 2003). The coexpression of BiP by a recombinant baculovirus has been shown to reduce aggregation and increase secretion of baculovirus expressed murine IgG in *T. ni* derived cells (Hsu *et al.*, 1994). Taniai *et al.* (2002) have investigated whether coexpression of BiP can improve the secretion of AcAaIT expressed AaIT (rAaIT) in Sf-21 cells. They found that coexpression of BiP increased the amount of soluble rAaIT, however, the amount of active rAaIT that was secreted into the culture medium was not improved. Protein disulfide isomerase (PDI) is another factor within the ER that is known to help protein folding and secretion in insect cells by catalyzing the oxidization, reduction, and isomerization of disulfide bonds *in vitro* (Hsu *et al.*, 1996; Ruddon and Bedows, 1997). Coexpression of a PDI expressing baculovirus with an AaIT expressing baculovirus was also ineffective in increasing the amount of active AaIT that was secreted into the culture medium (Taniai, Inceoglu, and Hammock, unpublished data).

6.9.3.4.3. Expression of multiple synergistic toxins At least six distinct receptor sites are found on the voltage gated sodium channels of mammals and insects that are the molecular targets of a broad range of neurotoxins. Two additional receptor sites are found on the insect sodium channel that are the molecular targets of insect selective excitatory and depressant scorpion toxins (Cestele and Catterall, 2000). On the basis of binding experiments using radiolabeled toxins, the depressant toxins bind to two noninteracting binding sites (one showing high affinity and the other low affinity) on the insect sodium channel (Gordon *et al.*, 1992; Zlotkin *et al.*, 1995; Cestele and Catterall, 2000). The excitatory toxins bind only to the high-affinity receptor site (Gordon *et al.*, 1992). Herrmann *et al.* (1995) have shown that when excitatory and depressant toxins are simultaneously coinjected into larvae of the blowfly *S. falculata* or *H. virescens*, the amount of toxin required to give the same paralytic response is reduced five- to tenfold in comparison to the amount required when only one of the toxins is injected. On the basis of this synergism, they suggested that speed of kill of recombinant baculovirus(es) could be further reduced by: (1) the coinfection of two or more recombinant baculoviruses that each express toxin genes with synergistic properties; or (2) genetic modification such that two or more synergistic toxin genes are simultaneously expressed.

Regev *et al.* (2003) have generated a recombinant AcMNPV (vAcLqIT1-IT2) that expresses both the excitatory LqhIT1 and the depressant LqhIT2 toxins under the very late *p10* and *polh* promoters, respectively. Time-response bioassays (at an LC_{95} dose) using neonate *H. virescens* showed that the ET_{50} of vAcLqIT1-IT2 was reduced by 41% (46.9 versus 79.1 h) in comparison to AcMNPV. In comparison, the ET_{50}s of recombinant AcMNPVs expressing only LqhIT1 (vAcLqIT1) or only LqhIT2 (vAcLqIT2) were 57.3 and 60.0 h, respectively. Thus, expression of both LqhIT1 and LqhIT2 by vAcLqIT1-IT2 resulted in a synergistic effect that reduced the ET_{50} by 10.4 h (18%) and 13.1 h (22%), respectively. A synergistic effect (15–19%) was also observed following coinfection of neonate *H. virescens* with a mixture of both vAcLqIT1 and vAcLqIT2 (ET_{50} of 48.8 h). Time-response bioassays (at an LC_{95} dose) using neonate *H. armigera* showed that the ET_{50} of vAcLqIT1-IT2 was reduced by 24% (69.1 versus 90.8 h) in comparison to AcMNPV. However, a synergistic effect was not elicited in comparison to neonate *H. armigera* infected with vAcLqIT1 or vAcLqIT2 alone. Since *H. armigera* is only a semi-permissive host of AcMNPV, Regev *et al.* (2003) hypothesized that inefficient oral infection may have diminished any synergistic effect. By intrahemocoelic injection (at an LD_{95} dose) of third instar larvae of *H. armigera*, they found that the ET_{50} of vAcLqIT1-IT2 (72 h) was reduced by 13 h (15%) and 70 h (49%) in comparison to larvae injected with only vAcLqIT1 or vAcLqIT2, respectively. In similar intrahemocoelic injection assays of third instar larvae of *S. littoralis* (nonpermissive by oral infection for AcMNPV), they found that the ET_{50} of vAcLqIT1-IT2 (54 h) was reduced by 43 h (44%) and 20 h (27%) in comparison to control larvae injected with only vAcLqIT1 or vAcLqIT2, respectively. Similar or decreased levels of synergism were found with a recombinant AcMNPV (vAcLqαIT-IT2) expressing both alpha and depressant scorpion toxins in orally and intrahemocoelically infected larvae of *H. virescens*, *H. armigera*, and *S. littoralis*.

Using thoracic neurons of the grasshopper *Schistocerca americana* Drury, Prikhod'ko *et al.* (1998) have shown that the spider and sea anemone toxins, μ-Aga-IV and As II, respectively, act at distinct sites on the insect sodium channel and synergistically promote channel opening. These toxins also showed synergism when injected into third instar blowfly *Lucilia sericata* and fourth instar fall armyworm *S. frugiperda*. Prikhod'ko *et al.* (1998) have generated recombinant AcMNPVs (vMAg4Sat2 and vhsMAg4SAt2) that coexpress both μ-Aga-IV and As II toxins under P_{SynXIV} or *hsp70* promoters, respectively. Time-response bioassay (at an LC_{95}

dose) using neonate *T. ni* or *S. frugiperda* showed that the ET_{50} of vMAg4Sat2 was reduced by 39% (60.6 versus 99.7 h) and 45% (56.8 versus 104.0 h), respectively, in comparison to AcMNPV. A synergistic effect, however, was not found in comparison to larvae infected with recombinant AcMNPVs expressing only μ-Aga-IV (vMAg4p+) or As II (vDASAt2). In similar bioassays, the ET_{50} of vhsMAg4SAt2 was reduced by 47% (52.3 versus 99.2 h) and 57% (48.3 versus 111.1 h), respectively, in comparison to AcMNPV. A synergistic effect, however, was again not found in comparison to larvae infected with vhsMAg4p+ or vDAhsSAt2. They hypothesized that synergism was not detected in the case of coexpression of these toxins under the very late P_{SynXIV} promoter (by vMAg4Sat2) because it takes time to activate this promoter during infection and, once activated, high enough levels of expression of either one of the toxins is sufficient to effectively debilitate the host insect. In the case of coexpression under the *hsp70* promoter by vhsMAg4SAt2, they hypothesized that lower ET_{50}s (i.e., a synergistic effect) may not be possible since it takes a minimum period of time (i.e., approximately 50 h) for the virus to initiate both primary and secondary infections within the host. Although synergism was not observed in terms of the ET_{50} (mean time at which 50% of the test larvae cease to respond to stimulus), synergism was observed in terms of the FT_{50} (mean time at which 50% of the test larvae cease feeding) of neonate *T. ni* infected with vhsMAg4SAt2 (at an LC_{95} dose by droplet feeding). The FT_{50} of vhsMAg4SAt2 infected neonates was lower than that of vMAg4p+, vDASAt2, and AcMNPV by approximately 25% (24.3 versus 32.3 h), 29% (24.3 versus 34.3 h), and 63% (24.3 versus 65.8 h). Prikhod'ko *et al.* (1998) suggested that 24 h may be the fastest time at which a recombinant baculovirus could stop feeding because of the time (approximately 12 h) that it takes to complete the primary infection cycle within the midgut. Furthermore, they suggested that an FT_{50} of 24 h is sufficiently rapid to make recombinant baculovirus pesticides competitive with chemical pesticides.

6.9.3.5. Toxin Interactions with Chemical Pesticides

Pyrethroids, carbamates, and organophosphates are common synthetic chemical pesticides that are used for protection against pest insects worldwide. Pyrethroids currently account for about 20% of the total market for insecticides (Khambay, 2002). Pyrethroids are the most commonly used chemical insecticides for the control of the tobacco budworm *H. virescens* and cotton bollworm *H. zea* in North America. Pyrethroids are divided into two groups, type I and type II, on the basis of the absence or presence, respectively, of a cyano (-CN) group in the alpha position of the carboxyl moiety. Both type I and type II pyrethroids target receptors in the sodium channel causing them to remain open and resulting in prolonged sodium influx that causes hyper-excitation of the nervous system of both insects and mammals. Insects, however, are more sensitive to pyrethroid action than mammals due to several factors including the relative concentration of pyrethroid metabolizing enzymes, binding kinetics of the pyrethroid to the receptor, and differential sensitivity of the insect and mammalian sodium channels to pyrethroid action (Soderlund *et al.*, 2002). Although the precise location of the pyrethroid receptor within the insect sodium channel is unknown, the binding site is apparently different from that of peptide toxins produced by spiders, sea anemones, and scorpions (Ghiasuddin and Soderlund, 1985; Herrmann *et al.*, 1995). The differential binding of pyrethroid and toxin molecules indicate that when they are both present within the sodium channel they can act independently, synergistically, or antagonistically.

McCutchen *et al.* (1997) have characterized the effect of low concentrations of six chemical pesticides (allethrin, cypermethrin, DDT, endosulfan, methomyl, and profenofos) on the efficacy of wild-type and recombinant baculoviruses. They found synergistic interactions when neonate *H. virescens* were exposed to AcAaIT and low concentrations (LC_{10}–LC_{20} at 24 h) of the type II pyrethroid (cypermethrin) and a carbamate (methomyl). The interactions of AcAaIT with allethrin, DDT, endosulfan, or profenofos were not synergistic but additive. Specifically, neonate *H. virescens* that were inoculated with 2000 polyhedra per larva (a greater than LC_{99} dose) of AcAaIT and immediately exposed to an LC_{10}–LC_{20} dose of cypermethrin or methomyl showed an LT_{50} of 30 h, a reduction of roughly 58% compared to control larvae infected with the virus alone. Neither synergistic nor antagonistic effects were observed in control experiments in which AcJHE.KK (a recombinant AcMNPV expressing a modified juvenile hormone esterase) was used in place of AcAaIT. Since the mode and site of action of JHE is putatively different from that of AaIT, this was not surprising. In contrast, the interactions of wild-type AcMNPV and the chemical pesticides (except for methomyl) were slightly antagonistic. McCutchen *et al.* (1997) have also examined the efficacy of AcAaIT in combination with a low dose of pyrethroid in a pyrethroid resistant strain (PEG strain) of *H. virescens*. Pyrethroid resistant neonate

H. virescens that were infected with AcAaIT (at a greater than LC_{99} dose) died approximately 11% faster (LT_{50} of 63 versus 71 h) than pyrethroid sensitive neonate *H. virescens* infected with AcAaIT. Furthermore, this decrease in the LT_{50} was not found in pyrethroid resistant neonates that were infected with wild-type AcMNPV (LT_{50}s of 94 and 92 h in the resistant and sensitive strains, respectively). McCutchen *et al.* (1997) thus suggested that the pyrethroid resistant larvae are more sensitive to the neurotoxin AaIT. They further suggested that the use of AcAaIT or other recombinant baculovirus might provide the means to deter the onset of insecticide resistance in the field and might be used to drive resistant populations towards susceptibility.

In related experiments, Popham *et al.* (1998b) tested the effectiveness of the coapplication of the type II pyrethroid deltamethrin and recombinant AcMNPVs expressing μ-Aga-IV, AS II, or Sh I (genes *mag4*, *sat2*, and *ssh1*, respectively) in neonate larvae of *T. ni* and *H. virescens*. The genes encoding these toxins were placed under the very late P_{SynXIV} (vMAg4p+, vSAt2p+, and sVVh1p+, respectively) or constitutively expressed *hsp70* (vhsMAg4p+, vhsSAt2p+, and vhsSSh1p+, respectively) promoters. By diet incorporation bioassays in neonate *T. ni* treated with a low dose (LC_{20}) of deltamethrin and a low dose (LC_{20}) of vMAg4p+, vSAt2p+, or vSSh1p+, they found additive effects in terms of larval mortality, but no synergistic effects. By droplet feeding bioassays in neonate *T. ni* treated with a low dose of deltamethrin and a high (LC_{75} or greater) dose of vMAg4p+, vSAt2p+, or vSSh1p+, they found that only the larvae exposed to both deltamethrin and vMAg4p+ showed a synergistic response in terms of FT_{50}, ET_{50}, and LT_{50}. In similar droplet feeding bioassays in neonate *T. ni* treated with a low dose of deltamethrin and a high dose of vhsMAg4p+, vhsSAt2p+, and vhsSSh1p+, they found no synergistic effects. Synergistic effects were observed in at least one time response parameter (FT_{50}, ET_{50}, or LT_{50}) in droplet feeding bioassays in neonate *H. virescens* treated with a low dose of deltamethrin and high dose of a toxin expressing AcMNPV. In all of the cases where a synergistic effect was observed, the coapplication of a high viral dose was also required. Thus, Popham *et al.* (1998b) suggested that (in contrast to the McCutchen *et al.* (1997) study discussed above) the coapplication of a pyrethroid and a recombinant baculovirus would confer little or no advantage in the field because low doses of the virus would most likely be applied. Furthermore, they suggested that the different outcomes of the McCutchen *et al.* (1997) study and their study might result from differences in the method of application of the pyrethroid.

A wide variety of venomous and nonvenomous animals, bacteria, and even plants possess peptide toxins that are highly potent and selective for lepidopteran insects and which have the potential to improve the insecticidal activity of recombinant baculoviruses. Rapid methods for the separation, purification, and identification of toxins from venom and other biological matrices have been developed (Nakagawa *et al*., 1997, 1998). These methods have been successfully used for the identification of a number of insecticidal peptide toxins, for example, AaIT5 from *A. australis* (Nakagawa *et al*., 1997) and ButaIT from the South Indian red scorpion *B. tamulus* (Wudayagiri *et al*., 2001). ButaIT is a short chain neurotoxin that targets the insect potassium channel, but is particularly interesting because it is highly selective towards the *Heliothine* subfamily but nontoxic against blowfly larvae and other insects. This high level of specificity may provide some unique advantages in comparison to other scorpion toxins. The concept of delivering individual toxins or combinations of toxins via baculoviruses remains a major route to practical application of insect selective peptide toxins. Whether used alone or in combination, the ever-increasing number of characterized insect selective toxins, and their compatibility and complementary nature to existing pest control strategies including chemical insecticides, provide us with extraordinary tools for "green" pest control.

6.9.4. Modification of the Baculovirus Genome

6.9.4.1. Deletion of the Ecdysteroid UDP-Glucosyltransferase Gene

Ecdysteroids are key molecules in the regulation of physiological events such as molting in insects. More than 60 different ecdysteroids have been isolated from insects and other arthropods, and about 200 phytoecdysteroids from plants (Nijhout, 1994; Henrich *et al*., 1999; Lafont, 2000; Dinan, 2001). Ecdysone was the first ecdysteroid to be isolated and is the best characterized. Following its production and secretion from the prothoracic glands, ecdysone is converted into 20-hydroxyecdysone in the hemolymph, epidermis, and fat body. 20-Hydroxyecdysone is the primary active form of the molting hormone in most insects. Ecdysteroids are often bound to specific carrier proteins that putatively help the ecdysteroid to penetrate cell membranes or increase the capacity of the hemo-

lymph for ecdysteroids. Like juvenile hormone, the titer of ecdysteroids in the hemolymph is determined by both their synthesis and their metabolism. During normal insect development, ecdysteroids are transported to the nucleus where they initiate a cellular response. The prevention of ecdysteroid transport results in the interruption of insect growth or abnormal development (or death).

Ecdysteroid UDP-glucosyltransferase is a baculovirus encoded enzyme that catalyzes the conjugation of sugar molecules to ecdysteroids (O'Reilly and Miller, 1989; O'Reilly, 1995). The conjugation of a hydrophilic sugar molecule to the ecdysteroid prevents it from crossing cellular membranes. Thus, conjugation effectively inactivates ecdysteroid function resulting in the inhibition of molting and pupation. O'Reilly and Miller (1989) were the first to identify a gene, *egt*, that encodes ecdysteroid UDP-glucosyltransferase in a baculovirus (AcMNPV). Homologs of the AcMNPV *egt* gene have been identified in approximately 90% (20 NPVs and 8 GVs, **Table 1**) of the baculovirus genomes that have been searched (Clarke *et al.*, 1996; Tumilasci *et al.*, 2003). Although the *egt* gene is commonly found in both NPVs and GVs, it is not essential for *in vitro* (in cultured insect cells) or *in vivo* (in larval hosts) replication of AcMNPV (O'Reilly and Miller, 1989, 1991). The *egt* gene has also been shown to be nonessential in the NPVs of *M. brassicae* (Clarke *et al.*, 1996), *L. dispar* (Slavicek *et al.*, 1999), *H. armigera* (Chen *et al.*, 2000), *H. zea* (Treacy *et al.*, 2000), *B. mori* (Kang *et al.*, 2000), and *A. gemmatalis* (Rodrigues *et al.*, 2001) (**Table 2**). Larvae of *S. frugiperda* or *T. ni* infected with vEGTDEL, an *egt* deletion mutant of AcMNPV, show earlier mortality and reduced feeding (by about 40%) in comparison to control larvae infected with wild-type AcMNPV (O'Reilly and Miller, 1991; Eldridge *et al.*, 1992a; Wilson *et al.*, 2000). Specifically, in time-mortality bioassays (at an LC_{90} or LC_{97} dose), the ST_{50} of vEGTDEL infected neonate *S. frugiperda* is reduced by approximately 22% (99.7 versus 127.2 h) in comparison to control larvae infected with AcMNPV. Furthermore, vEGTDEL infected larvae yield 23% fewer progeny viruses (polyhedra) in comparison to AcMNPV infected larvae. In second or fourth instar larvae of *T. ni*, vEGTDEL infection reduces the time to death by about 11% in comparison to AcMNPV infection. Virus yield is also lower in fourth instar larvae but not in the second instars. The *egt* gene thus provides a selective advantage to the virus in

terms of the production of progeny. Conversely, this suggests that removal of the *egt* gene generates a virus that is less fit in comparison to the wild-type virus. In general, deletion of the *egt* genes of other NPVs has resulted in improvements in the speed of kill of 15–33% in comparison to the wild-type virus (e.g., Treacy *et al.*, 1997; Popham *et al.*, 1998a; Slavicek *et al.*, 1999; Treacy *et al.*, 2000; Chen *et al.*, 2000; Pinedo *et al.*, 2003). However, examples in which deletion of the *egt* gene does not reduce speed of kill are also found. Popham *et al.* (1997) found that deletion of the *egt* gene of HzSNPV had no effect in terms of reducing the ET_{50} (67.3 versus 65.4 h) in neonate larvae of *H. zea* in comparison to the wild-type virus. Bianchi *et al.* (2000) found that LT_{50} of AcMNPV-Δ*egt*, an *egt* gene deletion mutant of AcMNPV, was the same as that of wild-type AcMNPV in second and fourth instar larvae of *S. exigua*. Sun *et al.* (2004) found that the ST_{50} of neonate larvae of *H. armigera* infected with HaSNPV-EGTD (*egt* gene deletion mutant of HaSNPV) was not significantly improved over HaSNPV infected larvae, whereas second–fifth instar larvae were killed more rapidly. Thus, they suggested that *egt* gene deletion affects the speed of kill of the virus more strongly in later instars than in earlier instars.

Mechanistically, it is still unclear how deletion of the *egt* gene improves the speed of kill. In second instar larvae of *S. exigua*, Flipsen *et al.* (1995) found that an *egt* gene deletion mutant of AcMNPV caused earlier degradation of the Malpighian tubules in comparison to the wild-type AcMNPV. They speculated that this earlier degradation results in the faster speed of kill. Another possibility is that the general level of protein synthesis is elevated in larvae infected with the *egt* deletion virus (due to relatively higher levels of active ecdysteroids). Consistent with this hypothesis, Kang *et al.* (2000) found that virus encoded and virus induced proteins are expressed earlier in the infection cycle and at higher levels in larvae of *B. mori* that are infected with BmEGTZ, an *egt* gene deletion mutant of BmNPV, in comparison to the larvae infected with the wild-type BmNPV. Thus, mature progeny virions may be made and released more quickly in larvae infected with BmEGTZ than in larvae infected with BmNPV resulting in a faster systemic infection and death. Kang *et al.* (2000) have also shown that virus specific and certain host specific proteins are induced in a concentration dependent manner by the injection of purified ecdysteroids into BmEGTZ infected larvae (24 h prior to injection of ecdysteroids), but not in larvae infected with BmNPV. Furthermore, using a histochemical assay they showed that virus transmission is positively correlated with the amount of ecdysteroids that are injected into a larva (i.e., the higher the amount of ecdysteroids injected, the faster the transmission of the virus). In contrast, O'Reilly *et al.* (1995) found that the pathogenicity of a recombinant *egt*-gene-deleted AcMNPV that expresses biologically active PTTH (vEGT⁻PTTHM) is dramatically reduced (LC_{50} of 280×10^5 versus 3.8×10^5 polyhedra per ml) in comparison to vEGTDEL. This effect was not found in a PTTH expressing recombinant AcMNPV (vWTPTTHM) in which the *egt* gene was functional. In vEGT⁻PTTHM infected larvae of *S. frugiperda*, the titer of ecdysteroids spiked at around 96 h p.i. (1162 ± 476 pg μl^{-1}) and quickly dropped at 120 h p.i. (45 ± 12 pg μl^{-1}). In contrast, in vEGTDEL infected larvae, the titer of ecdysteroids increased at 72 h p.i. (519 ± 199 pg μl^{-1}) and remained high at 96 h p.i. (282 ± 55 pg μl^{-1}) and 120 h p.i. (334 ± 80 pg μl^{-1}). Although the peak ecdysteroid titer in vEGT⁻PTTHM infected larvae appeared to be significantly higher than that found in vEGTDEL infected larvae, this may not be the case because a higher percentage (54.5 ± 21.0% versus 32.3 ± 5.1%) of the ecdysteroids in the vEGT⁻PTTHM infected larvae were in the conju-

gated form in comparison to vEGTDEL infected larvae.

An elegant approach to further improve the *egt* gene deletion construct has been to insert an insect selective neurotoxin gene cassette into the *egt* gene locus, thus generating a toxin expressing, *egt* gene inactivated construct. For example, Chen *et al.* (2000) inserted an AaIT-GFP gene cassette (*aait* and green fluorescent protein (*gfp*) genes driven by the *polh* gene promoters of HaSNPV and AcMNPV, respectively) into the *egt* gene locus of HaSNPV (also known as HearNPV) in order to generate HaCXW2. In time-mortality bioassays, they found that the ST_{50} of second instar *H. armigera* infected with HaCXW2 was reduced by 32% (63.9 versus 94.4 h) and 8% (63.9 versus 69.5 h) in comparison to control larvae infected with wild-type HaSNPV or HaCXW1 (a recombinant HaSNPV carrying *gfp* at its *egt* gene locus). Sun *et al.* (2002, 2004) also showed that HaCXW1 and HaCXW2 were effective pest control agents under field conditions. In their field experiments, second instar *H. armigera* were allowed to feed on HaCXW1 or HaCXW2 treated plots (1.8×10^{10} polyhedra per 0.015 hectare plot containing 800 cotton plants) for 12 h, then the larvae were transferred to artificial diet and reared at ambient temperature. The ST_{50} values of the larvae infected with HaCXW1 or HaCXW2 in the field were reduced by 15% (101 versus 119 h) and 26% (88 versus 119 h), respectively, in comparison to control larvae that were field infected with HaSNPV. Treatment of cotton plants in the field with HaCXW1 or HaCXW2 reduced leaf consumption by approximately 50% and 63%, respectively. The results of additional field trials using HaSNPV-AaIT (a recombinant HaSNPV expressing AaIT under a chimeric ph-p69p promoter at the *egt* gene locus) are discussed below.

From these results it appears that deletion of the *egt* gene from the baculovirus genome is a useful strategy to improve its speed of kill and consequently its insecticidal activity, but by itself the reduction in speed of kill is too small to be of commercial value. Deletion of the *egt* gene, however, reduces the number of progeny viruses that are produced in comparison to the wild-type virus. Thus, the fitness of the *egt* gene deleted virus appears to be reduced in comparison to the wild-type virus. Conceptually, removal of an endogenous gene from its genome is safer than the insertion of a heterologous gene because a "new" gene will not be introduced into the environment. In practice, however, it is believed that there will be no significant difference in the risk of a recombinant baculovirus pesticide in which an endogenous gene is deleted from the genome or in which a heterologous gene is inserted into the genome. Safety issues and fitness of the virus are further discussed below.

6.9.4.2. Removal of Other Nonessential Genes

In a comparative study of seven completely sequenced lepidopteran baculovirus genomes, Hayakawa *et al.* (2000a) identified 67 putative genes that were common to all seven. When Herniou *et al.* (2001, 2003) added four additional lepidopteran NPVs and a GV (i.e., a total of 12 completely sequenced lepidopteran baculoviruses) 62 common genes were identified. Considering that the genomes of most baculoviruses encode well over 100 putative genes, these findings suggest that a large number of genes in the genome of lepidopteran baculoviruses may serve auxiliary or host specific functions or help to improve the fitness of the virus. This hypothesis is consistent with the finding that 61 out of the 136 putative genes of BmNPV appear not to be essential for viral replication in BmN cells, i.e., some level of viral replication was detected even when a gene was deleted by replacement with a *lac*Z gene cassette (Kamita *et al.*, 2003b; Gomi, Kamita, and Maeda, unpublished data). These findings suggest that there are a number of target genes that can be removed from the baculovirus genome in order to decrease fitness, alter host specificity, or simply to obtain a virus that may replicate faster or more efficiently.

Dai *et al.* (2000) have identified a mutant of *S. exigua* MNPV (SeXD1) that is lacking 10.6 kb of sequence (encoding 14 complete or partial genes including an *egt* gene homolog) that corresponds to the region between 13.7 and 21.6 map units in the wild-type SeMNPV genome. Dose-mortality bioassays in third instar larvae of *S. exigua* showed that the LD_{50}s of SeXD1 and SeMNPV (403 and 124 polyhedra per larva, respectively) were not significantly different. Time-mortality bioassays indicated that the ST_{50} of third instar *S. exigua* infected with SeXD1 was reduced by 25% (70.2 versus 93.1 h) in comparison to control larvae infected with SeMNPV. Dai *et al.* (2000) did not further examine which gene or genes in this 10.6 kb region are involved in decreasing the virulence of SeXD1 in comparison to SeMNPV. Considering that deletion of the *egt* gene from other baculoviruses has been shown to reduce the survival times of larvae infected with these viruses, the *egt* gene homolog of SeMNPV appears to be a prime candidate as the gene involved in reducing the virulence. However, several of the other genes that were deleted in this region are commonly found in other baculoviruses and may play roles in enhancing infection (e.g., *gp37*) or dissemination (e.g., v-*cath*, *chiA*, and

ptp-2) of the virus. Genes that help to enhance virulence or improve dissemination, but are nonessential, are potential targets for deletion in order to reduce the fitness of the virus.

As discussed above, the ST_{50} of larvae that are infected with an *egt* gene-deleted mutant baculovirus is often reduced in comparison to larvae that are infected with the wild-type virus. This reduction in survival time often results in the production of fewer progeny viruses (i.e., fewer polyhedra per larva) suggesting that the fitness of the *egt* gene deleted virus will also be reduced in comparison to the wild-type virus. Two other baculovirus genes that are involved in altering the virulence of the baculovirus are *orf603* (Popham *et al.*, 1998a) and *Ac23* (Lung *et al.*, 2003) both of AcMNPV origin. The LC_{50} of an AcMNPV variant (V8) in which the *orf603* gene is truncated is not significantly different from that of AcMNPV. The AcMNPV V8 variant (as well as other mutants in which the *orf603* gene was specifically inactivated) shows an ET_{50} that is reduced by approximately 12% (e.g., 88.5 versus 100.8 h) in comparison to a revertant virus (i.e., a virus in which the *orf603* mutation was repaired). In an attempt to further decrease the speed of kill of the V8 variant of AcMNPV, Popham *et al.* (1998a) inserted the *tox34* gene under the control of either the *p6.9* or *hsp70* promoter into the *egt* gene locus of V8 generating V8EEp6.*9tox34* and V8EEHSP*tox34*, respectively. In time-mortality bioassays in neonate larvae of *S. frugiperda* (at an LC_{95} dose), the ET_{50}s of V8EEp6.*9tox34* and V8EEHSP*tox34* were reduced by approximately 34% (58.2 versus 88.2 h) and 42% (51.2 versus 88.2 h), respectively, in comparison to control larvae infected with V8EGTdel, an *egt* gene deletion mutant of V8. However, in comparison to larvae infected with viruses in which the *orf603* gene was not deleted (but expressing the *tox34* gene under the *p6.9* or *hsp70* promoter at the *egt* gene locus), no differences were found in the ET_{50}s. They speculated that the relatively small decrease in speed of kill elicited by deletion of the *orf603* gene was masked by expression of the toxin gene.

A low-pH-activated fusion protein called GP64 is found in the envelopes of all group I NPVs, but lacking in group II NPVs. A different low-pH-activated envelope fusion protein called the F protein (Westenberg *et al.*, 2002) has been identified in group II NPVs. F proteins were first identified in LdMNPV (Pearson *et al.*, 2000) and SeMNPV (Ijkel *et al.*, 2000); however, F protein homologs are found in the genomes of all of the sequenced baculoviruses (i.e., both group I and group II NPVs and GVs) (Hayakawa *et al.*, 2000a; Herniou *et al.*, 2001). The F proteins of group II NPVs can functionally substitute for GP64 (Lung *et al.*, 2002), whereas the F proteins of group I NPVs appear not to function in membrane fusion (Pearson *et al.*, 2001). Lung *et al.* (2003) found that Ac23, the F protein homolog of AcMNPV, is not essential for AcMNPV replication in Sf-9 or High 5 cells or larvae of *T. ni*. The growth curve of *Ac23*null, an *Ac23* deletion mutant of AcMNPV, is indistinguishable to those of a repair virus of *Ac23*null (*Ac23*null-repair) or wild-type AcMNPV. *Ac23*null and *Ac23*null-repair also show indistinguishable lethal doses in larvae of *T ni*. However, in survival-time bioassays, the survival times of neonate or fourth instar *T. ni* that are infected with *Ac23*null are at least 28% (26 h) longer than those of control larvae infected with *Ac23*null-repair or AcMNPV (i.e., viruses that carry the *Ac23* gene). Interestingly, although not quantified, Sf-9 cells infected with *Ac23*null appear to produce significantly lower yields of polyhedra in comparison to Sf-9 cells infected with the control viruses (G.W. Blissard and O.Y. Lung, personal communication).

Wandering is a behavior that normally occurs only at the end of the larval stage in lepidopteran larvae (Nijhout, 1994; Goulson, 1997). At this stage, holometabolous insects stop feeding, void their gut, and look for a suitable location to pupate. Baculoviruses can artificially induce wandering in infected larvae to increase virus spread (Evans, 1986; Vasconcelos *et al.*, 1996; Goulson, 1997). It is recently found that baculovirus induced wandering requires a virus encoded protein tyrosine phosphatase (*ptp*) gene using a *ptp* gene deleted mutant of BmNPV (BmPTPD; S.G. Kamita, S. Maeda, and B.D. Hammock, unpublished data). Time-mortality bioassays (at an LC_{99} dose) showed that the ST_{50}s of BmPTPD or BmNPV infected neonate larvae of *B. mori* were not significantly different (88.1 and 81.7 h, respectively). BmPTPD infected neonates, however, did not display any symptoms of virus induced wandering as did the BmNPV infected neonates. Thus, the *ptp* gene is directly involved in increasing the dissemination of the virus. Removal of this gene may reduce the dispersal (and consequently fitness) of the virus in the field.

6.9.4.3. Alteration of Host Range

Although baculoviruses have been isolated from more than 400 insect species (Tanada and Kaya, 1993), most baculovirus isolates are permissive only in the original insect host from which they were isolated. Thus, the host range of individual baculoviruses is considered to be narrow. Among

baculoviruses, AcMNPV has a relatively wide host range being infectious against more than 30 insect species (Gröner, 1986) including a large number of pest insect species. The baculovirus must overcome a number of obstacles both at the organismal and cellular levels in order to replicate and eventually kill the insect host. At the organismal level, the polyhedra must first dissociate and release ODVs that can establish a primary infection. As discussed above, the dissociation of the polyhedra requires high pH and the presence of proteases, whereas the released ODVs must pass through at least three midgut barriers prior to establishing a systemic infection. At the cellular level, the BV must recognize and attach to a receptor on the cell surface, and enter the cell via endocytosis. Subsequently, the nucleocapsid must translocate to a nuclear pore, enter the nucleus, uncoat to release viral DNA, express early genes, initiate viral DNA synthesis, express late genes, and assemble and release mature virions. The baculovirus is able to express some early genes in a wide variety of insect cells (Miller and Lu, 1997; Thiem, 1997). Significantly, reduced levels of viral DNA synthesis and late gene promoter activity are also observed in some nonpermissive insect cells lines. Thus, the host range of a baculovirus may be limited, at least in terms of insect hosts, to its ability to: (1) express the entire complement of early genes; (2) synthesize genomic DNA at normal levels; (3) express late/very late genes at normal levels; and/or (4) assemble and release mature virions. Other key factors in the ability of a baculovirus to productively infect a host cell include its ability to inhibit: (1) the premature or global cessation of protein synthesis (Thiem, 1997) and (2) virus induced apoptosis (Miller *et al*., 1998; Clem, 2001).

The gypsy moth *L. dispar* and the *L. dispar* derived Ld652Y cell line are nonpermissive hosts of AcMNPV (Gröner, 1986; Du and Thiem, 1997a; Chen *et al*., 1998). AcMNPV infection of Ld652Y cells induces cytotoxicity and a premature cessation of host and viral protein synthesis (Du and Thiem, 1997b; Mazzacano *et al*., 1999). An *L. dispar* multicapsid NPV (LdMNPV) gene, host range factor 1 (*hrf-1*), has been identified that promotes AcMNPV replication in Ld652Y cells (Thiem *et al*., 1996; Du and Thiem, 1997a) and gypsy moth larvae (Chen *et al*., 1998). LdMNPV *hrf-1* does not function as an apoptotic suppressor (Du and Thiem, 1997b), however, *in vitro* translation assays indicate that the mechanism of translation arrest involves defective or depleted tRNA species (Mazzacano *et al*., 1999). In neonate larvae of *L. dispar*, the LC_{50} of a recombinant AcMNPV carrying the *hrf-1* gene of LdMNPV (vAcLdPD) is reduced by greater than 1800-fold (1.2×10^5 versus 2.2×10^8 polyhedra per ml) in comparison to AcMNPV. The LC_{50} of vAcLdPD, however, was still tenfold higher (1.2×10^5 versus 1.1×10^4 polyhedra per ml) than that of LdMNPV in neonate *L. dispar*. In second instar larvae of *H. zea*, the LC_{50} of vAcLdPD is 5.8-fold lower (5.49×10^5 versus 3.17×10^6 polyhedra per ml) than that of AcMNPV. However, the LC_{50} of AcLdPD was not significantly different to that of AcMNPV in second instar larvae of *P. xylostella* (AcMNPV resistant insect) and *S. exigua* (AcMNPV sensitive insect).

Two different types of antiapoptotic genes, *p35* and *iap*, have been identified in baculoviruses (Clem *et al*., 1996; Clem, 2001; Bortner and Cidlowski, 2002). The *p35* gene of AcMNPV was first shown by Clem *et al*. (1991) to function as an inhibitor of apoptosis in baculovirus infected Sf-21 cells. The P35 protein is an inhibitor of caspases (Bump *et al*., 1995; Xue and Horvitz, 1995) in a very wide variety of organisms (Clem, 2001; Bortner and Cidlowski, 2002). The first *iap* gene was identified by Crook *et al*. (1993) in *Cydia pomonella* GV. Subsequently, *iap* gene homologs have been identified in at least 10 other baculoviruses and a wide range of other organisms (Clem, 2001). The wild-type AcMNPV induces apoptosis in SL2 cells, a cell line derived from the Egyptian cotton worm *S. littoralis* (Chejanovsky and Gershburg, 1995; Du *et al*., 1999). The yield of AcMNPV BV in SL2 cells infected with AcMNPV is approximately 2700-fold lower than that of Sf-9 cells infected with AcMNPV. A recombinant AcMNPV (vHSP-P35) that overexpresses the *p35* gene of AcMNPV under the *hsp70* promoter does not induce apoptosis in SL2 cells; however, vHSP-P35 still produces low yields of BV (Gershburg *et al*., 1997). Lu *et al*. (2003) have found that AcMNPV is able to efficiently replicate in SL2 cells and larvae of *S. littoralis*, if it expresses higher levels of IE1 (an essential, multifunction protein that was first identified by its ability to transactivate baculovirus early genes) relative to IE0 (another protein that is capable of transactivating baculovirus early genes). The IE0 product is a longer form (by 54 N-terminal amino acids) of the IE1 product that is the result of transcriptional initiation from the *ie0* transcription initiation site and removal of the *ie0* intron (Friesen, 1997). Lu *et al*. used two approaches to increase the level of IE1 relative to IE0. First, they generated a mutant virus that expressed lower levels of IE0 by disrupting the *ie0* promoter by insertion of a 519 bp-long DNA fragment or a chloramphenicol acetyltransferase gene. Second, they generated

a recombinant AcMNPV (vHsp-1) that expressed a second copy of the *ie1* gene under the constitutively expressed *hsp70* promoter. Both of these approaches generated genetically modified AcMNPVs with host ranges that extended to *S. littoralis*.

At present, overexpression of AcMNPV *ie1* and insertion of LdMNPV *hrf-1* into the AcMNPV genome are the only ways in which the host range of AcMNPV can be extended to include pest insect species. Other AcMNPV genes that are involved in extending host range or dramatically increasing virulence include *p35* (Clem *et al.*, 1991; Hershberger *et al.*, 1992; Clem and Miller, 1993; Griffiths *et al.*, 1999), the DNA helicase gene *p143* (Maeda *et al.*, 1993; Croizier *et al.*, 1994), host cell specific factor 1 (*hcf-1*; Lu and Miller, 1995), late expression factor 7 (*lef-7*; Lu and Miller, 1995), and immediate early gene 2 (*ie2*; Prikhod'ko *et al.*, 1999). The roles of these genes in host range expansion and increase of virulence is discussed in the previous chapter.

6.9.5. Safety of GM Baculoviruses

The safety of a synthetic chemical or biologically based pesticide can never be assured with absolute confidence. Thus, when society considers whether or not a new pesticide is "safe," a better question to ask might be: What level of risk are we as a society willing to accept for a given benefit? In the case of chemical pesticides, the general public and a wide array of researchers (scientists, medical doctors, governmental regulators, statisticians, pathologists, ecologists, etc.) have analyzed the actual, potential, and perceived risks that they pose to human health and the environment. In general, all of these stakeholders agree that the benefits of chemical pesticides sufficiently outweigh any short- or long-term risks that they may pose. Society is thus willing (and should be willing) to accept some level of risk for a given benefit (e.g., increased yields of food, fiber, and feed from a given amount of natural resource). There are of course instances in which society has determined that the costs and risks associated with a particular pesticide (e.g., DDT) outweigh the benefits. In terms of the use of a GM baculovirus pesticide, this leads us to the following questions: (1) what are the risks associated with the field release of a GM baculovirus? (2) are these risks worth the benefits? and (3) are these risks any greater than the risks associated with the use of a chemical insecticide? A number of research studies and essays have addressed the first question. Miller (1995) and Hails (2001) suggest that the primary focus of assessing the risks of the field release of a GM baculovirus should include:

1. How the GM baculovirus affects nontarget species.
2. Whether the introduced gene provides a selective advantage to viral replication, survival, and/or host range (i.e., is fitness improved).
3. Should the introduced gene transfer to another organism, will this event provide a selective advantage to that organism.

6.9.5.1. Potential Effects of a GM Baculovirus on Nontarget Species

The potential of natural and recombinant baculoviruses to induce a deleterious effect upon vertebrates has been extensively studied (Burges, 1981; Black *et al.*, 1997). More than two dozen different baculoviruses have been tested in a wide range of vertebrates including 10 different mammalian species, birds, and fish. The baculoviruses in these tests were administered by various routes including inhalation, topical application, injection (intravenous, intracerebral, intramuscular, intradermal), and orally. Baculovirus induced deleterious effects were not observed in any of these tests. Direct and indirect tests on human subjects have also been conducted including oral administration of high (greater than 10^9 polyhedra) doses of polyhedra of HzSNPV over a period of 5 days (Heimpel and Buchanan, 1967). The blood of workers who were involved in the production of HzSNPV during a 26 month long period was analyzed for infectious baculovirus, baculoviral antigens, or baculoviral antibodies – none were detected (Black *et al.*, 1997). Furthermore, the ubiquitous baculovirus load from foods in our diet may be quite high (Heimpel *et al.*, 1973; Thomas *et al.*, 1974). For example, Heimpel *et al.* (1973) found that a square inch (approximately $6.5\,cm^2$) of cabbage taken from a store shelf may contain up to 2×10^6 polyhedra suggesting that consumption of a single serving of coleslaw ($16\,in^2$ of cabbage) exposes us to up to 3.2×10^7 polyhedra. These studies indicate that we live under constant exposure to baculoviruses with no apparent deleterious effects. The lack of deleterious effects is not completely unexpected since polyhedra are extremely insensitive to the neutral or acidic pH conditions of the vertebrate digestive system. Thus, any polyhedra that are normally ingested while eating coleslaw, for example, pass through the digestive tract and are either excreted intact or should any ODVs be released they are quickly inactivated first by the action of pepsin at low pH and subsequently by the pancreatic proteases at neutral pH (Black *et al.*, 1997; Miller and Lu, 1997).

Beginning in 1995, two studies have shown that baculoviruses can serve as highly efficient vehicles for the transfer of foreign genes into the nuclei of primary cultures of human, mouse, and rat hepatocytes and human hepatoma cell lines (Hofmann *et al*., 1995; Boyce and Bucher, 1996). Since then, baculoviruses have been shown to be able to transduce a number of mammalian cell types including human neural cells (Sarkis *et al*., 2000), human fibroblasts (Dwarakanath *et al*., 2001), human keratinocytes (Condreay *et al*., 1999), and several established mammalian cell lines (Boyce and Bucher, 1996; Shoji *et al*., 1997). Nonmammalian, vertebrate cell lines (e.g., fish cells) have also been transduced with a recombinant baculovirus (Leisy *et al*., 2003; Wagle and Jesuthasan, 2003). At first glance, these studies appear to raise concerns about the risks of baculoviruses that are used for pest control. However, upon careful consideration it is believed that they provide further evidence as to the safety of GM baculoviruses. First, these studies show that although the baculovirus can enter the mammalian cell, productive baculovirus infection does not occur even following inoculation at exceptionally high multiplicities of infection (MOI) of up to 1500 pfu per cell using a virus inoculum that was concentrated by ultracentrifugation (Hofmann *et al*., 1995; Barsoum *et al*., 1997; Shoji *et al*., 1997; Kost and Condreay, 2002; Hu *et al*., 2003). Furthermore, the inoculated cells did not show any visible cytopathic effects, grew normally, and showed normal plating efficiencies. Second, in all of these examples, the foreign gene is expressed only when placed under a promoter that is specific for mammalian cells (e.g., cytomegalovirus immediate early, Rous sarcoma virus long terminal repeat, simian virus 40, etc.). Foreign gene expression was never observed under a very late baculoviral promoter. Third, although transduction was successful in established cell lines and primary cultures, the direct application of baculoviruses for gene delivery to the liver *in vivo* is strongly reduced or inhibited because the baculovirus activates the complement (C) system (Sandig *et al*., 1996; Hofmann and Strauss, 1998). The C system represents a first line of host defense of the innate immune system for the elimination of foreign elements (Liszewski and Atkinson, 1993). Baculoviruses possess a number of characteristics including their inability to replicate in mammalian cells and induce any deleterious effects that make them ideal gene delivery vectors for human gene therapy and as a screening systems for proteins and other molecules of human health interest (Lotze and Kost, 2002).

All of the studies to date indicate that there are no known risks associated with human (or other vertebrate) exposure to baculoviruses. Thus, a second focus in the discussion of the safety of recombinant baculoviruses should focus on nontarget lepidopterans and other invertebrates such as predatory or beneficial insects. As discussed above and in the previous chapter, the normal host range of a baculovirus is generally limited to the lepidopteran insect species from which it was originally isolated (Gröner, 1986). This assessment of "host range," however, is potentially problematic because it is often based upon the ability of a baculovirus to elicit virus specific symptomology or death. Huang *et al*. (1997) have tested seven different recombinant NPVs (based on AcMNPV, BmNPV, LdMNPV, or OpMNPV) carrying a reporter gene encoding β-galactosidase, secreted alkaline phosphatase (SEAP), or luciferase under the control of an early (ETL) or very late (*polh*) promoters. These reporter viruses were tested in 23 different insect species from eight insect orders (Blattodea, Coleoptera, Diptera, Hemiptera, Homoptera, Lepidoptera, Neuroptera, and Orthoptera) and 17 families. The reporter viruses were initially injected into the test insects by hemocoelic injection. Insects that supported virus replication (i.e., on the basis of expression of the reporter protein) by injection were subsequently tested by *per os* (oral) inoculation with the preoccluded form of the virus. The use of these reporter viruses allowed the detection of both symptomless and pathogenic infections. By the injection experiments, β-galactosidase, SEAP, and luciferase activities were found only in the lepidopteran larvae. Consistent with previous reports, AcMNPV had the widest host range in the 10 lepidopteran hosts that were tested, whereas LdMNPV was the most host specific. Host range following *per os* inoculation was more limited in comparison to inoculation by injection. In fact two species, the monarch butterfly *Danaus plexippus* and gypsy moth *L. dispar*, that appeared to be susceptible (to AcMNPV, OpMNPV, and BmNPV) by injection were not susceptible by *per os* inoculation. Additionally, as pointed out by Cory and Myers (2003) the host range of a baculovirus in the field may be considerably narrower due to spatial or temporal differences that are not found in the laboratory.

Other studies have looked at whether natural enemies of lepidopterans such as parasitoids, scavengers, and predators (McNitt *et al*., 1995; McCutchen *et al*., 1996; Heinz *et al*., 1995; Li *et al*., 1999; Smith *et al*., 2000b; Boughton *et al*., 2003) are adversely affected when they prey upon larvae that are infected with recombinant or wild-

type viruses. The social wasp *Polistes metricus* is a beneficial insect that preys on lepidopteran larvae (Gould and Jeanne, 1984). McNitt *et al.* (1995) analyzed five developmental parameters (i.e., larval development time, pupal development time, larval mortality, mean nest size, and mean number of adults per nest) in order to assess colony health and individual vigor of *P. metricus* that fed on lepidopteran larvae infected with recombinant AcMNPVs expressing AaIT or TxP-I. These toxins were expressed under either the constitutive *hsp70* or very late *polh* promoter. There were no significant differences in any of the developmental parameters tested when the *P. metricus* fed on uninfected or virus infected (at 3 days before exposure to *P. metricus*) fourth or fifth instar *S. frugiperda*. In related experiments, McCutchen *et al.* (1996) allowed the parasitic wasp *Microplitis croceipes* to parasitize second instar *H. virescens* that were subsequently infected with AcAaIT, AcJHE.KK, or AcMNPV (at a greater than LC_{99} dose, 5×10^4 polyhedra per larva) at various times (0, 48, 72, 96, or 120 h) postparasitization. The survival of the parasitoid was less than 4% at 0 and 48 h postparasitization but increased gradually until 120 h postparasitization, when there was no significant difference in the virus or mock treated *H. virescens*. There were no significant differences in terms of time taken for emergence of the adult wasp, ability of the F_1 wasps to oviposit, or sex ratios of the F_1 wasps. However, there were significant differences in the time (205–216 versus 228 h) taken for emergence of the larval parasitoid from virus infected *H. virescens* in comparison to mock infected *H. virescens*. This was particularly evident in the AcAaIT infected larvae. McCutchen *et al.* (1996) suggested that the parasitoid larva responds to the poor condition of its host by prematurely emerging. Additionally, wasps that developed from AcAaIT or AcJHE.KK infected larvae were significantly smaller than wasps that developed from mock infected larvae.

The green lacewing, *Chrysoperla carnea* Stephens, insidious flower bug, *Orius insidiousus* (Say), red imported fire ant, *Solenopsis invicta* Buren, big-eyed bug, *Geocoris punctipes* (Say), convergent lady beetle, *Hippodamia convergens* Guerin-Meneville, and twelve-spotted lady beetle, *Coleomegilla maculata* DeGeer are generalist predators that attack larval lepidopterans such as *H. virescens*. Heinz *et al.* (1995) have looked at the development times of green lacewings and flower bugs that fed upon near-dead second instar larvae of *H. virescens* (three per day) that were infected with a greater than LC_{99} dose (5×10^4 polyhedra per larva) of AcAaIT or AcMNPV. They found no significant differences in the survival percentages of insects that fed upon AcAaIT-, AcMNPV-, or mock-infected *H. virescens*. There was a significant but short (19.1 versus 20.6 days) decrease in the larva-to-adult development time in green lacewings that fed upon AcAaIT or AcMNPV infected *H. virescens* in comparison to lacewings that fed upon mock infected *H. virescens*. One may speculate that the protein quality in the prey might be reduced due to overexpression and agglomeration of the toxin proteins resulting in these subtle differences. Li *et al.* (1999) have investigated the life history traits (rate of food consumption, travel speed, fecundity, and adult survival) of fire ants, big-eyed bugs, and convergent lady beetles fed on second instar *H. virescens* that were infected with one of seven viruses (AcMNPV, HzSNPV, HzSNPV expressing LqhIT2 under the *ie1* gene promoter, or AcMNPV expressing LqhIT2 or AaIT under the *ie1* or *p10* gene promoters) at 24 or 60 h prior to predation by the predator. No significant shifts in the life history characteristics were detected in predators that fed on any of the virus infected larvae in comparison to predators that fed on healthy larvae.

Boughton *et al.* (2003) have analyzed the adult survival, developmental time, and oviposition rates of green lacewings and twelve-spotted lady beetles fed upon first or second instar *H. virescens* that were infected with $100 \times LC_{50}$ doses of AcMLF9.ScathL (recombinant AcMNPV expressing a basement membrane degrading protease under the *p6.9* gene promoter) or AcMNPV. Unexpectedly, lacewings that fed on the AcMLF9.ScathL infected *H. virescens* showed significantly elevated survival rates in comparison to AcMNPV infected or uninfected *H. virescens*. Boughton *et al.* (2003) speculated that the protease expressed by AcMLF9.ScathL enhanced the efficiency of feeding of the lacewing. No significant differences were found in developmental time, time to onset of oviposition or mean daily egg production of lacewings that fed on virus infected or uninfected larvae. Most of the twelve-spotted lady beetles that fed exclusively on *H. virescens* (either uninfected or virus infected) died. There was no evidence that feeding on AcMLF9.ScathL infected larvae induced any adverse effects in comparison to AcMNPV infected larvae. Furthermore, neither the lacewing nor lady beetle exhibited any feeding preferences for AcMLF9.ScathL-, AcMNPV-, and mock-infected insects. On the basis of these findings, Boughton *et al.* (2003) concluded that there was no greater risk to insect predators by the use of AcMLF9.ScathL in comparison to the use of AcMNPV as a biological pesticide. Smith *et al.*

(2000a) have investigated the density and diversity of nontarget predators under field conditions following the application of recombinant baculoviruses (AcMNPV or HzSNPV expressing scorpion toxin LqhIT2 under the *ie1* gene promoter) on cotton. They found that predator densities and diversity were similar between recombinant and wild-type baculovirus treated plots. In contrast, the chemical pesticide (esfenvalerate) treated plots had consistently lower predator populations.

Taken together, these studies indicate that: (1) the amount of baculovirus expressed toxin or protease that accumulates in the larvae is not sufficient to induce any adverse effects on the predator; (2) the baculovirus is not infectious towards the predatory insects; and (3) the toxin or protease encoding gene is not expressed in the predatory insect. In some cases, there appear to be some costs associated with the beneficial insects that prey upon virus infected larvae. However, these costs are significantly lower in comparison to the costs associated with the application of synthetic chemical pesticides. The development of selective recombinant insecticides should augment any IPM program by reducing the impact on nontarget species, including beneficial insects. Consequently, the resurgence of primary pests and outbreaks of secondary pests should be minimized.

6.9.5.2. Fitness of GM Baculoviruses

Fitness is a term that describes the ability of an organism to produce progeny that survive to contribute to the following generation (Cory, 2000). In order to estimate the relative fitness of a recombinant baculovirus in comparison to the wild-type baculovirus, five key parameters should be assessed: speed of kill, yield, transmission, dispersal, and persistence. Speed of kill (or time to death), virus yield, and transmission rate can be easily determined by laboratory bioassays (as discussed above) and in some cases under field conditions. Although the relationship between speed of kill (generally quantified in terms of LT_{50}) and virus yield is complex, faster speed of kill generally results in dramatically lower virus yields. This correlation between improved speed of kill and reduced virus yield is found regardless of the parental virus that is genetically modified, and for modifications in which an effector gene is inserted or when an endogenous gene is deleted from the genome. For example, the speeds of kill of third, fourth, or fifth instar larvae of *T. ni* that are infected with AcAaIT or AcJHE.KK are reduced by approximately 30% and 8%, respectively, in comparison to control larvae infected with AcMNPV. These faster speeds of kill result in reductions of approximately 80% and 40% in the yields (polyhedra per milligram of cadaver) of AcAaIT and AcJHE.KK, respectively, in comparison to the yield of AcMNPV (Kunimi *et al.*, 1996). Dramatic reductions of up to 95% in virus yield (polyhedra per microgram of cadaver) are found in second and fourth instar larvae of AcTOX34.4 infected *T. ni* in comparison to control AcMNPV infected larvae (Burden *et al.*, 2000). The corresponding reductions in the mean times to death are 50–60%. A reduction in virus yield is also found by deletion of the *egt* gene of AgMNPV (Pinedo *et al.*, 2003). The mean lethal times of third instar larvae of *A. gemmatalis* infected with various doses of vAgEGTΔ-*lacZ* is reduced by 10–26% in comparison to control larvae infected with the same dose. The yield (polyhedra per gram of cadaver) of vAgEGTΔ-*lacZ* is reduced by approximately 50% in comparison to control larvae infected with the wild-type AgMNPV. Similar results are found in fifth instar larvae of *S. frugiperda* infected with vEGTDEL, which produce 23% fewer polyhedra per insect (the yield of virus per milligram of cadaver is not, however, significantly different) in comparison to control larvae infected with AcMNPV (O'Reilly and Miller, 1991). O'Reilly *et al.* (1991) and Ignoffo *et al.* (2000) speculated that this correlation between improved speed of kill and reduced virus yield results from the considerably reduced size of recombinant baculovirus infected larvae at the time of death.

Milks *et al.* (2001) have focused on intrahost competition between AcAaIT and AcMNPV or AcAaIT and TnSNPV in larvae of *T. ni* that were synchronously or asynchronously infected. They found no differences in the fitness of the genetically modified or wild-type viruses in terms of virus yield. The most important factors in these mixed infections were dose and timing. The virus that was inoculated at the highest dose or the virus that was first inoculated was the one that had the competitive advantage. These findings are not unreasonable when one considers that there are no significant differences in the replication rates of toxin gene carrying and wild-type baculoviruses in cell culture.

A key component of the transmission rate of a virus is its pathogenicity or potency (often quantified in terms of the LD_{50} or LC_{50}). In general, the pathogenicity of a baculovirus is not significantly changed following the insertion of a neurotoxin gene into its genome (McCutchen *et al.*, 1991; Tomalski and Miller, 1992; Prikhod'ko *et al.*, 1996; Harrison and Bonning, 2000b), although there are a few exceptions in which relatively small

(threefold or less) increases or decreases have been observed (Chen *et al.*, 2000; Harrison and Bonning, 2000b). Deletion of an endogenous baculovirus gene such as *egt* also results in no significant (O'Reilly and Miller, 1991; Slavicek *et al.*, 1999) or relatively small (Pinedo *et al.*, 2003) differences in pathogenicity. However, the pathogenicity of the virus can be dramatically increased (i.e., lower LD_{50} or LC_{50}) by 4- to 100-fold by genetic modifications that improve the ability of the virus to penetrate the midgut, i.e., by the expression of enhancins (Hayakawa *et al.*, 2000b; Popham *et al.*, 2001) or incorporation of *Bt* toxin into the polyhedra (Chang *et al.*, 2003). In these cases, it is believed that the enhancin or *Bt* toxin helps the virus to pass more easily through the midgut and establish a more rapid systemic infection. In contrast, however, there were no significant differences in the LC_{50} values of recombinant AcMNPVs expressing basement membrane degrading proteases (stromelysin-1, gelatinase A, of cathepsin L) under early or late promoters (Harrison and Bonning, 2001).

Another component of the transmission of a virus is the rate at which the virus and host come into contact. This component is obviously more difficult to quantify in the field. As described above, neurotoxin-induced paralysis will cause the insect to fall off the plant (Cory *et al.*, 1994; Hoover *et al.*, 1995; Sun *et al.*, 2004). This knock-off behavior results in lower levels of foliage contamination, thus the likelihood that a second host insect will come into contact with the recombinant virus (at least during feeding on the plant) will be reduced. In contrast, the wild-type virus infected larvae will most likely die on the plant, thereby increasing the potential for contact between the virus and host. Lee *et al.* (2001) have examined this behavioral effect in a greenhouse microcosm. They found that the wild-type AcMNPV out-competed recombinant viruses (AcAaIT or AcJHE.SG) for a niche in the greenhouse microcosm. AcMNPV and AcJHE epizootics lasted for 8 weeks after the initial release of the virus, whereas the AcAaIT epizootic ended by the fourth week after release. Additionally, AcMNPV polyhedra also increased to greater numbers in the soil in comparison to AcAaIT or AcJHE.SG after 8 weeks. A reduction in wandering behavior resulting from the inactivation of the *ptp* gene may also reduce foliage contamination as discussed above. In both of these examples, the transmission rate of the recombinant baculovirus should be reduced because the likelihood of a host insect and virus coming into contact is reduced.

Dispersal is another parameter that should be assessed in order to determine the fitness of a virus. Abiotic and biotic agents that are known to disperse baculoviruses include rainfall, air currents, predators, parasites, scavengers, and grazing mammals (Fuxa, 1991; Fuxa and Richter, 1994). Predatory and scavenging insects have been found to carry (within their digestive tracts) and disperse recombinant virus (in excrement) at rates of up to 125 cm per day over a period of up to 10 days (Lee and Fuxa, 2000). Thus, recombinant virus induced behavioral changes of the host larvae such as knock-off effects that reduce predation and scavenging will also reduce the dispersal of the virus. Additionally, the ability of the biotic agent itself to disperse the recombinant baculovirus may be reduced. For example, parasitic wasps that develop within larvae of *H. virescens* that are infected with recombinant baculoviruses are significantly smaller than wasps that develop within wild-type virus infected larvae (McCutchen *et al.*, 1996). Thus, the ability of the smaller wasps to travel, and subsequently disperse the recombinant virus, may be reduced because it has less energy reserves and reduced flight capability in comparison to wasps that developed on wild-type virus infected larvae.

Persistence is the final parameter that should be considered when determining the relative fitness of a genetically modified baculovirus. In general, inactivation by sunlight (ultraviolet radiation) is the primary route of inactivation of polyhedra in the environment (Ignoffo and Garcia, 1992; Black *et al.*, 1997; Ignoffo *et al.*, 1997). In contrast, soil and foliage are factors that can protect the virus from sunlight and subsequently increase its persistence (Peng *et al.*, 1999). Knock-off or other behavioral changes induced by the recombinant virus may increase their relative concentrations in the soil such that the recombinant's persistence is increased. In contrast, however, the transmission rate of this recombinant should be reduced because the potential for contact between the virus and host is reduced. The cuticle is another factor that can protect the virus from sunlight such that viral persistence is increased. Fuxa *et al.* (1998) found that the cadavers of *T. ni* that are killed by recombinant viruses (AcAaIT, AcJHE.KK, or AcJHE.SG) take much longer to disintegrate (4–7 days versus 1 day) in comparison to AcMNPV killed *T. ni*. Another report by Ignoffo and Garcia (1996) found, however, that there is no significant difference in the time to cell lysis following death by AcAaIT or AcMNPV (lysis took 1.7 versus 1.5 days, respectively). Clearly, viral fitness is dependent upon a large number of intricately integrated factors. Finally, it is also important to consider as suggested by Hammock (1992) that genetically modified baculoviruses are designed to

be biological insecticides and not biological control agents that will become permanently established. Thus, a recombinant baculovirus should by its very design show reduced fitness in comparison to the wild-type.

6.9.5.3. Movement of the Introduced Gene to Another Organism

The insecticidal efficacy of natural baculoviruses is dramatically improved by insertion of a foreign gene into the genome or inactivation (deletion) of an endogenous gene from the genome or a combination of both. The insertion strategy generally involves the insertion of an effector gene that encodes a protein that is detrimental to the target insect, alters its life cycle or stops it from feeding. The deletion strategy generally involves the inactivation of an endogenous gene (e.g., *egt* or *orf603*) by inserting another gene into its coding sequence. This other gene can be a marker gene such as *lacZ* or an effector gene as described above. In both cases, the genes are placed under a baculoviral or insect promoter. Several critical points should be kept in mind with these strategies. First, the genes are placed under promoters that are active only in insect cells (and in the case of late/very late baculoviral promoters, these promoters also require the products of baculoviral early genes for activity). Thus, should the effector gene and its promoter somehow jump to the genome of a noninsect cell, the gene will not be expressed. Second, the proteins encoded by the effector genes are chosen because they target some critical aspect of the pest insect life cycle or body. The proteins are not biologically active in the noninsects (although it is possible that they may induce an immunological response). Thus, if the effector gene somehow jumps to the genome of a noninsect cell, and if this gene is somehow expressed, detrimental effects will not result.

Genomic variants of baculoviruses are often found in individual field collected insects (Cherry and Summers, 1985; Maeda *et al*., 1990; Shapiro *et al*., 1991; Hodgson *et al*., 2001); this suggests that recombination and/or transposition events commonly occur between baculovirus genomes. Extensive homology between the donor and recipient DNA molecules and replication of both DNA molecules is required for high-frequency recombination to occur (Kamita *et al*., 2003b). Such conditions may occur when two heterologous viruses (that share some genomic homology) infect the same cell within the same insect. This scenario is the most likely one in which an effector gene of a GM baculovirus will jump to another organism (i.e., another insect virus). Should the effector gene jump to another virus under these conditions, the fitness of the new recombinant virus will be reduced in comparison to the original GM baculovirus and it too should be rapidly eliminated from the environment. In a second scenario in which the effector gene jumps from the GM baculovirus to the genome of the insect host, the effector gene could cause an adverse effect. However, these effects should be limited to a single individual because once this individual dies the effector gene will also "die." It is also possible that heterologous or random recombination events may lead to the movement of an effector gene to another organism. The same arguments that were made in regard to the homologous recombination based movement can be made in this case. However, the likelihood of heterologous recombination is much lower than the likelihood of homologous recombination.

6.9.6. Field Testing and Practical Considerations

Laboratory and greenhouse testing has generated a great deal of knowledge about the efficacy, safety, and environmental fate of GM baculovirus pesticides as described above. Mathematical models have also been generated to evaluate the effectiveness and ecological consequences of the release of GM baculoviruses (Dwyer and Elkinton, 1993; Dwyer *et al*., 1997; Dushoff and Dwyer, 2001). Field testing, however, over both the short-term (e.g., single growing season) and long-term (e.g., multiple seasons and years) is still necessary to confirm the findings of laboratory and greenhouse tests and the accuracy of mathematical models. The commercial potential of GM baculoviruses and practical considerations regarding their use can also be determined by field testing. Issues regarding the commercialization of GM baculovirus insecticides including marketing, *in vivo* and *in vitro* production, formulation, storage, and public acceptance are discussed in detail by Black *et al*. (1997).

Some of the earliest field trials of GM baculoviruses (occlusion-negative AcMNPVs carrying junk DNA or *lacZ* marker gene) were performed in England during the mid to late 1980s (Levidow, 1995; Black *et al*., 1997). In the USA, the first field trial (a 3-year study) of a GM baculovirus (a *polh* gene deleted AcMNPV that was co-occluded with wild-type AcMNPV) was begun in 1989 (Wood *et al*., 1994). These early field trials were performed primarily to analyze the environmental persistence of the virus. These trials showed that the persis-

tence of occlusion-negative constructs is exceptionally low. The first field trial to test the efficacy of an occlusion-positive, AaIT expressing AcMNPV (AcST-3) was performed in 1993 (Cory *et al.*, 1994). Cory *et al.* (1994) found that cabbage plants treated with AcST-3 showed 23–29% lower feeding damage (by third instar larvae of *T. ni*) in comparison to wild-type AcMNPV treated cabbage plants. This reduction in feeding damage (approximately 50% reduction) was not as large as that found in the laboratory trials (Stewart *et al.*, 1991). The reduction in feeding damage during the field trial was due to the earlier death of AcST-3 infected larvae in comparison to AcMNPV infected larvae. Cory *et al.* (1994) also found that the yield of AcST-3 was tenfold lower (9.9×10^7 versus 9.6×10^8 polyhedra per larva) in comparison to AcMNPV. Furthermore, they found that under the high (10^8 polyhedra per ml) dose treatments the majority (62%) of the larvae of AcST-3 treated cabbage were knocked off the plant whereas none were knocked off the AcMNPV treated cabbage. They speculated that both the behavioral (knock-off) and pathological (reduced yield per larva) differences between the recombinant and wild-type viruses would have important implications for risk assessment as discussed above.

The American Cyanamid Company performed the first field trials in the USA (one in Georgia and the other in Texas) to test the efficacy of an occlusion-positive, *egt* gene deleted, AaIT expressing AcMNPV in 1995 and 1996 (Black *et al.*, 1997). They found that this virus killed target insects faster than wild-type AcMNPV or an *egt* gene deleted AcMNPV, which resulted in increased control of the target insect. In 1997 and 1998, field trials were conducted by academic scientists and scientists at DuPont Agricultural Products (Smith *et al.*, 2000a) to assess (1) the efficacy of recombinant baculoviruses in protecting cotton, (2) the impact of recombinant virus introduction on predators, and (3) the ability of predators to disperse recombinant baculoviruses. Two occlusion-positive constructs (one based on AcMNPV and the other on HzSNPV) expressing LqhIT2 were tested. Depending upon the timing of the application, they found that the LqhIT2 expressing viruses were able to protect cotton from damage better than the wild-type virus (AcMNPV or HzSNPV) and as well as a synthetic chemical pesticide (esfenvalerate). Predator densities and diversity were similar between the recombinant and wild-type virus treated plots, whereas plots treated with the chemical pesticide had consistently smaller predator populations. Finally, they found that at 2–5 days after the initial application of virus, a very small percentage (0.2%) of predators that were caught and evaluated carried DNA from a recombinant virus. In 1998, Treacy *et al.* (2000) (American Cyanamid Company) conducted field trials in the USA (two in Georgia and one in North Carolina) to test the efficacy of two occlusion-positive constructs (AcMNPV and HzSNPV based) expressing AaIT in protecting cotton. They found that the recombinant HzSNPV (at 5 or 12×10^{11} polyhedra per hectare) protected cotton against heliothine complex larvae at slightly better levels than either the recombinant AcMNPV or *Bt* toxin (Dipel 2X, Abbott Laboratories, at 1121 g (WP) per hectare).

In 2000, Sun *et al.* (2004) conducted field trials in People's Republic of China (in Henan and Hubei provinces) to test the efficacy of HaSNPV-AaIT (an occlusion-positive recombinant HaSNPV expressing AaIT at the *egt* gene locus) in protecting cotton. Cotton plant plots treated with HaSNPV-AaIT showed significantly less damage to squares, flowers, and bolls in comparison to plots treated with the wild-type HaSNPV or HaSNPV-EGTD (HaSNPV with a deletion in its *egt* gene). In 2001 and 2002 (Hubei province), treatment of cotton plants during the entire growing seasons with HaSNPV-AaIT increased the yield of cotton lint by approximately 18% (1250 versus 1023 and 1800 versus 1474 kg per hectare in 2001 and 2002, respectively) in comparison to wild-type HaSNPV treated plots. The yield of cotton lint in plots treated with HaSNPV-AaIT was not significantly different from the yield (1083 and 1994 kg per hectare in 2001 and 2002, respectively) in plots treated with chemical pesticides (λ-Cyhalothrin EC, endosulfan, β-Cypermethrin on different dates).

Numerous field trials have been conducted over the past 10 years at geographically distant sites using several types of GM baculovirus constructs and under different cropping situations. These trials show that GM baculoviruses are effective and safe pesticides with efficacy that can be at levels similar to synthetic chemical pesticides or *Bt* toxin. The field trials also indicate that the recombinant baculovirus will not persist in the environment and has very little, if any, adverse activity against beneficial insects.

6.9.7. Concluding Remarks

The majority of people in both developed and developing countries are dependent upon others to produce or otherwise provide the minimum requirements of food, water, and/or shelter necessary for survival. A society must carefully manage and allocate its limited resources in order to provide these

minimum requirements for all of its members. Over the past five decades, the use of synthetic chemical pesticides has significantly increased the yields of food, fiber, and feed that producers are able to generate from a given amount of land. Although chemical pesticides have without a doubt improved the efficiency of agricultural output and reduced the incidence of disease by killing disease vectors, chemical pesticides are also a source of environmental pollution and both acute and chronic problems for human health. The inappropriate use of chemical pesticides has also helped to generate pesticide resistant insects. These problems are often intensified in developing countries because of poor governmental regulation and training in the appropriate use of these agents. Furthermore, the high costs of the newest generation of synthetic chemical pesticides are precluding their widespread use in many developing countries. These pressures in the agricultural industry are making biological control agents highly attractive as supplements or replacements for synthetic chemical pesticides in integrated pest management schemes.

While biological pesticides avoid chemical residue problems, many such agents lack sufficient potency and speed of action in the field (at least until recently) to be attractive alternatives. As discussed in this chapter, a fresh approach to biological insect control involves using the best genes of nature to enhance insecticidal properties of naturally occurring baculoviruses. Several laboratories, including the authors', have developed NPVs that have the knock-down speed of classical chemical insecticides on the noctuiid complex of insect pests while not harming nontarget species. The viruses are applied like classical insecticides, but they present no residue problems, and they are active on insects resistant to classical insecticides. Industry and academic scientists have overcome most of the limitations associated with natural baculovirus pesticides, especially in terms of effective crop protection, through the use of recombinant DNA techniques and other technologies. Furthermore, should baculoviruses appear to offer sufficient commercial potential for investment, many of the remaining limitations (e.g., those that are specific to a particular cropping situation) can be quickly addressed and overcome. The safety of baculoviruses has been thoroughly investigated and there is no evidence that natural or recombinant baculoviruses provide an increased threat to human or environmental health.

A large number of genetically modified baculovirus pesticides have been described in the scientific literature and, undoubtedly, many more have been tested in academic, governmental, and commercial laboratories. With the currently available genes and parental viruses, it is believed that the fastest speed of kill (median lethal time) that can be achieved is around 48 h because the virus will most likely have to undergo two replication cycles before the host insect is killed. Feeding cessation (median time to feeding cessation) will occur earlier, perhaps as early as 24–36 h postinfection. Feeding cessation at 24 h postinfection should be sufficient to make GM baculovirus pesticides competitive with synthetic chemical insecticides in terms of the protection of many types of crops. In terms of a “best performing” GM baculovirus pesticide, AcMNPV offers the widest host range in terms of infectivity against pest insect species. To this parental virus we would insert at the *egt* gene locus a gene encoding AaIT fused to a bombyxin signal sequence that is expressed under a chimeric late–very late promoter (e.g., P_{SynXIV}). We prefer the AalT encoding gene instead of the mite toxin encoding gene (although the mite toxin gene appears to be more insecticidal) because its mode of action is known and the action of AaIT is synergized with pyrethroid insecticides. LqhIT2 is a viable alternative to AaIT. Also, in comparison to the other insect selective toxins such as those from spiders and sea anemones, AaIT and LqhIT2 have undergone more testing. We prefer expression under a baculovirus late-very promoter because of the slightly improved selectivity that such a promoter has in comparison to baculovirus early or constitutive promoters. We prefer the bombyxin signal sequence because it has been shown to efficiently secrete a wide variety of proteins in a wide variety of insect cells. Deletion of the *egt* gene may reduce the fitness of the virus. Other parental viruses such as HzSNPV or RoMNPV are also viable options for pest species that are not highly susceptible to AcMNPV. Additionally, the coexpression of a protease or polyhedrin-*Bt* toxin fusion protein may help the virus to penetrate the midgut more quickly resulting in a faster systemic infection.

The safety and effectiveness of GM baculoviruses as pest insect controlling agents has been studied for more than 25 years. During this time, thousands of peer-reviewed studies on the basic biology, host range, ecology, efficacy, safety, and applications of natural and recombinant baculoviruses have been published. Baculoviruses are very commonly used in hundreds of academic and commercial laboratories as protein expression vectors, as gene transfer vehicles, for surface display, and as a model system to study large DNA viruses. Natural baculoviruses are used as effective pest insect control agents in several regions of the world. This chapter primarily reviews (1) major milestones in the development of

recombinant baculoviruses for pest insect control, (2) current strategies to generate recombinant baculoviruses with improved feeding prevention and speed of kill, and (3) potential risks associated with the use of recombinant baculoviruses for pest insect control. A tremendous knowledge base is now available regarding the efficacy and safety of genetically modified baculoviruses for pest insect control. Despite this, there are some that would argue that there are unseen and unpredictable risks associated with the release of any genetically modified organism into the environment. The authors agree with this, but would also like to argue that it is impossible to completely avoid all risk associated with the use of any pesticide. We believe that the benefits afforded by GM baculoviruses far outweigh any unseen or unpredicted risks that they pose, especially in comparison to the potential risks associated with the use of chemical pesticides or genetically modified plants. The current research indicates that GM baculovirus pesticides meet or exceed the high standard of expectation set by synthetic chemical insecticides. GM baculovirus pesticides are safe, effective, and ready for immediate use.

This chapter shows that the generation of exceptionally safe and efficient biological pesticides, which readily compete with chemical pesticides, has been achieved. The technology has been tested for many years and the results are not completely unsatisfactory, and indeed are favorable in many cases. However, GM baculoviruses still have limited use in the field. Therefore, it is concluded that these are other reasons why the implementation of an available, safe, and effective pest control technology is not moving at the pace it should have done. Several world-class pesticide manufacturing companies have shown interest in the technology throughout the years. They obtained and licensed critical patents and started their own research programs that positively synergized the efforts of others. On the one hand, this commercial interest has brought excitement and acceleration to the field, on the other hand, the cancellation of their biologicals programs after several years of research have taken a high toll on the commercialization of GM baculoviruses. Were the cancellations based on scientific knowledge or the ineffectiveness or safety of the viruses? Presented here are the studies that indicate otherwise. Was profitability an issue? GM baculoviruses now compete with chemical pesticides and examples of profitable industrial manufacturing schemes of non-GM baculoviruses exist. Was public perception an issue? Recombinant organisms have been safely used for many years now and chemical pesticides have more proven side effects than highly specific baculoviruses. Thus, we believe that the lack of implementation of GM baculoviruses is primarily due to a psychological effect.

Academic laboratories have already done their part by introducing GM baculovirus technology for the benefit of mankind and by presenting proof on its profitability. However, in the process, we may also have been shown that it is quite easy to take the technology and use it without regard to the intellectual property rights. This by itself should not be an excuse because legal ways to protect international patent rights exist. To negate the negative psychological effects of seemingly unsuccessful commercialization is, therefore, the greatest problem in this field of research as we see it. There is also more to do in terms of introducing the end-users to the merits of GM baculoviruses. One thing academic researchers might have done more efficiently is better outreach. This might have induced the agricultural cooperatives to look at this new alternative earlier on and might have helped them to start production on the farm or on a large scale. The intellectual property rights as they are currently held probably exclude this possibility. So why not publicize all relevant patents to encourage the technology rather than burying it? This is a possibility that all private and public patent holders should consider at this point. The Brazilian experience is exemplary and could be a model for other parts of the world. In that instance, even though studies were initiated by the government, cooperatives and private companies eventually showed interest in commercial production of non-GM baculoviruses.

Throughout the years, attempts have been made on many occasions to liaise with the leading scientists in the field in order to achieve a level of organization and to initiate private commercial interest. But the time has now come to put all the work done in perspective by either increasing the cooperation between everyone in the field to obtain a positive result or perhaps accepting the fact that this group of biopesticides will never reach the shelves. We believe that efforts should be directed towards more practical aspects of the field including increased outreach activities and free access to the technology. A discussion involving all interested parties of the problems associated with immediate commercialization will be critical. Countries where GM baculoviruses are actively used could of course provide insight into how to successfully commercialize GM baculoviruses. The studies to date on GM baculoviruses presented in this chapter clearly show that it would be a great waste to abandon this technology.

Acknowledgments

This work was funded in part by grants from the USDA (2003–35302-13499), NIEHS (P30 ES05707), and NIH (AI58267). We thank Dr. B.C. Bonning for critical review of the manuscript and N.M. Wolf for access to data prior to publication.

6.10 The Biology and Genomics of Polydnaviruses

B A Webb, University of Kentucky, Lexington, KY, USA
M R Strand, University of Georgia, Athens, GA, USA

6.10.1. Introduction to the Biological System

The Polydnaviridae are a unique group of viruses that are specifically associated with parasitoid wasps in the families Braconidae and Ichneumonidae (Webb *et al*., 2000). There are an estimated 40 000 species of parasitoids that carry polydnaviruses (PDVs) (Whitfield, 2000), and many of these species are of great economic importance as biological control agents of insect pests. The hosts of PDV-carrying parasitoids are almost exclusively larval stage Lepidoptera (moths and butterflies). Two genera of PDVs are currently recognized: the bracoviruses (BVs), which are associated with braconids, and the ichnoviruses (IVs), which are associated with ichneumonids (Webb *et al*., 2000). PDVs are the only viruses with segmented DNA genomes and all have a similar life cycle. PDVs persist as stably integrated proviruses in the genome of associated wasps and replicate in the ovaries of females. The life cycle and transmission of PDVs within the context of the parasitoid life cycle are shown schematically in Figure 1. When the female wasp lays an egg into a host, she injects a quantity of virus that infects hemocytes and other tissues. PDVs do not replicate in the wasp's host, but the virus confers protection from the host's immune system and alters other aspects of host physiology that allow the parasitoid to develop successfully. Thus, a true mutualism exists between PDVs and wasps, as viral transmission depends on parasitoid survival and parasitoid survival depends on infection of the host by the virus. The mutualistic association between PDVs and wasps has also profoundly affected the organization of PDV genomes such that they are unlike any other viruses. This chapter reviews the function of polydnaviruses in relation to our current understanding of polydnavirus genome structure and composition.

6.10.1.1. Fundamental Observations and the Discovery of Polydnaviruses

Like many other areas of biological research, the study of polydnaviruses began with a series of observations by early investigators. These observations then led to more detailed studies that continue to fascinate researchers today. To give the reader a historical perspective of the field, the discussion begins by recapitulating some of these early discoveries.

Entomologists have known for more than a century that the reproductive tracts of female wasps

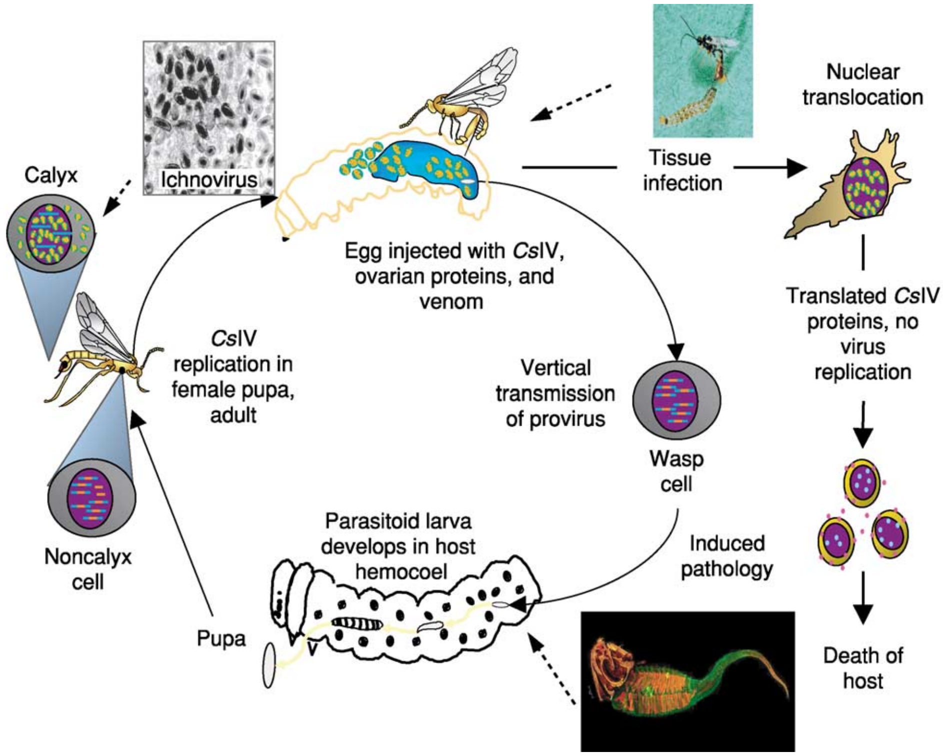

Figure 1 Parasitoid and polydnavirus life cycle. *Cs*IV, ichnovirus of *Campoletis sonorensis*.

could be easily isolated by anesthetizing the insect, grasping the ovipositor with forceps, and then gently pulling until the ovipositor separates from the wasp's body. Attached to the ovipositor are the common and lateral oviducts, ovaries, and accessory glands that together comprise the female's reproductive tract. Numerous investigators examined and described the reproductive morphology of parasitoids from many families (Clausen, 1940). In the late 1960s, however, researchers using a dissecting microscope and intense light noticed that the lateral oviducts of braconids and ichneumonids contained numerous eggs and a dense fluid with an iridescent blue color. Tearing of the oviduct resulted in extrusion of this highly viscous fluid that remained closely associated with the wasp eggs. Upon examination by electron microscopy, the fluid was found to consist of densely packed particles that structurally resembled viruses. The first species examined in this way was the campoplegine ichneumonid *Venturia canescens*. These observations led to the particles being called virus-like particles (VLPs) (Rotheram, 1967, 1973; Stoltz *et al*., 1976). Ironically, the VLPs of *V. canescens* are unusual in that they lack DNA (see Section 6.10.2). However, further characterization of VLPs from other species of ichneumonids led to the discovery that most contained double-stranded, circular DNAs (Vinson and Scott, 1975; Stoltz and Vinson, 1979a; Krell *et al*., 1982). Studies of braconids also identified DNA-containing virus like proteins (VLPs) that ultrastructurally resembled baculoviruses (Stoltz *et al*., 1976; Stoltz and Vinson, 1977). Based on the characteristics of these DNAs, morphology of the particles, and life cycle, these VLPs were recognized as a phylogenetically distinct family of viruses named the Polydnaviridae (Brown, 1986; Stoltz *et al*., 1995; Webb *et al*., 2000).

The virus-containing fluid of the oviduct was formally named "calyx fluid" upon learning that PDVs replicate specifically in the calyx cells that form the junction between the ovarioles and oviduct (Stoltz and Vinson, 1977, 1979). It was also recognized that the blue color of calyx fluid was due to diffraction of light through the densely packed viruses. To assess the functional importance of PDVs in parasitism, initial experiments focused on collecting calyx fluid, separating it from the wasp eggs, and then separately injecting wasp eggs and calyx fluid into host larvae. These studies demonstrated that wasp eggs rarely survive in the absence of calyx fluid, whereas hosts injected with calyx fluid exhibit many of the symptoms of hosts naturally parasitized by the wasp. Coinjection of calyx fluid and wasp eggs also resulted in successful development of the parasitoid that was indistinguishable from natural parasitism (Edson *et al*., 1981). This indicated that

PDVs alone are able to induce significant alterations in the physiology of the lepidopteran host. Coinjection of calyx fluid and wasp eggs resulted in successful development of the parasitoid that was indistinguishable from natural parasitism (Edson *et al*., 1981). Thus, PDVs induce changes in the physiology of the lepidopteran host that permit survival and development of wasp eggs and larvae. Viral transcripts from parasitized hosts were detected by investigators of several parasitoid–host systems (e.g., Blissard *et al*., 1987; Harwood *et al*., 1994; Hayakawa *et al*., 1994; Strand, 1994; Asgari *et al*., 1996; Galibert *et al*., 2003) but our understanding of virus function has benefited more recently from detailed analysis of PDV genomes (see Section 6.10.2). These data shed important light on the role PDVs have in the parasitized host (see Section 6.10.3), and in turn led to questions about the relationship between genome organization as related to biological activity (see Section 6.10.4). In particular, recent analyses strongly suggest that genome organization has been influenced by the restriction of viral replication to the parasitoid, which imposes important constraints on PDV function in parasitized hosts (Stoltz, 1993; Webb, 1998; Turnbull and Webb, 2002). The diversity of genes encoded by PDVs, and the physiological effects they have on parasitized hosts suggest that significant opportunities exist for using these viruses in insect control (see Section 6.10.5). Understanding the relationship between genome organization and physiological functions will also be essential to developing an understanding of the origins and evolution of PDVs (see Section 6.10.6). The genomic diversity and complexity of PDV genomes also raise important questions and opportunities regarding the direction and future of polydnavirus research (see Section 6.10.7).

In presenting this historical overview, an attempt has been made to convey the most important early observations of this field, while simultaneously outlining the chapter's organization. Research on polydnaviruses has now progressed well beyond these primary observations. But this background should be kept in mind, as we discuss PDV research in more technical detail because the significance and limitations of the work is best appreciated when related to the fundamental biology of these fascinating systems.

6.10.1.2. Parasitoid Biology and Phylogenetic Distribution of Polydnaviruses

Parasitoids are free-living insects as adults but are parasites of other arthropods during their immature stages. Hosts are usually located by the adult female, who lays her eggs in or on the host's body. The parasitoid larva then completes its development by feeding on host hemolymph and/or tissues. Parasitoids usually have limited host ranges and parasitize only a specific life stage (egg, larval, pupal, adult). Most parasitoids also complete their development by feeding on a single host, with hosts almost always being killed as a consequence of parasitization (Vinson and Iwantsch, 1980). Parasitoids in which a single offspring develops per host are referred to as solitary species, while parasitoids that produce two or more offspring per host are called gregarious. Parasitoids are also distinguished by whether larvae feed on the outside (ectoparasitoids) or inside (endoparasitoids) the hosts, and whether hosts cease to develop after parasitism (idiobionts), or remain mobile and continue to grow after parasitism (koinobionts). Idiobionts include ectoparasitoids that permanently paralyze their hosts and endoparasitoids that attack sessile host stages like eggs or pupae. Most koinobionts are endoparasitoids that parasitize insect larvae. Taxonomically, approximately 80% of all parasitoids belong to the order Hymenoptera (ants, bees, and wasps), 15% to the order Diptera (flies), and the remaining species are restricted to a few genera in other insect orders (Quicke, 1997).

The order Hymenoptera is divided into several lineages that include sawflies or woodwasps, and the monophyletic suborder Apocrita, which contains most species of parasitoids (Dowton and Austin, 1994; Whitfield, 1997). The Apocrita are usually divided into nine superfamilies. One of these superfamilies is the Ichneumonoidea, which itself is divided into the families Braconidae and Ichneumonidae (**Figure 2**). The Ichneumonoidea are all parasitoids and represents one of the largest recognized superfamilies in the animal kingdom with an estimated 100 000 species. As noted above, the family Polydnaviridae and the associated genera of bracoviruses and ichnoviruses are restricted exclusively to this superfamily. The phylogenetic relationships among braconids are sufficiently well characterized to conclude that the approximately 17 000 species of braconids that carry BVs comprise a monophyletic lineage, which has been associated with PDVs for at least 60 million years (Whitfield, 1997, 2000). This lineage consists of four subfamilies known to carry PDVs (Microgastrinae, Cardiochilinae, Miracinae, and Cheloninae) and several others that may carry PDVs but that have not been examined and confirmed to do so (Shaw and Huddleston, 1991; Dowton and Austin, 1994). The evolutionary transitions among subfamilies in the Ichneumonidae are less clear as no comprehensive phylogenetic analysis of the family has yet been published (Quicke *et al*.,

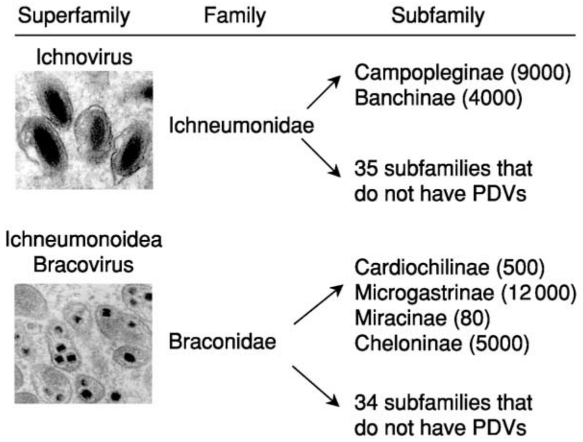

Figure 2 Phylogeny of PDV-containing parasitoids. Micrographs show ichnovirus and bracovirus virion structure (courtesy of D. Stoltz). Parenthetical numbers represent estimated number of species within each genus (estimates courtesy of M. Sharkey).

2000). However, nearly all species that carry IVs belong to the currently recognized subfamily Campopleginae, which contains approximately 9000 species. Previous studies suggest that IVs may also occur in at least some genera of Banchinae and Ctenopelmatinae (Stoltz and Whitfield, 1992). Recent analyses using both morphological and 28S rDNA data do not conclusively support the Campopleginae as monophyletic, nor do they resolve the relationship between campoplegines and banchines (Quicke *et al.*, 2000). Regardless of these uncertainties, the absence of PDVs among any of the basal extant lineages of the Ichneumonoidea strongly suggests that the association of BVs with braconids and IVs with ichneumonids arose independently. This conclusion is also corroborated by the distinct differences in morphology (see below) and nucleic acid sequences (see below) between IVs and BVs (Webb, 1998; Whitfield and Asgari, 2003).

All PDV-carrying ichneumonids are solitary endoparasitoids of lepidopteran larvae that completely consume the host and pupate within the remnant host cuticle. PDV-carrying braconids in the subfamilies Microgastrinae, Miracinae, and Cardiochilinae are either solitary or gregarious endoparasitoids. These species also parasitize larval stage Lepidoptera but unlike ichneumonids are primarily hemolymph feeders (Strand, 2000). Upon completing development, the larva chews its way out of the host to pupate. The moribund host usually retains a full complement of internal tissues but nonetheless dies shortly after wasp emergence (Beckage, 1993; Harvey and Strand, 2002). Braconids in the subfamily Cheloninae are solitary egg–larval parasitoids that oviposit into egg stage Lepidoptera, but their offspring complete development in the host's final larval stadium (Lawrence and Lanzrein, 1993).

The vast majority of PDV-carrying parasitoids have restricted host ranges, usually being able to parasitize only a few species of hosts. It is also common for the same host species to be parasitized by more than one species of PDV-carrying wasp. Hosts that are parasitized by a given wasp are referred to as being permissive, while species that do not support parasitoid development are nonpermissive or resistant. The permissive hosts for a given PDV-carrying species of parasitoid are almost always in the same family and often are in closely related genera.

Host insects respond to parasitoid attack behaviorally with defensive movements and evasive maneuvers. Even when parasitized, physiological responses to parasitization can still kill the parasitoid through immune responses, which can kill the parasitoid eggs or developing larvae (see Section 6.10.3.1.1). Indeed, whether or not the host immune system is able to recognize and kill the parasitoid often defines permissiveness. Thus, endoparasitoids must develop mechanisms to overcome host behavioral and physiological defenses to survive, while potential hosts have evolutionary needs to respond to those mechanisms. This life or death evolutionary competition occurs at every parasitization event, and therefore it is not surprising that the viruses, which mediate this process, are highly evolved and distinctive biological entities. There are also instances of parasitoid attack in which host larvae show behavioral and physiological symptoms of parasitization but the wasps fail to develop. Such host larvae are termed pseudoparasitized (Beckage and Gelman, 2004) and may represent up to 10% of the instances of "stinging" or apparent oviposition events. Similar phenotypic effects can be induced by injection of virus only, and it is likely that the natural instances of pseudoparasitism are due to oviposition of nonviable eggs or introduction of virus-containing calyx fluid into the hosts without an egg (Edson *et al.*, 1981; Cui *et al.*, 2000). It is possible that instances of pseudoparasitism described above result from successful immune responses to the parasitoid egg but failed immune responses to virus infection. In rarer instances, host larvae may show transient symptoms of parasitization such as a delays in growth but then recover to develop and pupate normally. This phenomenon is more commonly observed in semipermissive or nonpermissive hosts (Cui *et al.*, 2000). It is likely that these events represent failure of the polydnavirus to effectively suppress host immune responses, resulting in host responses that kill wasp eggs or larvae and/or suppress virus expression.

6.10.1.3. Polydnavirus Biology

Several reviews of PDV–parasitoid host associations have been written since their discovery. Some have emphasized the physiological effects of polydnaviruses on host insects (Stoltz and Vinson, 1979a; Beckage, 1993; Strand and Pech, 1995; Schmidt *et al.*, 2001). Others describe virion structure, genome organization, and transmission (Fleming and Krell, 1993; Stoltz, 1993; Webb, 1998; Turnbull and Webb, 2002; Kroemer and Webb, 2004), or provide comparative overviews of parasitoid–PDV associations (Stoltz and Vinson, 1979a; Stoltz and Whitfield, 1992). While literally tens of thousands of parasitoid species carry polydnaviruses, only a few of these species have been studied in any detail. The reader should keep this important point in mind and anticipate that new phenomena involving PDVs are likely to be discovered as additional species are examined. In this review, we consider polydnavirus systems are broadly considered, focusing both on traits that appear to be shared universally among species as well as on features that have been described in only one or two instances but that are nonetheless considered to be significant.

6.10.1.3.1. Polydnavirus life cycle PDV life cycles have been described as having "two arms" (Stoltz, 1993). Virus replication and vertical transmission occur only in the wasp, while viral genes disrupting physiology in the parasitized host function only in that "arm" of the life cycle (**Figure 1**). Both IVs and BVs replicate from proviral DNA in specialized cells of the wasp oviduct (i.e., the calyx cells). Virus replication is first detected in the late pupal stage with virus released from calyx cells by budding (in IVs) (Volkoff *et al.*, 1995) or cell lysis (in BVs) (Stoltz *et al.*, 1976) and accumulating to high concentrations in the oviduct lumen. When the wasp parasitizes its host a quantity of virus is delivered with the wasp egg. The virus enters lepidopteran cells where a host-specific subset of viral genes is expressed without detectable virus replication. Viral gene expression prevents the host immune system from killing the parasite egg thereby enabling wasp survival (Prevost *et al.*, 1990; Strand, 1994; Asgari *et al.*, 1996; Lavine and Beckage, 1996; Cui *et al.*, 2000). Virus transmission to subsequent generations is ensured by stable integration of proviral DNA in the wasp genome (Fleming and Summers, 1991; Gruber *et al.*, 1996; Savary *et al.*, 1999).

6.10.1.3.2. Polydnavirus morphology and physical characteristics Morphologically, all IVs have biconvex nucleocapsids, about 85 × 330 nm, surrounded by two unit membranes (**Figure 2**). BVs in contrast have cylindrical nucleocapsids of similar width (40 nm) but of highly variable length (25–100 nm) surrounded by a single unit membrane (Stoltz and Vinson, 1977) (**Figure 2**). Ichnovirus nucleocapsids are assembled in calyx cell nuclei and appear to acquire single envelope in the nucleus at the periphery of the virogenic stroma during virion assembly (Stoltz and Vinson, 1979a; Norton and Vinson, 1983; Yin *et al.*, 2003). IVs then appear to acquire transiently additional membranes upon exit from the nucleus and transit to the cellular membrane. However, these membranes are lost with the virion's second (external) membrane eventually acquired as viral particles bud from calyx cells. By contrast, BVs are singly enveloped and are released into the oviduct lumen by cell lysis (Stoltz *et al.*, 1976; Stoltz and Vinson, 1977; Wyler and Lanzrein, 2003). BVs may consist of a single nucleocapsid within a virion or multiple nucleocapsids may be embedded within a protein matrix in a manner similar to that of baculoviruses (Stoltz and Vinson, 1977, 1979a) (**Figure 2**). Ultrastructural studies indicated that BVs were released by cell lysis with continued production of virions requiring continued production of virus-producing cells from the calyx (Stoltz and Vinson 1979a). Although virions appeared to be released by cell lysis, analysis of calyx fluid from braconid wasps showed little evidence of cellular debris. This observation was clarified by studies of Wyler *et al.* (2003), who described a structure in the braconid calyx that serves to collect cellular debris, thereby preventing it from entering the calyx fluid, while allowing entry of virions.

Polydnavirus virions are complex with 4-25 proteins visualized by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) (Stoltz *et al.*, 1995; Webb *et al.*, 2000). Few of these proteins have been characterized. Genes encoding two proteins from the *Campoletis sonorensis* ichnovirus (*Cs*IV) have been cloned and analyzed. One of the two genes encodes a protein with a predicted molecular weight of 44 kDa and is not encoded within the viral genome (Deng *et al.*, 2000). The other encodes a 15 kDa protein that is virally encoded (Deng and Webb, 1999). Asgari *et al.* (2003) recently characterized two polydnavirus proteins as similar to the heat shock protein 70 and calreticulin, and hypothesized that these structural proteins may serve chaperonin-like functions. Other structural proteins have been isolated from the *V. canescens* VLPs (that lack nucleic acid) and associated with immune suppression of the host (Asgari *et al.*, 1998, 2002). One can speculate that these structural proteins on the VLPs are

related to PDVs but direct supportive evidence is lacking. Polydnavirus virions also have lipid and carbohydrate moieties but these are essentially uncharacterized (Stoltz *et al.*, 1995; Webb *et al.*, 2002).

6.10.1.3.3. General organization of polydnavirus genomes PDVs are unique among DNA viruses in having segmented double-stranded genomes (**Figure 3**). PDV segments are closed circular DNA molecules ranging in size from 2.0 to over 30 kb (Webb, 1998). BVs generally have fewer but larger segments than IVs (Kroemer and Webb, 2004). Conventionally, PDV segments are identified alphabetically from the smallest to the largest with comigrating DNA segments identified by a numerical suffix (e.g., O^1, O^2 etc.). DNA segment number is quite variable ranging from as few as 6 to over 50 (Stoltz *et al.* 1995; Tanaka *et al.*, unpublished data). Estimates of PDV genome sizes are complicated by comigrating segments and internal sequence homologies between segments (segment nesting) (**Figure 4**), but have been estimated to range from 150 to over 250 kb. A further complication in estimating genome size is that both BV and IV genomes have some segments that appear to be present in hypermolar ratios relative to other segments. The significance of this packaging strategy is considered below (see Section 6.10.4). It is also essential to emphasize that PDV genomes exist in two states: the circular episomal form packaged into

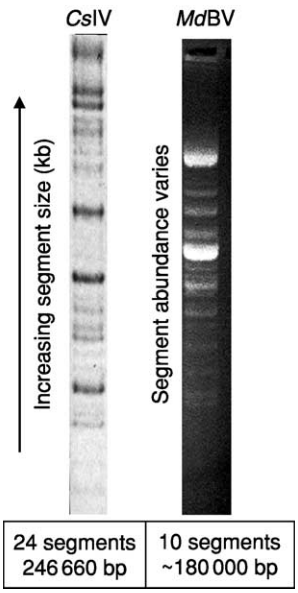

Figure 3 Polydnavirus genomes. Ichnovirus (*Cs*IV) and bracovirus (*Md*BV) genomes are shown after electrophoresis of undigested viral DNA on agarose gels and staining of DNA with ethidium bromide.

nucleocapsids during replication in calyx cells, and the linear proviral form integrated into the wasp genome that exists in all other cells of the wasp's body (Stoltz, 1993; Webb, 1998). Proviral segments seem to be dispersed within the wasp genome in IVs (Fleming and Summers, 1986) but appear to be organized in tandem array in BVs (Savary *et al.*, 1997; Pasquier-Barre *et al.*, 2002; Drezen *et al.*, 2003) (see Section 6.10.2).

Polymorphisms have been described from BV genomes and used to demonstrate Mendellian inheritance of variable segments (Stoltz *et al.*, 1986). Similar polymorphic loci were even present in individual laboratory wasps of a *Cotesia melanoscela* BV (*Cm*BV) laboratory colony having a highly similar genetic background (Stoltz and Xu, 1990). Stoltz and Xu (1990) suggested that inbreeding may lead to a greater number of polymorphisms due to continual interactions between homologous sequences, although relaxed selection pressures associated with the presence of related genes may also contribute.

Little is known about PDV genome packaging strategy. BV nucleocapsids are variable in length, and release of DNA from nucleocapsids by osmotic shock allowed release of circular DNA segments of variable length, which corresponded in size distribution to the nucleocapsid lengths (Gruber *et al.*, 1996). The interpretation of these data is that BV segments are singly encapsidated, and nucleocapsids and their lengths are determined by the size of the encapsidated segment (Gruber *et al.*, 1996; Strand *et al.*, unpublished data). There have been no experimental investigations of IV nucleocapsid packaging although the size of IV capsids is large enough to encapsidate an entire genome equivalent.

6.10.1.3.4. Timing and morphology of polydnavirus replication Replication of IVs is first detected in the late pupal stage of female wasps and continues during the adult stage. Replication is restricted to hypertrophied calyx cell nuclei and has no deleterious effect on the wasp (Stoltz and Vinson, 1979a; Norton and Vinson, 1983). Replication is closely linked with oviduct maturation and may be induced by increasing levels of the insect steroid hormone 20-hydroxyecdysone (20E) (Webb and Summers, 1992). The rate and cytology of replication differ between pupal and adult stages, with increased replication occurring following adult emergence (Volkoff *et al.*, 1995).

Replication of BV segments begins in the oviduct calyx cells during the pupal stage of female parasitoids with the amplification and excision of proviral segments (Albrecht *et al.*, 1994; Gruber *et al.*, 1996; Pasquier-Barre *et al.*, 2002). Wyler and Lanzrein

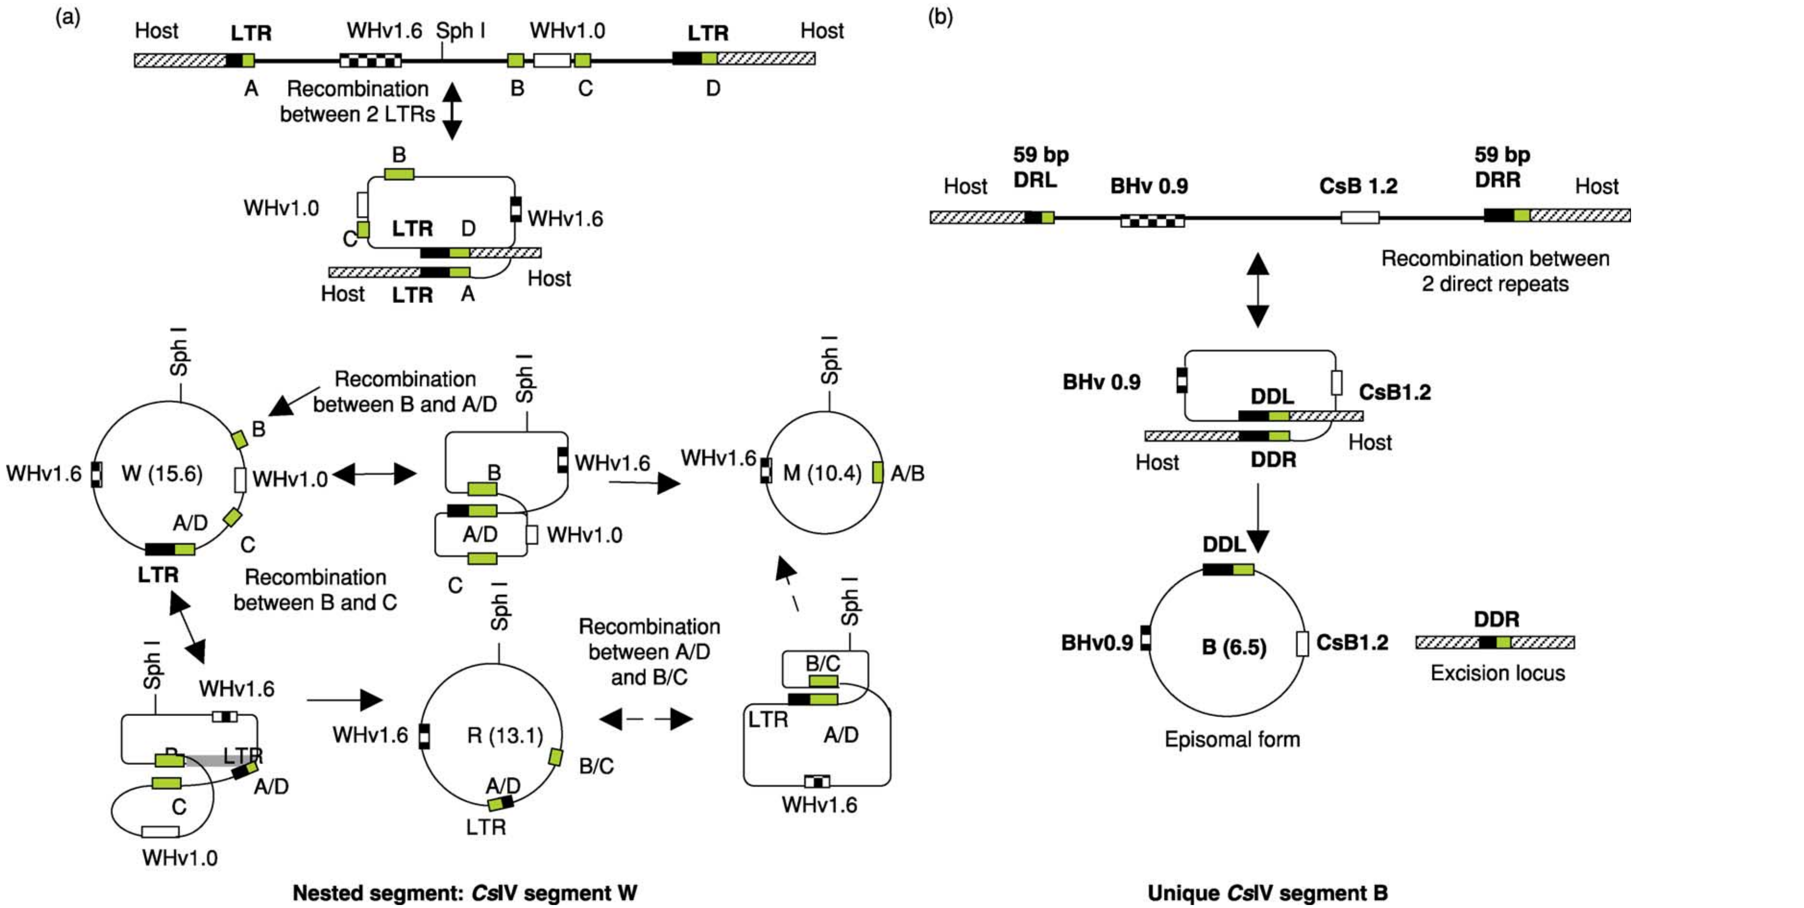

Figure 4 Segment types in ichnovirus genomes. Nested (a) and unique (b) segments are shown in their integrated state and episomal states. Linear schemata show proviral DNA while circular forms are encapsidated within virions. Junctional repeats thought to be important for excision of proviral segments and intramolecular recombination events in nested segments are indicated. DRL, direct repeat left; DRR, direct repeat right; LTR, long terminal repeat.

(2003) describe the morphogenic changes that occur in *Chelonus inanitus* as calyx cells differentiate and *Chelonus inanitus* BV (*Ci*BV) replication begins. As the calyx differentitates, elongated cells appear adjacent to the calyx region of the ovarioles. The calyx cells mature through several stages with cells lower in the calyx showing progressively larger nuclei, and increasing DNA content as measured by propidium iodide staining (Wyler and Lanzrein, 2003). Ribosomes and nuclear pores become abundant around the hypertrophied nuclei and as calyx cells differentiate, and are thought to be important for assembly and transport of mature virion proteins to the nucleus. As cells mature through intermediate stages, calyx cell nuclei become greatly enlarged and develop virogenic stroma with virion envelopes visible at the periphery of the stroma (Wyler and Lanzrein, 2003). Nuclei of mature calyx cells are filled with virions and the nuclear membrane breaks down just prior to cell lysis (Wyler and Lanzrein, 2003). An epithelial cell layer that separates the lysed calyx cells from the oviduct lumen appears to have a phagocytic role and capture debris from the lysed calyx cells. The epithelial layer also seems to be involved in transport of mature virions into the calyx fluid. Because BV calyx cells lyse, continued production of BV virions requires further differentiation of progenitor calyx cells and lysis of the cells after they mature.

6.10.1.3.5. Fate of polydnaviruses in parasitized hosts Most PDV-carrying parasitoids oviposit into the hemocoel of the host larva. Microscopic observations indicate that PDV infection of host tissues is rapid with viral nucleocapsids appearing in proximity of host cell nuclei as early as 2 h post oviposition (Stoltz and Vinson, 1979a). As IVs enter host cells the outer virion membrane appears to fuse to or dissolve the basement membrane, while the inner membrane of the virion fuses with the cellular membrane allowing the virion to enter the cell. The virion nucleocapsid then moves to the nucleus and releases viral DNA within the nucleus. BV virions appear to penetrate the basement membrane and then fuse with the cellular membrane. The BV nucleocapsid is translocated to nuclear pores, where the virion aligns with the pores and nucleocapsid contents, likely viral DNA, appear to be released into the nucleus through the nuclear pore. Although both IV and BV virions enter a variety of tissues, hemocytes are almost always the most heavily infected tissue in terms of the amount of detectable viral DNA (Stoltz and Vinson, 1979b; Strand *et al.*, 1992; Li and Webb, 1994; Strand, 1994; Yin *et al.*, 2003). Preferential infection of hemocytes could be due to the fact that wasps oviposit directly into the hemocoel, and hemocytes are the first cells virions encounter. The fact that hemocytes also lack a basement membrane may further facilitate infection. Chelonine braconids oviposit in host eggs making the process of infection of host tissues different from the scenario described above. These parasitoids often oviposit in host eggs before host tissues are formed, and even cells are often undifferentiated when virus is introduced. Wyder *et al.* (2003) showed that after oviposition *Ci*BV from *C. inanitus* initially remains close to but then enters cells of the host embryo 5–10 h post oviposition. Whether this delay in *Ci*BV infection occurs to allow differentiation of host cells is not known. However, most *Ci*BV DNA is still detected in hemocytes with lesser amounts being present in the fat body, nervous tissue, and the digestive system. The fact that *Ci*BV preferentially infects hemocytes may indicate that PDVs do have very specific tissue tropisms, suggesting that this tropism is also important for PDV pathogenesis in the chelonine wasps.

After infecting hemocytes and other host cells, BVs and IVs persist in episomal form until the host is consumed by the developing parasitoid. Viral transcripts are expressed in some host–parasite systems at near steady-state levels beginning 2–4 h after wasp oviposition and continuing until the wasp's progeny completes development (Theilmann and Summers, 1986; Strand *et al.*, 1992). In other systems, viral expression is transient (Asgari *et al.*, 1996) or in the case of chelonine braconids is delayed until late in the life cycle (Johner *et al.*, 1999) (see below). Unlike the situation in host larvae, some BV and IV DNA segments can persist for months or even years in established lepidopteran cell lines (Kim *et al.*, 1996; McKelvey *et al.*, 1996). Volkoff *et al.* (2001) detected expression of a viral gene (*K19*) over 3 years after infection of Sf9 cells by *Hd*IV from the ichneumonid *Hyposoter didymator*. More recently, Gunderson-Rindal and Lynn (2003) detected random insertion of some segments from *Glyptapanteles indiensis* BV (*Gi*BV) into chromosomal DNA of a *Lymantria dispar* cell line. Integration target sites shared a common motif (CATG), and upstream of this site were similarities to an insect retrotransposon that potentially suggest that viral DNA insertion involves a host-mediated transposition mechanism. These results also suggest the possibility that PDV genetic material could be horizontally transferred to lepidopteran hosts and exchanged between PDV genomes carried by different parasitoids that parasitize the same species of host.

6.10.2. Polydnavirus Genomics

As in other areas of biological research, genomic studies are significantly impacting our understanding of PDVs with the full implications of this work still to be realized. As a result, the polydnavirus genome website has been established and is updated periodically as new genome sequence information becomes available (http.//www.pdvdb-dev.ctegd.uga.edu). In organizing this section, first an overview of PDV genomes that applies to both IVs and BVs is provided. Then the unique organizational features of IV and BV genomes, and the major gene families they encode.

Polydnavirus genomes are unlike other viral genomes. Sequencing of encapsidated viral segments and genomes indicates that PDV genomes are largely noncoding (Cui and Webb, 1997; Wyder *et al.*, 2002). Generally, the genes encoded on these viral segments also have no homology with genes found on other viruses (Asgari *et al.*, 1997; Cui and Webb, 1997; Johner and Lanzrein, 1999; Hilgarth and Webb, 2002; Volkoff *et al.*, 2002; Falabella *et al.*, 2003) (see Section 6.10.6). Genes commonly encoded by DNA viruses such as viral DNA polymerases are absent and most of the genes that are found on PDV segments appear to be related to the pathogenic functions these viruses have in parasitized hosts. (Blissard *et al.*, 1989; Cui and Webb, 1997; Strand *et al.*, 1997) (see Section 6.10.3). Based on data generated in authors' laboratories and elsewhere, PDV genomes overall appear to have very low gene densities and many genes are spliced. PDV genomes also appear to have multiple copies of selected DNA segments and/or genes, and many genes have diverged into multiple variants that together form gene families.

6.10.2.1. Polydnavirus Genome Organization and Segment Types

As discussed above (see Section 6.10.1), PDV genomes are composed of multiple circular double-stranded DNA segments packaged in multiprotein capsids surrounded by single (BVs) or double (IVs) lipid envelopes (Webb, 1998; Turnbull and Webb, 2002). While both IV and BV genomes are composed of multiple circular dsDNAs, recent molecular analyses have discovered distinct differences in how their genomes are organized, how they replicate, and the genes they encode. Current knowledge of PDV genomics summarized below.

6.10.2.1.1. IV genomes IV genomes usually have more than 20 DNA segments ranging in size from 2 to 28 kb with genome sizes estimated to range from 75 kb to greater than 250 kb (Webb, 1998; Trudeau *et al.*, 2000). The genome of the *Cs*IV is composed of 22 nonredundant segments encoding approximately 248 kb of unique sequence (Turnbull and Webb, 2002; Lindstrom and Webb, unpublished data) (**Figure 4**). The *Campoletis chlorideae* IV genome, a closely related IV (*Cc*IV), has over 20 genomic segments and a genome estimated to be 130 kb (Yin *et al.*, 2003). Other IVs such as those associated with parasitoids of the genus *Hyposoter* are organized similarly to *Cs*IV (Stoltz *et al.*, 1981; Krell *et al.*, 1982; Volkoff *et al.*, 1995), although they tend to have smaller viral segments in greater numbers.

The sequence of the *Cs*IV genome has recently been completed. It is comprised of 22 nonredundant segments. The overall nonredundant *Cs*IV genome size (which excludes nested "daughter" segments) is 248 kb. There are at least 67 kb of partially redundant (daughter) segments making the genome size larger (~315 kb), if all the different genome segments are simply added. The *Cs*IV genome is approximately 60% A+T and greater than 60% noncoding. Portions of essentially every *Cs*IV segment have homology to other segments, primarily in coding regions. Every *Cs*IV segment encodes at least one gene, with the majority of the predicted genes transcribed in the same orientation within a segment. An exception is that the three genes on segment Q (12.1 kb) are encoded on opposite strands. Interestingly, segment Q is also the only segment known to encode members of more than one gene family (*rep* and *vinnexin*).

As discussed above (see Section 6.10.1), replication and assembly of IVs occurs only in the ovarian calyx cells of female parasitoids, and is temporally associated with changes in ecdysteroid titers that induce synthesis and melanization of the adult cuticle late in pupal development (Norton and Vinson, 1983; Whitfield, 1997). Limited data suggest that IV proviral segments are dispersed within chromosomal DNA of the parasitoid host (Fleming and Summers, 1991; Cui and Webb, 1997). DNA sequence across junction sites of integrated proviral IV segments shows that viral sequences are flanked by nucleic acid that is not encapsidated, suggesting that wasp genomic DNA separates IV segments (Fleming and Summers, 1991; Cui and Webb, 1997; Rattanadechakul and Webb, 2003). We do not currently know, however, whether or not IV segments are clustered on one or more chromosomes. The integration loci of *Cs*IV segments are surprisingly variable. For example, proviral DNA integration sites

may have short imperfect terminal repeats (e.g., 59 bp in segment B) or long perfect terminal repeats (e.g., 1186 bp in segment W) (Fleming and Summers, 1991; Cui and Webb, 1997). A single copy of the repeat is retained after recombination produces circular viral segments (Rattanadechakul and Webb, 2003).

Most IV segments excise from unique integration loci and form a stable segment. Segment B (**Figure 4**) is typical of such a "unique" segment. Segment B is 6516 bp in size and encodes two genes. *BHv*0.9 is a 900 bp mRNA expressed in parasitized insects. This gene is a member of the *Cs*IV *rep* gene family and contains a single copy of a 540 bp sequence also present on viral segments B, H, I, and O^1. The *BHv*0.9 gene does not have a signal peptide making the presumptive target of BHv0.9 the virus-infected cell. The segment B integration site is characterized by a 59 bp imperfect direct repeat with the excised segment having one copy of the repeat (Fleming, 1991; Rattanadechakul and Webb, 2003). Either the left or the right repeat can be present on an excised segment. Segments I, G^1, G2, G3, H, M^1, are also known to be orphan segments (Hilgarth and Webb, 2002). Unique segments may encode multiple genes from the same gene family with segment Z encoding nine *rep* genes, but outside of coding sequences the DNA sequence of these segments is "unique." There is no evidence of large regions of repetitive sequence within segments in the noncoding regions of these segments (Hilgarth, 2002). For example, the 6585 bp segment B has no repeats longer than 30 bp at 70% similarity. This and other repetitive sequences within the unique segments are almost exclusively found within expressed genes.

However, large repeats are obvious on many of the most abundant segments. Many of these abundant segments in IV genomes exhibit a phenomenon referred to as segment nesting. Nested segments also excise from unique integration loci but unlike unique segments, give rise to additional segments after excision via intramolecular recombination (**Figure 4**). *Campoletis sonorensis* and *H. fugitivus* IV segments W, V, and U (*Cs*IV), a U and L in *Hf* IV are known to be nested segments. Nested segments generate smaller "nested" segments from larger "parental" molecular through intramolecular recombination at intrasegmental repeats (Xu and Stoltz, 1993; Cui and Webb, 1997; Webb and Cui, 1998). Whether these repeats contribute functionally to segment nesting or whether the repeats result from the evolution of the phenomenon is not known. Segment nesting also is likely to occur in the *Hd*IV, as coding and noncoding sequences of segments C and G have been shown to cross hybridize strongly with larger genome segments (Y and Z, respectively) in *Hd* IV genomic Southern blots (Galibert *et al*., 2003). Segment nesting produces as many as five segments from a single proviral segment, with some viral genes preferentially retained on the progeny segments. Cui and Webb (1997) suggested that nesting provides a means for amplifying viral gene copy numbers. Webb and Cui (1998) manipulated virus infectious dose to show that viral gene copy number can directly affect viral protein titers in parasitized hosts. This may be particularly important for PDVs, as these viruses do not replicate after infection of lepidopteran cells (Strand *et al*., 1992) but expression of viral genes is essential for parasitoid (and virus) survival (see Section 6.10.4).

Segment nesting has been studied in the most detail in *Cs*IV segment W (15 812 bp) (Cui and Webb, 1997) (**Figure 4**). Segment W gives rise to segments R, M, and C^2 through intramolecular recombination events at a 350 bp recombination repeat, which is present in three copies on segment W. Segment W encodes four genes, of which two are expressed in parasitized insects (*WHv*1.0 and *WHv*1.6) and two are expressed in the wasp during virus replication (*WCs*1 and *WCs*2). *WHv*1.0 and *WHv*1.6 are members of the *cys-motif* gene family, while *WCs*1 and *WCs*2 genes are also related and comprise a viral gene family expressed in wasp ovarian cells during virus replication. The Segment W repeat is a 1186 bp direct repeat that is 100% identical and found at both termini of the integration locus. The excised segment contains a single copy of the recombination repeat. Segment W is itself composed of 2.5 copies of a 5 kb repeated region with significant internal sequence complexity, as indicated by an abundance of short direct and inverted repeats (Cui and Webb, 1997). Segment W appears to have evolved by sequential duplication of a 5 kb ancestral sequence that encoded a single *cys-motif* gene and a single *WCs* gene. There is also evidence that other nested segments result from repeated duplication with internal repeats, probably contributing to the phenomenon of segment nesting.

There may be a correlation between the integration repeat structure of viral segments and the efficiency with which they excise and/or replicate. Segment W has lengthy 100% identical terminal repeats and occurs as an abundant, nested segment in the *Cs*IV genome. By contrast, segment B has much shorter, imperfect terminal repeats and is a unique segment that is present in lower copy number (Webb, 1998; Rattanadechakul and Webb, 2003). Hypermolar segments are common in PDV genomes, suggesting the existence of an undescribed mechanism for controlling segment copy number (Webb, 1998; Webb and Cui, 1998; Turnbull and

Webb, 2002). Rattanadechakul and Webb (2003) suggest that gene families may be associated with particular segment types (nested versus unique; hypermolar versus nonhypermolar), and such organization may contribute to regulation of gene expression in parasitized hosts.

Savary *et al*. (1997) and Webb (1998) proposed that PDV replication may occur in a rolling-circle mechanism with excision of proviral DNA followed by amplification of circular episomes. A rolling-circle replication mechanism may be more efficient if genome segments are dispersed in the wasp genome. Data from Barre *et al*. (2002), Drezen *et al*. (2003), Marti *et al*. (2003) and Pasquier-Barre *et al*. (2002) support an alternative model for BVs. In this model, larger chromosome regions are amplified before excision of individual viral segments for encapsidation in virions. Individual viral segments do not replicate after excision from the amplified precursor (Pasquier-Barre *et al*., 2002; Drezen *et al*., 2003; Marti *et al*., 2003).

IV virions are uniform in size and shape, and have capsid dimensions that would support encapsidation of an entire genome complement (Krell *et al*., 1982). However, there are no data that directly address segment packaging in IVs. Experimentally, this is a difficult issue as virion shape is uniform and the virus does not replicate after infecting lepidopteran cells. More refined cytological and molecular studies are needed to better understand IV excision, amplification, and packaging.

6.10.2.1.2. BV genomes BV genomes are typically composed of fewer, larger segments than IV genomes, with size estimates ranging from 125–250 kb. Sequencing of the *Microplitis demolitor* BV (*Md*BV) genome was recently completed (Webb *et al*., unpublished data). *Md*BV consists of 15 segments that range in size from 4 kb (segment A) to 32 kb (segment O) (**Figure 3**). Total genome size is approximately 184 kb. Like *Cs*IV, *Md*BV segments exist in nonequimolar ratios with segment O being much more abundant than the others. The *Md*BV genome is also largely (>80%) noncoding and unlike *Cs*IV is AT-rich (65%). Some *Md*BV segments (like D–F, H, I) are unique, while others (O, M) consist of unique domains that are not shared by other segments, and repetitive domains that are shared among segments. No segment nesting *per se*, as occurs in IVs, has been found. Searches for open reading frames (ORFs) identify four gene families encoding predicted proteins of >100 amino acids on several *Md*BV segments. Some of these genes were known from prior studies while others were not. Several orphans without homology to known genes have also been identified. In addition, some segments, like D, have no ORFs for predicted proteins >15 amino acids. This suggests that these segments are either nonfunctional in parasitism or have functions other than gene expression. Sequence comparison also reveals no sequence homology between *Cs*IV and *Md*BV.

Analysis of *Glyptapanteles indiensis* BV (*Gi*BV) identifies 13 segments ranging from 11 kb to greater than 30 kb (Gundersen-Rindal and Dougherty, 2000). *Toxoneuron nigriceps* BV (*Tn*BV) (formerly *Cardichiles nigriceps*) has six major segments ranging from 6 kb to over 23 kb (Varricchio *et al*., 1999). The *Cotesia congregata* BV (*Cc*BV) has an unusually large number of segments for a BV, at least 20, which range from less than 10 kb to greater than 20 kb in size (de Buron and Beckage, 1992). Recent sequencing of the *Md*BV genome indicates that although genome segments appear larger and migrate slower than IV segments, most BV segments are similar in size to sequenced IV segments (Strand *et al*., unpublished data) (**Figure 3**). BV segments may appear relatively larger because of differences in higher-order structure as they appear to have relaxed circular topologies (Wyder *et al*., 2002), whereas IV segments are supercoiled (Krell *et al*., 1982). As relaxed circular topologies have slower mobilities on agarose gels, mobility of BV segments would be reduced relative to IV segments, and molecular weight standards thereby making BV segments appear relatively larger than IV segments.

In contrast to IV virions, BV virions vary in length with multiple nucleocapsids often observed within the singly enveloped virions (Stoltz and Vinson, 1977, 1979; Chen *et al*., 2003). There is evidence that individual capsids package single genome segments, with the length of the capsid corresponding to segment length (Albrecht *et al*., 1994). Experimental evidence also suggests that BV segments are clustered and occur in tandem arrays in the wasp chromosomal DNA (Savary *et al*., 1997; Belle *et al*., 2002; Wyder *et al*., 2002). Probes from three different viral segments (EP1, VP1, and VP2) in the *Cc*BV genome hybridized to the same location on subtelocentric chromosome 5 in adult wasp brain and gonad metaphase spreads, suggesting that *Cc*BV genome segments are clustered in a macrolocus near the telomeric end of this chromosome (Belle *et al*., 2002). Savary *et al*. (1997) showed that the proviral *Cc*BV EP1 segment is adjacent to proviral segment (A) in wasp genomic DNA providing further evidence that BV segments may be linked in tandem arrays. Wyder *et al*. (2002) have also shown that probes flanking regions of two known viral segments (*Ci*V12 and *Ci*V14) in the *C. inanitus* BV

(*Ci*BV) genome hybridize to other *Ci*BV segments in Southern blots of calyx DNA.

Like IV segments, BV segments exhibit hypermolarity (Wyder *et al*., 2002; Gunderson-Rindall and Lynn, 2003) and contain sequences that cross-hybridize to multiple segments. Probes made from three different regions of *Ci*V14 consistently hybridized to two viral genomic segments (one larger than expected) in Southern blots of *Ci*BV DNA suggesting that *Ci*V14 may be nested in a larger segment (Wyder *et al*., 2002).

As with IV segments, initiation of BV segment replication begins during the pupal stage of female parasitoids through amplification and excision of proviral segments (Albrecht *et al*., 1994; Gruber *et al*., 1996; Pasquier-Barre *et al*., 2002). Details of the morphogenic processes that occur during calyx cell differentiation and replication of *Ci*BV were discussed above (see Section 6.10.1). In terms of molecular events associated with replication, Marti *et al*. (2003) used quantitative polymerase chain reaction (PCR) to show that *C. inanitus* calyx cells become polyploid (estimated 30×) concurrent with nuclear hypertrophy and the onset of viral replication. With primers specific to one viral genome segment (*Ci*V12), the same study found that proviral sequences are selectively amplified in their integrated form following conversion of calyx cells to a polyploid state (Marti *et al*., 2003). From pupal stages 3b–6, the abundance of excised *Ci*V12 DNA is similar relative to the quantity of *Ci*V12 chromosomal excision locus, suggesting that viral DNA segments are not further amplified following conversion to individual circular episomes (Marti *et al*., 2003). A 15 bp imperfect direct repeat flanks the integrated form of *Ci*V12 and is involved in the excision of extrachromosomal segments from *C. inanitus* genomic sequences (Gruber *et al*., 1996). Extrachromosomal segments appear to form via juxtaposition and recombination of terminal repeats to generate a single copy of the repeat at the "empty" wasp genomic locus and in excised segments. Viral segments appear in females only after pupal stage 3 (Gruber *et al*., 1996), and coincident with maturation of the ovaries, oocytes, and ovarioles (Albrecht *et al*., 1994). Male wasps do not produce detectable levels of extrachromosomal *Ci*BV DNA in *C. inanitus* (Gruber *et al*., 1996).

In *C. congregata* quantitative PCR data indicate that virus replication begins by day 4 of the pupal stage. Pasquier-Barre *et al*. (2002) detected replication of the *Cc*BV EP1 segment within a large progenitor molecule containing both A and EP1 genome segments. Production of the progenitor molecule precedes recombination events that form individual A and EP1 circles, and individual circles are not amplified after formation (Pasquier-Barre *et al*., 2002).

The amplification of large progenitor molecules prior to episome formation, as proposed in Drezen *et al*. (2003), Marti *et al*. (2003), and Pasquier-Barre *et al*. (2002), may be an efficient mechanism of replication, particularly if viral genome segments are clustered in tandem arrays on a single chromosome and replicative cells are continuously produced from progenitor cells with virus released by cell lysis. For example, clustering of viral segments at one genomic locus could allow assembly of replication machinery at this locus. Replication of progenitor molecules prior to excision of individual circles allows for coamplification of segments but does raise questions as to how hypermolar segments are produced in BVs. There is evidence from the *Md*BV genome that at least some apparently hypermolar segments, as visualized on agarose gels, are actually due to multiple comigrating segments of approximately the same size (Deborde *et al*., unpublished data). Processes downstream of DNA replication could mediate control over segment hypermolarity. For example, segment copy number could depend on the efficiency with which individual episomes are excised from progenitor molecules, the efficiency with which they circularize, or the efficiency with which they are packaged into virions. Unlike circular episomes, linear progenitor molecules are not known to be encapsidated in BV virions (Pasquier-Barre *et al*., 2002).

6.10.2.2. IV Gene Families

PDV infection of host tissues coincides with severe physiological changes in the parasitized insect including alteration of host hormones, developmental arrest, and suppression of the cellular and humoral immune responses (Shelby and Webb, 1994; Balgopal *et al*., 1996; Webb, 1998; Shelby *et al*., 2000). Immunosuppression and developmental arrest require PDV gene expression (Fleming and Krell, 1993; Webb, 1998), and this viral gene expression occurs in the absence of viral DNA replication. An important characteristic of both IV and BV gene expression is that most viral genes are related to other viral genes that are expressed in the parasitized host. That is, they are members of gene families thought to be required for parasitism of the host and successful development of the parasitoid's offspring. Why PDV genes are needed in multiple copies remains to be explained.

PDV genes have been classified by their expression patterns, with class I genes expressed only in the parasitoid, class II genes expressed only in the

parasitized lepidopteran host, and class III genes expressed in both hosts (Theilmann and Summers, 1987, 1988; Stoltz, 1993). Some of class II genes encode members of gene families that alter host physiology, thereby enabling the survival of parasitoid progeny (Stoltz, 1993; Webb, 1998). Class I genes are likely involved in virus replication and packaging. Class III genes may play important roles in both the parasitoid and its lepidopteran host (Theilmann and Summers, 1987, 1988; Stoltz, 1993; Webb, 1998).

Few class I genes have been identified and characterized from IVs. Deng and Webb (1999) describe a 699 bp class I gene on *Cs*IV segment Y that encodes a 92 amino acid structural protein (p12) associated with *Cs*IV virions. Expression of mRNA from the *p12* gene coincides with the onset of viral replication in wasp ovaries, and the protein is detected only in extracts of ovarian tissues and on *Cs*IV virus particles. This pattern of *p12* expression suggests that it is a viral gene encoding a virion protein that is expressed only in the female parasitoid (Deng and Webb, 1999). By contrast, another *Cs*IV virion protein, p44, is encoded in the wasp genome but is not encapsidated (Deng and Webb, 2000). Genome sequence analyses indicate that many genes such as *p44* are involved in viral replication but are not encapsidated. By this definition they are not part of the viral genome, if one defines the viral genome on the basis of which genes are encapsidated. The only described class III genes are some members of the *rep* gene family from *Cs*IV (see Section 6.10.2.2.2). In contrast, many more class II genes from IVs have been studied. The most intensively studied IV in this regard is *Cs*IV. Below, the *Cs*IV class II genes that have been identified are first summarized. Then class II genes from other IVs are discussed.

6.10.2.2.1. *Cys-motif* genes The *cys-motif* genes are the most studied genes in the *Cs*IV genome These genes are recognized on the basis of a conserved, cysteine-rich motif. These motifs are composed of invariable cysteine residues flanked by hypervariable amino acids present in one or more copies in gene family members (Dib-Hajj *et al*., 1993; Turnbull and Webb, 2002). The *cys-motif* genes also have a highly conserved exon and intron structure, hydrophobic signal peptides, and N-terminal glycosylation sites in their predicted amino acid sequences (Blissard *et al*., 1987; Dib-Hajj *et al*., 1993; Cui and Webb, 1996). The nuclear magnetic resonance structure of the C-terminal cysteine-rich domain of one cys-motif protein (VHv1.1) indicates that the cysteine motifs of the proteins are held together by three disulfide bonds, forming a unique type of cystine knot (Einerwold *et al*., 2002). Residues lying within the cys-motif are highly variable, being less conserved than would be expected under conservative selection pressures (Dib-Hajj *et al*., 1993; Dupas *et al*., 2003).

*Cs*IV genome sequence analysis has identified ten known and putative *cys-motif* genes located on unique segments A, A′, F, and L, and on nested segments U, V, and W (Lindstrom *et al*., unpublished data). Functions and expression patterns of the V and W *cys-motif* genes (*VHv*1.1 and *VHv*1.4, and *WHv*1.0 and *WHv*1.6, respectively) have been studied in some detail (see Section 6.10.3). Blissard *et al*. (1987, 1989) suggested that the presence of multiple *cys-motif* gene variants may enable differential expression patterns and/or differential tissue targeting to provide optimal suppression of cellular immune responses during different stages of parasitoid development. Although there is little experimental data to support this possibility from study of the W and V *cys-motif* genes, investigations are under way to characterize expression patterns and functions of the newly discovered *cys-motif* genes.

6.10.2.2.2. The *rep* genes The *rep* genes were originally described based on a conserved 540 bp repeat and cross-hybridization of this repeat with several other *Cs*IV genome segments. (Theilmann and Summers, 1987, 1988; Fleming and Krell, 1993). Genome sequence analyses have shown that the *rep* gene family is the largest viral gene family identified to date, having 28 ORFs on ten unique *Cs*IV genome segments (Hilgarth and Webb, 2002; Volkoff *et al*., 2002). Although *rep* sequences are widespread within the *Cs*IV genome, most reside in predicted ORFs with *rep* related sequences detected in noncoding sequences showing evidence of rapid decay. The *rep* sequences encode predicted peptides that have an average amino acid identity of 43% (Hilgarth, 2002). The majority of the predicted *rep* genes encode a single copy of the repeat, although a number of predicted *rep* proteins possess two to five repeats arranged in tandem arrays (Theilmann and Summers, 1988; Fleming and Krell, 1993; Hilgarth and Webb, 2002).

Segments B, H, and O[1] have five *rep* genes that are expressed in parasitized *H. virescens* and/or *C. sonorensis* (Theilmann and Summers, 1987, 1988). Expression of *rep* genes can be detected in parasitized hosts at 2 h post parasitization (p.p.) Peak transcription is seen by 6 h p.p. with transcript levels essentially constant thereafter. The single segment B *rep* gene, *BHv*0.9, lacks introns and a signal peptide. It contains one 540 bp repeat element and is expressed in parasitized *H. virescens* hosts, but it is

not detected in *C. sonorensis* oviducts (Theilmann and Summers, 1988). *Rep* genes present on segments O^1 and H contain tandem arrays of *rep* sequences, and are expressed in the parasitized lepidopteran host and in female wasps.

More recently, *Cs*IV segment I (*I0.9*, *I1.1*, and *I1.2*) was sequenced and three additional members of the *rep* gene family were identified; the expression of these genes was detected in both *C. sonorensis* and parasitized *H. virescens* hosts (Hilgarth and Webb, 2002). Transcripts of *0.9 kb*, *1.1 kb*, and *1.2 kb* were detected by reverse transcriptase (RT)-PCR analyses, with expression levels of all three genes lower in *C. sonorensis* than in parasitized *H. virescens* tissues (Hilgarth and Webb, 2002). The *I0.9* and *I1.1* genes have a single copy of the 540 bp repeated sequence, whereas the *I1.2* encodes two repeats in a tandem array. Like other *rep* genes, segment I genes lack introns and signal peptide sequences. Anti-*rep* peptide antibodies detected *rep* protein products within cells although subcellular localization was not possible. Functions of the *rep*-encoded proteins remain largely uncharacterized (Hilgarth and Webb, 2002).

The *rep* gene family is also found in several other IV species. The *H. didymator* IV (*Hd*IV) has three *rep* genes expressed from segment E (*HdErep*1, *HdErep*2, and *HdErep*3), and the *Tranosema rostrale* IV (*Tr*IV) has one known and one putative *rep* gene expressed from segment F (*TrFrep*2 and *TrFrep*1) (Volkoff *et al*., 2002). Additional putative *rep* genes from *Hd*IV segment G and a polymorphic variant of *Hd*IV segment E have also been described (Volkoff *et al*., 2002; Galibert *et al*., 2003). Transcriptional analyses of the three *Hd*IV *rep* genes in lepidopteran cells shows that they encode transcripts of 790 nt, 1029 nt, and 936 nt, respectively (Volkoff *et al*., 2002). *HdErep*1 and *HdErep*2 transcripts are detected 4 h p.p./post infection (p.i.), with transcript levels maintained up to 8 days p.p. *HdErep*2 transcripts are detected at lower levels in *Hd*IV-infected cells and can be detected consistently only by RT-PCR (Volkoff *et al*., 2002). *TrFrep*1 was detected as a ~900 bp transcript showing peak expression by 1 day p.p. of sixth instar *Choristoneura fumiferana* larvae. Functions of the newly identified *Hd*IV and *Tr*IV *rep* genes also remain to be investigated (Volkoff *et al*., 2002).

6.10.2.2.3. The *vinnexin* genes The *Cs*IV viral innexin (*vinnexin*) gene family was identified by high homologies in protein sequence to invertebrate innexin gap junction proteins (Turnbull and Webb, 2002). The *Cs*IV *vinnexin* gene family has the fewest members containing only four genes (*Csvnx*-d1, *Csvnx*-q1, *Csvnx*-q2, and *Csvnx*-g1) on unique *Cs*IV segments D, G, and Q^2 (Turnbull and Webb, 2002). Three *C. sonorensis vinnexin* genes (*Csvnx*-d1, *Csvnx*-g1, and *Csvnx*-q2) are expressed in parasitized *H. virescens*, with *Csvnx*-d1 expression also detected in *C. sonorensis* tissues. Antibodies formed against a portion of the *Csvnx*-q2 protein localized to membranes of infected hemocytes (Turnbull and Webb, 2002). Innexin proteins are known to govern gap junction formation and cellular communication in invertebrate cells. Therefore, virally encoded *vinnexin* proteins may function to alter gap junction proteins in infected host cells by possibly modifying cell–cell communication during encapsulation responses in parasitized insects.

6.10.2.2.4. The *vankyrin* genes Annotation of the completed genome of *Cs*IV identified an additional novel gene family consisting of seven members on unique *Cs*IV segments P and I^2 (Kroemer and Webb, unpublished data) that contain ankyrin repeat domains. This viral ankyrin (*vankyrin*) gene family has weak but significant identities with the *Drosophila* dorsal/NF-κβ protein inhibitor (Iκβ) known as cactus. *Drosophila* cactus is a member of the Iκβ family of proteins, which are regulated inhibitors of the NF-κβ family of transcription factors (Ghosh *et al*., 1998). Gene targets of NF-κβ are highly diverse, but many are implicated in mammalian and insect immune responses, as well as in regulation of development (Engstrom *et al*., 1993; Kappler *et al*., 1993; Dushay *et al*., 1996; Ghosh *et al*., 1998; Manfruelli *et al*., 1999). Release of NF-κβ inhibition involves the direct degradation of Iκβ proteins bound to the transcription factors in the cytoplasm (Ghosh *et al*., 1998). Interestingly, the *Cs*IV-encoded *vankyrin* genes lack regulatory elements (nuclear export signals and destruction domains) associated with signal-induced and basal degradation of typical Iκβ proteins (Kroemer and Webb, unpublished data). Such a structure suggests a possible role for the *Cs*IV genes in irreversible binding to modify or inhibit NF-κβ signaling cascades within parasitized *H. virescens* hosts (see Section 6.10.3).

Recent sequence analyses of the *Hf*IV genome has also identified putative viral *ankyrin* genes. Homologs to the *Cs*IV *vankyrin* gene family are also likely to be present in the *Hd*IV genome, as probes of *Cs*IV *vankyrin* genes hybridize strongly to *Hd*IV DNA in Southern blot analyses (Volkoff *et al*., unpublished data). Conservation of this gene family suggests that it has an important function, and the putative association with ankyrin genes indicates that these genes may disrupt cellular signal transduction pathways.

6.10.2.2.5. Other IV genes The only other IV for which we have significant information on its encoded genes is *Hd*IV. In addition to having *rep*, *vinnexin*, and *vankyrin* genes, *Hd*IV also encodes a novel gene family composed of at least three genes (*M*24, *M*27, and *M*40) on genome segment M (Volkoff *et al*., 1999). *M* gene transcription can be detected from 4 h through the duration of parasitoid development. Members of the *M* gene family display similar protein structures with glycine- and proline-rich regions but are encoded by different *Hd*IV segments. Antibodies raised against M24 reacted with viral proteins and proteins in nonparasitized hosts, suggesting that some host peptides share epitopes with proteins encoded by the *M* genes. Volkoff *et al*. (1999) suggested the M proteins may exhibit host-related antigens as a mechanism for antigenic shielding of developing endoparasitoid larvae, although this hypothesis requires further experimental support.

Two other novel genes, *S6* and *P30*, were also recently described from *Hd*IV segments C and G, respectively. Both are expressed at high levels by 2 h p.i. in Sf9 cell cultures and within 1 day in parasitized *Spodoptera* larval tissues, primarily hemocytes (Galibert *et al*., 2003). The *S6* gene is predicted to encode a transmembrane protein, while the *P30* ORF encodes a predicted secreted and glycosylated protein with mucin-like motifs resembling those of the glc family in *Md*BV (see Section 6.10.2.3.1). The resemblence of the *Hd*IV P30 sequence to glc proteins of *Md*BV may further support the idea that common selection pressures may be driving convergent evolution of protein functions in the two PDV genera (Galibert *et al*., 2003). Characterization of the functions of P30 and S6 in the parasitized lepidopteran host may further support this hypothesis (Galibert *et al*., 2003) (see Section 6.10.3). Although most PDV genes are members of gene families, PDV genomes do encode some solitary genes that are essentially uncharacterized at this point. The *Cs*IV genome encodes at least seven solitary genes (not members of a gene family) that are recognized by gene finder programs. Similarly, the *Hd*IV genome encodes solitary genes including the *K19* gene from viral segment K that is persistently expressed in long-term *Hd*IV-infected cell lines (Volkoff *et al*., 2001). *K19* is a spliced gene containing two introns and encoding a cDNA with a short ORF and a long 3′ untranslated region composed of 13 imperfect sequence repeats. Functions of the *K19* gene and other solitary PDV genes remain to be investigated.

There are tens of thousands of IV- and BV-containing wasp species. Genes have been sequenced from only a few of these PDVs (~10); however, even these limited analyses demonstrate that viral genes vary significantly between species. Viral genomes may be specialized to meet requirements or constraints of specific host–parasitoid systems, and this specialization is evident in the viral genes and gene family compositions. The *T. rostrale* IV (*Tr*IV) seems well suited to test this possibility based on studies of its physiological effects that are discussed below (see Section 6.10.3). It would also be of interest to investigate the IVs from the Banchine group as phylogenetic analyses suggest independent origins for these viruses (see Section 6.10.1). One should expect to find functionally significant variation among the IVs as additional IV genomes are investigated and sequenced.

6.10.2.3. BV Genes

While BVs appear to be phylogenetically related (Whitfield, 2000; Whitfield and Asgari, 2003) (see Sections 6.10.1 and 6.10.6) there is only limited evidence of gene conservation among BVs from parasitoids in different genera characterized to date. This lack of conservation may reflect the fact that the polydnavirus systems, which have been characterized, largely reflect the three major divergent lineages of wasps within the BV containing groups. The lack of conservation also could reflect the rapidity of gene and genome evolution in polydnaviruses. Because there is relatively little evidence of gene family conservation among the BVs that have been studied to date, each species is discussed separately.

6.10.2.3.1. The *Microplitis demolitor* BV Genome analysis in combination with prior studies identified four families of class II genes. The *Md*BV *egf* gene family has three members (*egf*1.0, *egf*1.5, and *egf*0.4) encoded on viral genome segment O (Strand *et al*., 1997; Trudeau *et al*., 2000). The *egf* genes encode spliced transcripts with 5′ cysteine-rich regions that carry similarity to epidermal growth factor (EGF)-like cysteine-rich motifs (Strand *et al*., 1997; Trudeau *et al*., 2000). *Md*BV *egf* gene transcripts are detected in hemocytes of parasitized larvae, with highest levels of transcription observed between 12 h and 24 h p.p. followed by a rapid decline in expression (Strand *et al*., 1997). Peak expression of the *Md*BV *egf* genes coincides with physiological changes observed in host hemocytes; however, the exact function of the *egf* genes remains unclear (Strand *et al*., 1997). Secreted proteins containing EGF-like motifs (immunoevasive proteins (IEPs)) were described on the surfaces of eggs and PDV particles from the braconid endoparasite *Cotesia kariyai*, where they appear to promote immunoevasion (Tanaka *et al*., 2003). These data suggest that

*Md*BV *egf* genes may be derived from ancestral wasp genes having a role similar to that of the *C. kariyai* IEP proteins. The second class II gene is *glc*1.8 that was first described by Trudeau *et al.* (2000). Expression patterns of this gene are similar to that of *egf* genes in parasitized *Pseudoplusia includens*. The *glc*1.8 gene encodes a protein with hydrophobic N- and C-terminal domains flanking a heavily glycosylated core (Trudeau *et al.*, 2000). The glc1.8 protein, which localizes to the cellular surface of hemocytes, is important for disruption of host cellular immune response (Beck and Strand, 2003) (see Section 6.10.3). Annotation of the *Md*BV genome identified two additional gene families encoding predicted proteins with significant homologies to protein tyrosine phosphatases (PTPs) (see below) and Iκβ-like genes. PTPs are tyrosine dephosphorylating enzymes that occur in receptor-like and cytoplasmic forms often controlling intracellular signaling cascades (Stoker and Dutta, 1998; van Huijsduijen *et al.*, 2002). Receptor-like forms contribute to regulation of cell–cell adhesion, neuronal growth, and axon guidance, while cytoplasmic forms exhibit regulatory control over cell commitment and survival. Sequence analysis suggests all of the *Md*BV *PTP* genes are cytoplasmic. The discovery of Iκβ-like genes in the *Md*BV genome provide weak evidence that *Cs*IV and *Md*BV *vankyrin* genes are possibly derived from ancestral wasp sequences. Future experiments will likely be targeted to identify expression patterns and functions of *Md*BV-encoded *vankyrin* genes. Such studies will aid in understanding PDV evolution, and the forces driving convergent and/or divergent evolution among PDV genera.

6.10.2.3.2. *Cotesia* species BVs The *C. congregata* BV (*Cc*BV) genome encodes a family of three abundantly expressed genes: *EP*1, *EP*2, and *EP*3 (early protein 1, 2, and 3). The *EP* genes encode secreted, glycosylated proteins that are expressed within 30 min of *Manduca sexta* parasitization and accumulate to comprise over 10% of total hemolymph proteins by 24 h p.p. (Beckage *et al.*, 1987; Harwood *et al.*, 1994). The ability of EPs to be expressed in the parasitized host insect is closely correlated with the host range of the associated wasp, *C. congregata*. In permissive hosts EPs are rapidly and abundantly expressed, whereas nonpermissive hosts have greatly reduced expression of these proteins (Harwood *et al.*, 1998; Beckage and Tan, 2002). The physiological function(s) of EPs in the context of parasitized hosts is unclear.

Two genes (*Cr*V1 and *Cr*V2) from the *Cotesia rubecula* BV (*Cr*BV) are transiently expressed in parasitized hosts, *Pieris rapae* (Asgari *et al.*, 1997). *Cr*V1 (1.4 kb) and *Cr*V2 (1.1 kb) transcripts are only detected from 4–8 h p.p., with peak expression at 6 h p.p. (Asgari *et al.*, 1996). Both transcripts can be detected in fat body, with *Cr*V1 transcripts also being expressed in hemocytes of parasitized hosts. The highest levels of expression coincide with changes to hemocyte adhesive properties observed in parasitized insects (Asgari *et al.*, 1996). Analysis of the *Cr*V1 promoter with a reporter gene construct suggests that expression patterns may be mediated posttranscriptionally (Asgari and Schmidt, 2001). The CrV1 protein is glycosylated and contains a signal sequence allowing for secretion (Asgari *et al.*, 1996, 1997). CrV1 accumulates in the hemolymph, where a coiled-coil domain is important to binding and uptake of CrV1 by hemocytes (Asgari and Schmidt, 1997).

The *Cc*BV genome encodes a 1.4 kb transcript that is a homolog of *Cr*V1 (Le *et al.*, 2003). This transcript can be detected by 4 h p.p. in fat body and hemocytes and is seen until wasp emergence from the parasitized host. Interestingly, expression of the gene appears to require ovarian factors other than the virus itself as transcription of the *Cr*V1 homolog cannot be detected following injection of virus alone into *M. sexta* larvae (Le *et al.*, 2003). Expression of the *Cr*V1 homolog corresponds closely with the time of parasitoid emergence, and proteins may function in an analogous manner to CrV1 inhibiting hemocytic encapsulation in parasitized hosts (Asgari *et al.*, 1997; Le *et al.*, 2003). Using genomic sequence data, Whitfield (2002) has predicted that *Cr*V1 homologs exists in several additional *Cotesia* species.

Recently a novel lectin gene family shared by three *Cotesia* BVs has been described (Glatz *et al.*, 2003; Teramoto and Tanaka, 2003). Invertebrate lectins are often important recognition molecules in immune response, and function by binding carbohydrate moieties on the surfaces of foreign bodies (e.g., LPS in bacteria) during immune responses targeting them for hemocytic destruction (Glatz *et al.*, 2003; Teramoto and Tanaka, 2003). *Cr*BV encodes a gene (*Cr*V3) related to invertebrate C-type lectins that is expressed within 6 h p.p. in *P. rapae* larvae. CrV3 proteins are synthesized in parasitized fat body and hemocytes are heavily glycosylated, and are secreted into the hemolymph where they form oligomeric complexes (Glatz *et al.*, 2003). Two lectin genes (*Cky*811 and *Crf*111) were also recently described from the *C. kariyai* and *C. ruficrus* BV genomes (Teramoto and Tanaka, 2003). As with *Cr*V3, *Cky*811 and *Crf*111 transcripts can be detected within 6 h p.p. in hemocytes (also fat body for *Cky*811), and they encode proteins with C-type lectin motifs and signal peptides.

6.10.2.3.3. The *Chelonus inanitus* BV The BV associated with the egg–larval parasitoid *C. inanitus* (*Ci*BV) causes developmental arrest and disruption of the endocrine system in the last larval instars of parasitized *Spodoptera littoralis* hosts (Johner and Lanzrein, 2002) (see Section 6.10.3). Unlike gene expression patterns observed in larval parasitoids where viral transcripts are abundant shortly after parasitization, *Ci*BV gene expression appears to be delayed and synchronized with host larval development. *Ci*BV transcripts are detected in parasitized eggs but increase dramatically as host development proceeds. Transcripts are most abundant in the last larval instars of parasitized *S. littoralis* (Johner and Lanzrein, 2002). RT-PCR analyses of three *Ci*BV ORFs detected expression of the *Ci*BV genes in parasitized *S. littoralis* hosts and in pupae of female *C. inanitus*. One viral transcript was also expressed in the pupae of male *C. inanitus*, possibly providing evidence for transcriptional activity of proviral DNA (Johner and Lanzrein, 2002).

Recent analysis of four sequenced *Ci*BV segments (segments 12, 14, 14.5, and 16.8) did not detect ORFs related to previously described PDV genes (Wyder *et al.*, 2002). Seven predicted genes are encoded on the four sequenced *Ci*BV segments with preliminary evidence indicating that at least six of these genes are expressed. The known *Ci*BV genes contain multiple introns, with the two genes from segment 12 (*12g*1, *12g*2) having similarity to two genes of segment 14 (*14g*1, *14g*2). These data indicate that the two segments may represent an ancestrally duplicated sequence (Wyder *et al.*, 2002).

6.10.2.3.4. The *Glyptapanteles indiensis* BV As discussed above with *Md*BV, Chen *et al.* (2003b) also recently characterized a gene encoding a putative protein tyrosine phosphatase (*PTP*) gene in *Gi*BV. Using quantitative PCR, peak *Gi*BV *PTP* gene expression was detected in all tissues of parasitized *L. dispar* hosts within 2 h of parasitization followed by a decline apparent through 8 days. Since several *PTP* genes were also recently identified in the *Md*BV genome (see Section 6.10.2.3.1), this finding suggests that *PTP* genes may be conserved among BV genera (Chen *et al.*, 2003a).

Two additional novel *Gi*BV genes were recently recovered from a cDNA library of 24 h p.p. *L. dispar* hosts (Chen *et al.*, 2003b). These novel genes encode cDNA sequences and ORFs that hybridized to multiple genome segments suggesting they are members of gene families. Further investigations are required to better understand these potentially novel gene families in *Gi*BV.

6.10.2.3.5. The *Toxoneuron (Cardiochiles) nigriceps* BV *Toxoneuron nigriceps* BV (*Tn*BV) specific transcripts ranging in size from 0.3 to 3 kb were detected between 12 h and 48 h p.p. by Northern blot analysis of total RNA and polyadenylated RNA from parasitized *H. virescens* larvae (Varricchio *et al.*, 1999). Although functions of the viral transcripts are uncharacterized, the nucleotide sequence of one *Tn*BV gene (*Tn*BV1) sheds some light on its potential protein structure and cellular localization. *Tn*BV1 encodes a 467 nt spliced mRNA transcript expressed in the prothoracic glands of parasitized *H. virescens* larvae (Varricchio *et al.*, 1999). The deduced protein sequence lacks a signal peptide for secretion but includes 5′ and 3′ untranslated regions, a potential *N*-glycosylation site, and four potential phosphorylation sites. Recently, Falabella *et al.* (2003) characterized a second *Tn*BV gene (*Tn*BV2) transcribed in prothoracic glands and hemocytes of *H. virescens* larvae beginning by 6 h and peaking between 24 and 48 h p.p. *Tn*BV2 encodes a spliced gene with a signal peptide, several *N*-glycosylation and protein kinase C phosphorylation sites, and a conserved aspartyl-protease domain of a retroviral type.

6.10.3. Polydnavirus Function in Parasitized Hosts

As previously discussed, BVs and IVs accumulate to high densities in the calyces of female wasps and are injected into the parasitoid's lepidopteran host along with eggs, ovarian proteins (Ops), and venom during oviposition (Stoltz, 1993; Webb, 1998; Turnbull and Webb, 2002). Following infection of various tissues, PDV gene expression induces physiological alterations in the parasitized host that facilitate survival of the parasitoid's progeny. These include suppression of the host's immune system, changes in host growth and development, and alterations in metabolism (Strand and Pech, 1995; Schmidt *et al.*, 2001; Turnbull and Webb, 2002; Beckage and Gelman, 2003). Below are considered three aspects of polydnavirus function in hosts: the pathological effects PDVs have on host immunity and development, the function of isolated genes and their encoded proteins, and the potential role polydnaviruses play in successful parasitism.

6.10.3.1. Polydnavirus–Host Immune Interactions

The primary function of both BVs and IVs appears to be in protection of the developing parasitoid from the host's immune system (Schmidt *et al.*, 2001). Comparison of data across species indicate that

in some cases PDV-mediated immunosuppression requires direct infection and expression of viral genes in hemocytes, while in others immunosuppression involves both direct infection of hemocytes and secreted viral gene products (Li and Webb, 1994; Luckhart and Webb, 1996; Shelby and Webb, 1997). In some instances, PDVs also appear to have immune-related activities that do not involve gene expression. Insight into the molecular mechanisms underlying these effects derived from both genomic and functional data suggest that: (1) BVs and IVs immunosuppress hosts through the activity of different virulence genes; and (2) the shared organizational features of PDV genomes are likely important for function.

6.10.3.1.1. The host immune response toward the parasitoid Before considering the immunosuppressive functions of PDVs, it is important to briefly summarize how the host immune system responds to parasitoids in the absence of viral infection. Insects lack an acquired immune system but have a well-developed innate response that is subdivided into humoral and cellular defenses (Lavine and Strand, 2002). Humoral defenses include the production of antimicrobial peptides (Meister *et al.*, 2000; Lowenberger, 2001), reactive intermediates of oxygen or nitrogen (Bogdan *et al.*, 2000; Vass and Nappi, 2001), and proteolytic pathways like the phenoloxidase (PO) cascade that regulates melanization (Muta and Iwanaga, 1996; Gillespie *et al.*, 1997). Cellular defense refers to hemocyte-mediated immune responses (Lavine and Strand, 2002). The primary immune response toward parasitoids is encapsulation, which involves attachment of multiple layers of hemocytes to the surface of the parasitoid egg or larva.

As previously noted, PDV-carrying wasps are parasitoids of Lepidoptera whose hemocytes are divided into five classes: granular cells, plasmatocytes, spherule cells, oenocytoids, and prohemocytes (Gardiner and Strand, 1999; Nardi *et al.*, 2003). Granular cells are the main phagocytic cells in Lepidoptera and, along with humoral opsonins, are also essential for recognition of many encapsulation targets (Pech and Strand, 1996; Lavine and Strand, 2001; Lavine and Strand, 2002). Several humoral and cellular molecules have been identified from insects as pattern recognition receptors of pathogenic prokaryotes, but no humoral or cellular receptors have been identified and conclusively shown to recognize parasitoids (Lavine and Strand, 2002). Regardless, upon binding to a parasitoid, granular cells release cytokines that induce plasmatocytes to bind to the target and form a capsule (Pech and Strand, 1996; but see Willott *et al.* (1994) for an exception). The most potent known activator of lepidopteran plasmatocytes is the cytokine plasmatocyte spreading peptide (Clark *et al.*, 1997). Several other candidate molecules including eicosanoids have also been implicated in hemocyte activation events (Baines and Downer, 1992; Miller *et al.*, 1994; Diehl-Jones *et al.*, 1996). In turn, adhesion of plasmatocytes to the parasite and one another is mediated by integrins and potentially other classes of adhesion receptors like cadherins, Ig superfamily members, complement-like proteins, and selectins (Gillespie *et al.*, 1997; Levashana *et al.*, 2001). Once encapsulated, parasites are potentially killed by anoxia, reactive intermediates of oxygen (ROI) or nitrogen (RNI), toxic quinones associated with the melanization pathway, or cytotoxic molecules (Luckhart *et al.*, 1998; Nappi *et al.*, 2000).

6.10.3.1.2. Ichnovirus-immune interactions Edson *et al.* (1981) were the first to describe a role for IVs in protecting parasitoids from the host's immune system (see Section 6.10.1). In their study, *H. virescens* readily encapsulated *C. sonorensis* eggs in the absence of *Cs*IV but did not encapsulate the parasitoid when *Cs*IV was present. Furthermore, this effect required expression of one or more viral genes, as inactivated virus could not confer protection. Subsequent studies indicated that *Cs*IV and other IVs induce several alterations in hemocytes including cytoskeletal rearrangements, a decrease in the ability of granular cells and plasmatocytes to spread on foreign surfaces, and changes in the number of hemocytes in circulation (Stoltz and Guzo, 1986; Davies *et al.*, 1987; Guzo and Stoltz, 1987; Doucet and Cusson, 1996; Luckhart and Webb, 1996; Yin *et al.*, 2003). In the *Cs*IV system, hemocytes from noninfected hosts exhibit a decreased ability to attach to foreign surfaces when cultured in plasma from virus-infected hosts, which suggested that secreted proteins of host or viral origin could be involved in disruption of capsule formation (Davies *et al.*, 1987). Hemocytes from *Cs*IV-infected hosts are also unable to encapsulate eggs or other foreign targets, like glass, indicating that the host encapsulation response is broadly suppressed (Davies *et al.*, 1987). In contrast, *T. rostrale* IV (*Tr*IV) infection blocked encapsulation of *T. rostrale* eggs but had no effect on encapsulation of other targets suggesting suppression of the host encapsulation response is restricted to the parasitoid (Doucet and Cusson, 1996) (summarized by Lavine and Strand, 2002).

Ichnovirus infection also affects several elements of the humoral immune response. For example, *Cs*IV-infected hosts exhibit reduced levels of

lysozyme expression and several IVs are reported to reduce PO activity (Stoltz and Cook, 1983; Doucet and Cusson, 1996; Shelby *et al.*, 1998, 2000). Two major biochemical pathways exist, both involving the conversion of the inactive zymogen prophenoloxidase to the active PO, following recognition of foreign objects through activation of a serine protease cascade (Sugumaran, 1996). Recently, serine protease inhibitor activity was isolated from the calyx fluid of *V. canescens* (VcVLPs) (Beck *et al.*, 2000), though direct action on the serine proteases of the PO cascade was not shown. It is possible the *V. canescens* serine protease inhibitors block conversion of prophenolxidase to its active form as a mechanism for inhibiting defensive melanization. The second activation cascade involves synthesis of melanin by dopachrome isomerase activity on l-DOPA (Li *et al.*, 1994; Sugumaran, 1996). *Cs*IV infection reduces melanization by inhibiting synthesis of enzymes in the melanization pathway at the posttranscriptional level. The resultant changes in enzyme levels alter substrate availability and composition such that melanization is blocked (Hilgarth, 1995; Shelby *et al.*, 2000). In nonpermissive hosts of *C. sonorensis* melanization reactions are only temporarily depressed (Cui *et al.*, 2000) with recovery of melanization occurring as hemolymph, ovarial, and/or *Cs*IV protein titers decline.

While viral expression appears important in the immunosuppressive activities of IVs, a few studies indicate that some IVs passively protect parasitoids from encapsulation by coating the surface of the parasitoid egg. Surface features of the virions either prevent the parasitoid from being recognized as foreign by the host's immune system or in some way inhibit host hemocytes from being able to strongly adhere. This activity also does not require expression of any viral genes. For example, Cusson *et al.* (1998) found that *Tr*IV virions are physically associated with the chorion of *T. rostrale* eggs in a manner reminiscent of the VLPs of *V. canescens* that also associate themselves with the surface of the parasitoid egg. *Venturia canescens* VLPs lack nucleic acid but have capsids that are morphologically similar to other IVs (Rotheram, 1967). Hosts parasitized by *V. canescens* remain capable of mounting an encapsulation response against numerous foreign targets but are unable to encapsulate *V. canescens* because of VLPs and a hemomucin that coat the surface of their eggs (Rotheram, 1967; Feddersen *et al.*, 1986; Theopold *et al.*, 1996). The observations of Cusson *et al.* (1998) with *Tr*IV suggest a similar function.

Studies with *Cs*IV and selected other IVs indicate that virions infect several host tissues, and that hemocytes and fat body are principal sites of transcription (Fleming and Summers, 1986; Beliveau *et al.*, 2000; Galibert *et al.*, 2003; Yin *et al.*, 2003). However, few IV genes have been experimentally implicated in mediating any of the immune alterations described above. The *Cs*IV cys-motif proteins are secreted and bind to both granular cells and plasmatocytes (VHv1.1) (Li and Webb, 1994) or granular cells alone (VHv1.4) (Cui *et al.*, 1997). VHv1.1 and VHv1.4 are expressed in all infected tissues but the proteins are secreted and accumulate in the hemolymph where they bind to hemocyte surface proteins (Cui *et al.*, 1997). Experimental studies also indicate that VHv1.1 protein reduces but does not entirely block encapsulation of *C. sonorensis* eggs in hosts infected with a VHv1.1-expressing recombinant baculovirus (Li and Webb, 1994). Other IV genes are indirectly implicated in immunosuppression because of homology to genes with known function in immunity or because they are highly expressed in hemocytes. As discussed above (see Section 6.10.2), the *vankyrin* genes encoded by *Cs*IV and *Hf*IV (see above) share homology with insect Iκβ proteins. Work carried out in the past several years with *Drosophila* identifies NF-κβ transcription factors like Dif and Dorsal as important elements that activate transcription of antimicrobial peptide genes and stimulate other immune functions such as hematopoiesis (Qui *et al.*, 1999; Meister *et al.*, 2000). In most cells, NF-κβ factors are present in an inactive form in the cytoplasm of cells, retained due to complex formation with Iκβ proteins, like Cactus, that mask NF-κβ nuclear localization signals. Activation of transcription occurs when a signal is received and causes release of NF-κβ from its inhibitory Iκβ, followed by translocation of the NF-κβ transcription factor to the nucleus to activate gene expression (Qui *et al.*, 1999; Meister *et al.*, 2000). Thus, the presence of Iκβ-like genes in the genome of *Cs*IV suggest the virus may suppress the host immune response by binding host NF-κβs. The *P*30 ORF from *Hd*IV is likewise predicted to encode a mucin-like protein similar to the *glc* gene family of *Md*BV which has been shown to block adhesion of immune cells (Trudeau *et al.*, 2000; Beck and Strand, 2003; Galibert *et al.*, 2003) (see below). Products of the *vinnexin* genes from *Cs*IV share high homology to innexin gap junction proteins, and they are also expressed at high levels on *Cs*IV-infected host hemocytes (Turnbull and Webb, unpublished data). Gap junctions have been observed in hemocytic capsules between hemocytes but their functional significance was unknown. Identification of the *vinnexin* genes in PDV genomes suggests that disruption of normal

gap junction function may be a mechanism through which IVs prevent cellular encapsulation.

6.10.3.1.3. BV–host immune interactions BV-mediated immune suppression also usually involves infection of host tissues by viable, transcriptionally active virus (Guzo and Stoltz, 1987; Strand and Noda, 1991; Lavine and Beckage, 1995; Asgari *et al.*, 1996). The most important immunosuppressive activity is disruption of the host's encapsulation response. Whether disruption of capsule formation involves direct infection of hemocytes by virus, secretion of viral gene products into hemolymph which then interact with hemocytes, or both appears to vary among species. In the *M. demolitor* system, *Md*BV infection of *Pseudoplusia includens* irreversibly suppresses both encapsulation and phagocytosis (Strand and Noda, 1991; Strand and Pech, 1995; Lavine and Strand, unpublished data). Granular cells and plasmatocytes lose the capacity to bind to any foreign surface within 4 h of infection, and granular cells shortly thereafter undergo a high level of apoptosis. These alterations only occur if transcriptionally active virus directly infects hemocytes. Alterations in the adhesive properties of host hemocytes have also been described for BVs from other *Microplitis* species (Tanaka, 1982; Kadash *et al.*, 2003).

The effects of BVs from parasitoids in the genus *Cotesia* in contrast are more variable. Infection of *P. rapae* by *Cr*BV from *Cotesia rubecula* results in cytoskeletal alterations in hemocytes (Asgari *et al.*, 1996, 1997). These changes also correlate with reduced binding of *Helix pomatia* lectin which potentially binds a mucin on granular cells. Since transport of some surface mucins is mediated by actin filaments (Oliver and Specian, 1990), these results suggest that CrBV may interfere with transport of mucins and other factors to the cell surface that are required for adhesion. Severe and permanent inhibition of hemocyte binding to foreign surfaces is also reported for *Cm*BV from *C. melanoscela* and *Ck*BV from *C. kariyai* (Guzo and Stoltz, 1987; Tanaka, 1987).

In contrast, inhibition of encapsulation is accompanied by formation of hemocyte aggregations in *M. sexta* infected by *Cc*BV from *C. congregata* (Lavine and Beckage, 1996). Subsequent clearance of these aggregations is also accompanied by recovery of immune responses (Lovallo and Cox-Foster, 1999). FAD-glucose dehydrogenase (GLD) is activated only in immune activated plasmatocytes, making it a useful immune response marker (Cox-Foster and Stehr, 1994). Lovallo and Cox-Foster (1999) report that GLD activity increases after injection of ultraviolet-inactivated *Cc*BV, indicating that viral transcription is not responsible for this event. Uninfected hemocytes overlaid with purified *Cc*BV were still able to adhere, but preferentially reacted with other hemocytes rather than an introduced egg. Also, there was a reduction in overall adherence to glass (i.e., a foreign object) and formation of clumps of cells adhering to each other. Therefore, the virions were suggested to function as decoys that induced immune reactions to virus or virus-infected cells at a higher frequency than to the wasp egg. Cells participating in such aggregations would be subject to GLD-induced effects which include induction of apoptosis and cytolysis. Thus, GLD induction may contribute to changes in hemocyte populations and abrogation of an appropriately targeted encapsulation response to wasp eggs. The virus not destroyed during this "autoimmune response" is transcribed, presumably leading to sustained inhibition of immune responses via other mechanisms. In *Cc*BV, these symptoms occur in the majority of hemocytes by 24 h p.p. but are no longer evident by 8 days p.p. (Lavine and Beckage, 1996). Unlike other BV-carrying braconids, wasps in the genus *Chelonus* are all egg–larval parasitoids. Little is known about the role of chelonine BVs in immune suppression, but studies with *Ci*BV indicate that viral infection of the host protects *Chelonus* larvae from encapsulation but does not suppress capsule formation of latex beads. The mechanism underlying this parasitoid-specific effect is unknown as *Ci*BV is not known to affect the function of host hemocytes or humoral defense responses (Stettler *et al.*, 1998).

In terms of humoral immune responses, infection by several BVs reduces PO activity in the hemolymph of infected hosts (Stoltz and Cook, 1983; Beckage *et al.*, 1990; Strand and Noda, 1991). Upon bacterial immune challenge, hemocytes and fat body from *P. includens* and *Trichoplusia ni* upregulate expression of several antimicrobial peptides including cecropin, gloverin, lebosin, attacin, and lysozyme (Kang *et al.*, 1996a, 1996b; Liu *et al.*, 2000; Lundstrum *et al.*, 2002; Lavine and Strand, unpublished data). Interestingly, *Md*BV infection blocks inducible expression of these factors in fat body but has no effect on their expression in hemocytes (Lavine and Strand, unpublished data). This suggests that while cellular defense responses are compromised by *Md*BV infection, humoral responses that protect the host against prokaryotic pathogens remain at least partially functional.

As previously discussed for IVs, surface features of braconid eggs and larvae are sometimes as important in defense against encapsulation as BV infection of the host. Eggs of *C. kariyai* are coated by *Ck*BV virions, as well as other proteins secreted from ovarial cells (Hayakawa and Yazaki, 1997). Recent

studies identified two genes from *C. kariyai* that encode immunoevasive ovarial proteins (IEP1 and IEP2) (Tanaka *et al*., 2002). These genes are not encoded within the *Ck*BV genome but IEP proteins are on the surface of both *C. kariyai* eggs and *Ck*BV virions. IEP proteins also confer protection to eggs from encapsulation and elimination of *Ck*BV by hemocytes (Hayakawa and Yazaki, 1997; Tanaka *et al*., 2002). Virions do not coat the eggs of *T.* (*Cardiochiles*) *nigriceps* or *C. rubecula*, but the eggs of both species are coated with ovarial proteins that also inhibit encapsulation (Davies and Vinson, 1986; Asgari *et al*., 1998). In the case of *C. rubecula*, antisera raised against *Cr*BV cross-reacts with one of these proteins, Crp32, and when this protein is removed eggs are encapsulated by both nonparasitized and *Cr*BV infected hosts (Asgari and Schmidt, 1994). However, application of recombinant Crp32 to eggs restores protection (Asgari *et al*., 1998). Antibodies to Crp32 cross-react with two native proteins in host hemolymph. This indicates that Crp32 shares antigenic features with at least some host proteins and may protect eggs by conferring surface properties that resemble "self" to the host (Asgari *et al*., 1998). At the opposite extreme, eggs from *C. congregata* are fully susceptible to encapsulation and dependent upon *Cc*BV infection for protection, yet larvae have certain surface features that fully protect them from encapsulation even if transplanted into a nonparasitized host (Lavine and Beckage, 1996).

As with IVs, relatively few experimental studies clearly implicate specific BV genes in immunosuppression of hosts. Trudeau *et al.* (2000) described an *Md*BV gene, *glc* 1.8, that encodes a heavily glycosylated mucin-like protein, which is expressed by infected hemocytes and localizes to the cell surface. Beck and Strand (2003) recently used RNA interference (RNAi) to silence *glc*1.8 expression in a hemocyte-like cell line. Like hemocytes themselves, RNAi silencing of *glc*1.8 effectively restored normal adhesion activity to *Md*BV-infected cells suggesting that this gene plays a key role in disrupting encapsulation. Asgari and coworkers (Asgari *et al*., 1996, 1997; Asgari and Schmidt, 2002) reported that *Cr*BV transiently expressed two viral genes (*Cr*V1 and *Cr*V2) in the host fat body and hemocytes. Recombinant CrV1 protein, which binds to hemocytes via a putative leucine zipper domain, is endocytosed, and after endocytosis causes alterations in F-actin distribution and *H. pomatia* lectin binding, similar to what occurs in parasitized hosts. These results indicate that CrV1 is secreted and that altered lectin binding by hemocytes occurs after uptake of this viral protein. However, it is unclear from these studies whether CrV1 actually blocks *P. rapae* hemocytes from binding to or encapsulating any foreign target.

Other BV genes are indirectly implicated in immunosuppression because they share homology with known genes involved in regulation of immune responses in insects or other organisms. These include the Iκβ-like genes identified from *Md*BV that are structurally similar to the *Cs*IV *vankyrin* genes described previously (Webb and Strand unpublished data). The *PTP* genes identified from *Md*BV and *Gi*BV (Chen *et al*., 2003b) are also of interest as candidate suppressors of host cellular immune responses. *PTP*s have diverse functions but are particularly interesting from the perspective of immunity, because bacterial pathogens like *Yersinia pestis* express PTPs that block phagocytosis by dephosphorylating essential proteins in macrophages (Cornelis, 2002). Interestingly, the PTP from *Y. pestis* (YopH) also induces apoptosis in macrophages, either directly or indirectly by blocking NF-κB-dependent synthesis of antiapoptotic factors (Black *et al*., 2000; Cornelis, 2002). This suggests a role for either the *PTP* or *vankyrin* genes in the high level of apoptosis in granular cells infected by *Md*BV and potentially other BVs (Lavine and Beckage, 1995). Recent studies also describe a third gene family from three *Cotesia* BVs that encodes C-type lectins (Glatz *et al*., 2003; Teramato and Tanaka, 2003). As previously discussed, C-type lectins have been previously been implicated in insects as humoral pattern recognition receptors of prokaryotes (Jomori and Natori, 1991; Koizumi *et al*., 1999). What function these BV-encoded lectins might play in immunosuppression is unclear.

6.10.3.1.4. The potential effects of PDVs in disruption of insect antiviral defenses Little is known about antiviral defenses in insects. However, a few recent studies circumstantially suggest IVs and BVs reduce the efficacy of lepidopteran antiviral immunity. For example, coinfection with *Cs*IV allows the baculovirus *Autographa californica* M nucleopolyhedrovirus (*Ac*MNPV) in the normally resistant host, *Helicoverpa zea* (Washburn *et al*., 1995). *Manduca sexta* is a semipermissive host for the *Ac*MNPV but is more permissive when coinfected with *Cc*BV (Washburn *et al*., 2000). In both instances, increased permissiveness to *Ac*MNPV appears to be due to alterations in hemocyte function caused by the PDV. *Helicoverpa zea* hemocytes normally aggregate around foci of *Ac*MNPV infection and induce melanization (Trudeau *et al*., 2001). However, as previously discussed, IV and BV infection disrupt hemocyte adhesion and abundance, both of which likely

depress antiviral responsiveness. Other ovarial proteins like the IEPs from *C. kariyai* have also been implicated in helping BVs evade hemocyte antiviral responses (Tanaka *et al.*, 2003). Suppression of antiviral responses is also suggested by studies demonstrating that viral latency is sometimes broken by the immunosuppressive activity of PDVs (Stoltz and Makkay, 2003).

6.10.3.2. Polydnavirus–Host Developmental Interactions

The second major function of PDVs in parasitism is in host development. Lawrence (1986) divided parasitoids into "conformers" and "regulators" on the basis of their developmental interactions with the host. Conformers often coordinate their own development with that of the host but do not alter host development itself. Regulators in contrast disrupt host endocrine or other developmental pathways in a manner that facilitates successful development of the parasitoid. PDV-carrying parasitoids are almost always regulators that have a diversity of effects on host endocrine and nutritional physiology.

6.10.3.2.1. IV–host developmental interactions All known IV-carrying parasitoids are solitary, which means that only a single parasitoid offspring develops per host (Strand, 2000). Almost without exception, hosts parasitized by IV-carrying wasps exhibit reductions in weight gain, delays in molting, and are unable to undergo metamorphosis. The "juvenilization" of the host and disruption of metamorphosis are associated with specific alterations in endocrine physiology. Juvenile hormone (JH) is the key endocrine factor involved in maintenance of the larval stage, while juvenile hormone esterase (JHE) is the primary enzyme responsible for JH breakdown. *Cs*IV infection significantly reduces JHE activity in the host *H. virescens*, and it also suppresses 20-hydroxyecdysone (20E) titers by inducing the degeneration of the host's prothoracic glands (Dover *et al.*, 1988a and b; Shelby and Webb, 1997). Prothoracic gland degeneration, however, only occurs in the host's final instar indicating that *Cs*IV mediated inhibition of molting specifically blocks metamorphosis. Injection of *T. rostrale* calyx fluid (*Tr*IV) into penultimate instar *C. fumiferana* reduces JHE activity but it does not elevate JH titers (Cusson *et al.*, 2000). *Tr*IV also does not cause these glands to degenerate but it nonetheless suppresses 20E titers (Cusson *et al.*, 2000).

Ichnovirus infected hosts also exhibit alterations in metabolism. These include changes in the abundance of hemolymph proteins, free amino acids, and carbohydrate levels (Thompson, 1986; Vinson, 1990). Alterations in protein abundance may result from inhibition of protein synthesis at a posttranscriptional step (Shelby and Webb, 1994). This effect also appears to be selective. For example, *Cs*IV infection greatly reduces the abundance of arylphorin, a major hemolymph storage protein, but does not affect other major hemolymph proteins like Lipophorin and Transferrin (Shelby and Webb, 1994, 1997). Triglycerides and glycogen deposits in fat body are also greatly reduced in hosts parasitized by *C. sonorensis* (Hilgarth, 1995), but trehalose titers in hemolymph actually increase (Vinson, 1990). Overall, these data suggest IV infection affects nutrient stores of the host and may selectively alter specific factors in a manner that favors the developing parasite larvae. Thus far, no IV genes have been experimentally implicated in any of the endocrine or metabolic alterations that occur in infected hosts.

6.10.3.2.2. BV–host developmental interactions The developmental interactions between BV-carrying braconids and their hosts are more variable than those of IV-carrying ichneumonids. Microgastrine braconids like *Cotesia*, *Microplitis, Glyptapanteles* spp., and cardiochilines like *T. nigriceps* are all larval endoparasitoids that are either solitary (one offspring per host) or gregarious (multiple offspring per host). Most are able to oviposit in multiple instars of the host but their offspring complete development either obligately in the host's final instar or earlier depending on the species (Strand, 2000; Harvey and Strand, 2002). Viral expression in hosts parasitized by microgastrine and cardiochiline braconids usually begins within a few hours of parasitism (Turnbull and Webb, 2002). Hosts parasitized by solitary species thereafter exhibit severe reductions in weight gain, delays in molting, and inhibition of metamorphosis similar to those described for IV-carrying ichneumonids. Hosts parasitized by gregarious species are also inhibited from pupating but usually exhibit less severe alterations in weight gain. In contrast, chelonine braconids (*Chelonus, Ascogaster*) are all solitary, egg–larval parasitoids that induce precocious metamorphosis in their hosts such that initiation of pupation begins an instar earlier than normal (Lawrence and Lanzrein, 1993; Lanzrein *et al.*, 2001). The parasitoid then completes its larval development and emerges to pupate from the prepupal stage of the host. Viral expression in hosts parasitized by chelonines remains very low for many days after parasitism, but then expression of certain viral genes increases sharply immediately prior to the initiation of precocious metamorphosis (Johner *et al.*, 1999; Johner and Lanzrein, 2002).

BV infection contributes to many of the developmental alterations described in hosts although other wasp-derived factors, like teratocytes, venom, and the parasitoid larva itself (see above), also have important roles (Beckage and Gelman, 2003). For example, injection of *Md*BV from *M. demolitor* causes hosts to develop into larval–pupal intermediates, but injection of *Md*BV plus teratocytes results in complete inhibition of metamorphosis (Strand and Wong, 1991; Dover *et al.*, 1995). This occurs in part because *Md*BV or *Md*BV plus teratocytes elevate host JH titers (Balgopal *et al.*, 1996). These alterations appear to be due to both suppression of JHE activity and increased synthesis of JH by the host's corpora allata. They also implicate both *Md*BV and teratocytes in causing these changes. Studies with several other microgastrine and cardiochiline braconids also report an interactive role between BVs and teratocytes in developmental arrest and juvenilization of hosts (Pennacchio *et al.*, 1994; Dong *et al.*, 1996). Teratocytes secrete several proteins (Dahlman and Vinson, 1993), including TSP14 from *Microplitis croceipes* that shares some similarities with the *cys-motif* gene family of *Cs*IV (Dahlman *et al.*, 2003). Bioassays indicate that TSP14 inhibits protein synthesis and thus may contribute to developmental arrest by interfering with translation of certain host proteins (Dahlman *et al.*, 2003) (see Section 6.10.5).

Cotesia congregata also inhibits host metamorphosis by elevating hemolymph JH titers and interfering with processes that prevent prothoracic gland production and release of ecdysteroids (Beckage and Riddiford, 1982; Gelman *et al.*, 1998). These effects appear to involve *Cc*BV-mediated reductions in host JHE activity as well as secretion of JH by *C. congregata* larvae (Cole *et al.*, 2002). Inhibition of host metamorphosis by *C. kariyai* involves blockage of prothoracicotropic hormone release, while *T. nigriceps* disrupts ecdysteroid synthesis by prothoracic glands (Pennacchio *et al.*, 1994, 1997). In the case of *T. nigriceps*, experiments indicate that *Tn*BV infection of these glands reduces phosphorylation of proteins of the prothoracicotropic hormone-cAMP-prothoracic gland (Pennacchio *et al.*, 1998a, 1998b). Another factor implicated in causing the developmental delays that occur in hosts parasitized by *Cotesia* sp. is the discovery of bioactive peptides like growth blocking peptide and plasmatocyte spreading peptide (Hayakawa, 1990; Clark *et al.*, 1997; Strand *et al.*, 1999). In addition to functioning as an important cytokine in plasmatocyte activation, elevated titers of these factors also cause delays in molting and the onset of metamorphosis (Strand *et al.*, 1999). Studies with *C. kariyai* indicate that *Ck*BV infection induces a significant increase in growth blocking peptide titer in *Pseudaletia separata* (Hayakawa, 1991; Ohnishi *et al.*, 1995). Lastly, studies with *C. congregata* and *C. kariyai* describe alterations in levels and storage of neurotransmitters in the host nervous system that potentially impact both development and behavior (Noguchi *et al.*, 1995; Zitnan *et al.*, 1995).

Fewer studies have been conducted with BV-carrying egg–larval parasitoids but experiments with *C. inanitus* clearly indicate that calyx fluid (*Ci*BV), synergized by venom, developmentally arrest *S. littoralis* larvae in the prepupal stage by suppressing ecdysteroid synthesis and/or release (Grossniklaus-Burgen *et al.*, 1998; Steiner *et al.*, 1999; Lanzrein *et al.*, 2001). Reed and Brown (1998) also report that *Chelonus curvimaculatus* and *Ascogaster quadridentata* secrete ecdysteroids that may be involved in synchronizing the timing of parasitoid emergence from the host.

A diversity of nutritional alterations in hosts occur after BV infection that include dramatic changes in protein, lipid, and carbohydrate metabolism (summarized by Thompson, 1993; Thompson and Dahlman, 1998). These effects may be directly caused by expression of viral gene products and other factors like teratocytes, or indirectly arise as a consequence of the changes that occur in host endocrine physiology. Regardless, metabolic redirection is hypothesized to serve the parasitoid's nutritional needs at the expense of host tissues. Nakamatsu *et al.* (2001), for example, conducted experiments showing that *Ck*BV and venom from *C. kariyai* alter growth and metabolic efficiency of *P. separata*. Several hemolymph proteins are also down regulated by *Cc*BV from *C. congregata* and *Ck*BV from *C. kariyai*, including the hemolymph storage protein Arylphorin (Beckage and Kanost, 1993). Associated with these metabolic changes are reductions in the size of the host fat body and gonads (Yagi and Tanaka, 1992; Reed and Brown, 1998), suggesting that metabolic alterations in the host enhance nutrient availability to the parasitoid larva at the expense of host tissues.

As with IVs, almost no BV genes have been clearly linked to causing any of these endocrine, metabolic, or developmental alterations in hosts. In the *T. nigriceps–H. virescens* system, *Tn*BV potentially encodes several genes with protein kinase inhibitor (PKI) activity (Varricchio *et al.*, 1999). At least one *Tn*BV transcript, *Tn*PDV1, localizes to prothoracic gland cells with irregular morphology (Varricchio *et al.*, 1999). The transcript has a single putative N-linked glycosylation site, four potential phosphorylation sites, and lacks a signal peptide. Although *Tn*PDV1

does not exhibit any similarities to PKI genes in the National Center for Biotechnology Information nr-database, indicating that it may not be the source of the PKI activity, it may, however, be the source of observed cytological abnormalities. Similarly, the numerous *PTP* genes described previously could also play a role in disrupting protein kinase associated signaling pathways. Unlike gene expression patterns observed in larval parasitoids where viral transcripts are abundant shortly after parasitization, *Ci*BV gene expression patterns in hosts parasitized by *C. inanitus* are delayed and synchronized with the onset of precocious metamorphosis (Johner *et al*., 1999). Recent analysis of four sequenced *Ci*BV segments (12, 14, 14.5, 16.8) identifies several genes expressed in parasitized hosts including *14g*1 and *14g*2, which are upregulated fivefold and 1000-fold, respectively, in *S. littoralis* at the onset of precocious metamorphosis (Johner and Lanzrein, 2002). These genes share no significant homology with known genes, but the timing of their activity suggests they play an important role in regulating host development.

6.10.4. Polydnavirus Genome Structure–Function Relationships

The essential function of both IVs and BVs in the context of their symbiotic associations with parasitic wasps is inhibition of host cellular immune responses that otherwise kill endoparasitic wasp eggs and larvae. Cursory comparison of their genomes (**Figure 3**) suggests that they may use similar approaches in that PDVs are the only highly segmented DNA viruses. However, sequence analyses of representative IV and BV genomes reveals no sequence similarity but common structural features, suggesting that these viruses may have related strategies for acquiring and delivering pathogenic genes to host insects. Among the similar features are: (1) the presence of gene families distributed between abundant and relatively rare segments; (2) the existence of large amounts of noncoding sequence and spliced genes; and (3) the near complete absence of viral genes that can be associated with virus replication.

We consider some features of PDV gene families important for effective targeting of viral genes to disrupt host immunological responses. These include structural features that facilitate regulating gene dosage (hypermolarity, gene families, the presence of introns). Other features appear more relevant to maintenance of an effective symbiosis between the wasp and the virus. In the absence of replication, segment nesting may provide a mechanism for increasing gene copy number and elevating levels of specific gene products. Similarly, the presence of introns in some of the most highly expressed PDV genes suggests that this may enhance gene expression or mRNA stability as it is known to do in other eukaryotic systems (Le *et al*., 2003). Evolution of multiple variants in turn may provide the means to invade multiple hosts or interact with related signaling pathways in different cells or tissues.

The PDV literature emphasizes the obligate mutualisms between PDVs and their wasp hosts as contributing to the unusual features of PDV genome organization, replication, and function (Stoltz, 1993; Webb, 1998; Turnbull and Webb, 2002). Polydnaviruses are the biological mediators of parasitoid survival in the parasitized host, and they must evolve within the constraints imposed by these two very different types of insect associations. PDVs must be reliably transmitted, a function defined by the genetic assocation with the wasp genome. PDVs must also effectively disrupt parasitized host physiological systems, a function defined by the virus interaction with the genome of the lepidopteran host (Webb, 1998; Webb and Cui, 1998). In regard to PDV interactions with the wasp and lepidopteran genomes several characteristics of polydnavirus genomes are notable.

Polydnavirus genomes are integrated in wasp genomes. PDVs do not encode genes for structural proteins, viral polymerases, or transcription factors common in other DNA viruses. To support virus replication these genes must reside in the wasp genome and such viral genes have been transferred to the nuclear genome in both BVs and IVs during PDV evolution suggests that there is some benefit to having these genes encoded by the nuclear genome. One rather obvious benefit would be to allow more virulence genes to be packed into virions for delivery to the host during parasitization. Of potentially more significance (evolutionarily) is that translocating a gene essential for virus replication from a viral to a nuclear genome makes the virus dependent on the nuclear genome for its replication. In an evolutionary context such an event would fix the genetic association between (polydna)virus and host by making the association obligatory for virus replication. Such a genetically dependent association exposes the viral genome to evolutionary processes that lead to reduction and specialization of dependent microbial genomes (Andersson and Kurland, 1998). This evolutionary process has been termed “reductive evolution” and results in loss of genes that are nonessential to the mutualism to the viral genome, as well as amplification and/or elaboration of those microbial genes that are essential to the mutualism (Andersson

and Kurland, 1998). It is notable that PDVs genes are not truly "lost" but transferred to the nuclear genome in much the same way that many genes that were once in mitochondria are now expressed from nuclear genomes. Although reductive evolution is widespread in dependent obligate mutualisms, PDVs have two "hosts" with essential function in both. The evolutionary impact of these biological symbioses is thus more complex.

6.10.4.1. Gene Acquisition

Polydnavirus mutualisms have clearly been considered in light of the symbiotic theory for the origin of eukaryotic organelles (symbiogenesis) (Federici and Bigot, 2003), and the concept of reductive evolution (Webb, 1998; Shelby and Webb, 1999; Turnbull and Webb, 2002). However, the way in which PDVs acquire virulence genes has received relatively less consideration. PDVs do encode identifiable genes, and without exception these genes appear to be of eukaryotic rather than viral or microbial origin. Some PDV genes are quite closely related to cellular genes and have similar functional activities (e.g., PTPs, innexins). Presumably such genes were acquired from the wasp hosts and are now deployed against the parasitized host by the PDV. Moreover, many genes of cellular origin are members of viral gene families, suggesting a recurring organizational theme in which viral genes are acquired from the host, and their functions elaborated and specialized within the viral gene families. Some of these families have identifiable homologies to insect genes involved in signal transduction systems (e.g., *PTP*, *egf*, and *vankyrin*) or surface-mediated recognition (e.g., *glc* and *vinnexin*). It is also noteworthy that even though there is a consistent organizational theme in which PDV genomes encode relatively few PDV gene families (about three to seven), the complement of gene families differs markedly among viral species both within and between the PDV genera. For example, the BV gene families differ considerably among the systems studied to date, but studies of BV phylogeny strongly support the conclusion that all BV-containing wasps share a common ancestor (Whitfield, 1997). Thus, PDV genome organization is retained but the identity of the genes expressed shows considerable variation.

Proviral integration is stable through many wasp generations (Fleming and Summers, 1991), though low levels of excision occur in all tissues (Stoltz *et al.*, 1986) and some viral segments are able to integrate into cellular DNA after infection (Kim *et al.*, 1996; McKelvey *et al.*, 1996; Volkoff *et al.*, 2001).

6.10.4.2. Gene Amplification

Polydnavirus genome segments vary in number and molarity (Stoltz *et al.*, 1981), which results in unequal viral gene copy number and protein titers within the parasitized host (Webb and Cui, 1998). Segments contain large amounts of noncoding sequence, which may be comprised of highly repetitive regions (Webb *et al.*, unpublished data). The variability of PDV gene families suggests that gene duplication and divergence are common in the evolution of these viruses (Webb, 1998). Fleming and Krell (1993) suggest that PDV gene families provide mechanisms for tissue-specific and temporal regulation of gene expression, and there is some experimental support for this hypothesis (Asgari and Schmidt, 2001).

However, site and temporal regulation does little to explain the pronounced differences in segment molarity in PDVs. Gene duplication, segment hypermolarity, and segment nesting likely have important roles in regulation of gene dosage by providing a means to control mRNA levels of important genes. This is particularly important in PDV systems where viral functions are essential but occur in the absence of virus replication in parasitized hosts (Fleming and Krell, 1993; Webb, 1998). Webb and Cui (1998) documented a direct correlation between viral gene copy number and viral protein titers in parasitized hosts, and Cui *et al.* (2000) showed a link between gene expression patterns, gene function, and host range of *C. sonorensis* in relation to the VHv1.4 cys-motif protein.

The amplification of large progenitor molecules prior to episome formation may be an efficient mechanism of replication, particularly if viral genome segments are clustered in tandem arrays on a single chromosome and replicative cells are continuously produced from progenitor cells with virions released by cell lysis. For example, clustering of viral segments at one genomic locus could allow assembly of replication machinery at this locus. Replication of progenitor molecules prior to excision of individual circles allows for coamplification of segments, but does raise questions as to how hypermolar segments are produced in BVs. There is evidence from the *Md*BV genome that at least some apparently hypermolar segments, as visualized on agarose gels, are actually due to multiple segments of approximately the same size comigrating on these gels (Deborde *et al.*, unpublished data). Processes downstream of DNA replication could mediate control over segment hypermolarity. For example, segment copy number could depend on the efficiency with which individual episomes are excised from

progenitor molecules, the efficiency with which they circularize, or the efficiency with which they are packaged into virions.

6.10.5. Polydnavirus Research and Insect Control

This review began with a description of the parasitoid biology that led to discovery of basic biological phenomena as related to polydnavirus and wasp mutualisms. The primary role of PDVs in their mutualism is to inhibit insect immune responses and thereby permit successful parasitization. Secondarily some PDVs impact other aspects of host physiology thereby causing a rapid and pronounced inhibition of host growth and development. Conceptually, the isolation of viral genes that render lepidopteran insects more susceptible to disease and inhibit growth of host larvae should be useful for development of novel control strategies. One can easily envision the direct use of viral genes expressed in transgenic plants or recombinant baculoviruses to disrupt the physiology of pest insects and, thereby, inhibit insect growth or render the pest more susceptible to disease. Alternatively, PDVs genes and their encoded proteins may be used to study the affected lepidopteran physiological systems. In such an approach one would seek to identify novel insect targets that would enable targeted development of new classes of insecticidal compounds that inhibit insect growth and/or immunological systems. To this point, no PDV genes have been used directly for insect control, but there are clear indications that researchers are interested in and exploring such PDV genes and their potential utility.

Given the significance of the effects that PDVs have on insect physiology one might question the lack of movement towards developing PDV-based insect control strategies. However, PDVs are nonreplicative and therefore not amenable to mutational analyses. It is only in recent years that genomic approaches have elucidated the full complement of viral genes, and this work is only now entering the literature. As a result, analyses of PDV gene function is still at an early stage and, for its stage in development, shows reasonable promise.

There are reasons to suspect that PDV genes and proteins may have limitations that could limit there use in insect control strategies. In particular, the reliance of PDVs on gene families and mechanisms for controlling gene dosage suggest that it may be necessary to understand the roles of gene families and gene dosage in PDV function, before rational approaches can be developed to exploit PDV pathogenicity. For example, it may be necessary to express multiple viral genes from a single gene family to reproduce the biological effects caused by polydnavirus infection. Also there is good reason to question whether or not PDV genes that are normally expressed after infecting host cells would function when expressed from plant systems and subsequently ingested.

There are approaches that can be envisioned to overcome some of the potential limitations to utilizing PDV genes. Researchers are already investigating the potential for PDV genes to enhance other insect viruses, notably baculoviruses (Soldevila *et al.*, 1997; Washburn *et al.*, 2001). Such strategies could clearly overcome limitations associated with delivering PDV proteins to target insects via ingestion. Despite these cautionary considerations experimental evidence is developing that suggests that genes derived from PDVs have considerable promise for insect control.

6.10.5.1. Genes Inhibiting Insect Growth

One of the most dramatic effects of parasitization or PDV infection can be the reduction in insect growth. It is not uncommon for virus-infected insects to exhibit weight reductions of 50–75% relative to control insects over a 2–3 day period. However, isolation of genes inhibiting insect growth is problematic experimentally, in that it requires development of *in vivo* assays capable of direct measurement of "growth" or weight gain. Shelby and Webb (1994, 1996) approached this problem by showing that synthesis of lepidopteran storage proteins, which are abundantly synthesized in rapidly growing larvae, are dramatically inhibited by PDV infection. Subsequently, this effect was used to study the biochemical activity and ultimately associate inhibition of growth with a *cys-motif* gene from teratocytes (Dahlman *et al.*, 2003; Maiti *et al.*, 2003). This investigation documented that a *cys-motif* gene isolated from the teratocytes of a braconid wasp, *M. croceipes*, inhibited insect growth when injected (Dahlman *et al.*, 2003), or when ingested after expression of the recombinant protein in transgenic plants (Maiti *et al.*, 2003). This teratocyte gene, *TSP14*, is structurally related to the *Cs*IV *cys-motif* genes, suggesting that these viral genes may have direct effects on insect growth. Current work in this area is directed to expression and analysis of PDV function in similar assays.

6.10.5.2. Genes Disrupting Insect Immunity

Although inhibition of host immune responses is likely the most potent physiological effect of PDVs, this effect may not seem promising for utility in insect control. However, the aforementioned

expression of PDV genes in baculoviruses (Washburn *et al.*, 2001) had the objective of enhancing baculovirus pathogenicity and/or host range by using PDV genes to suppress the host immune response to baculovirus infection. So the immunosuppressive activity of PDVs is also being investigated. It is at least conceptually possible that a PDV immunosuppressive activity could be used to persistently inhibit pest immune systems, so that a high enough percentage of insects succumb to disease to suppress insect populations below economic injury levels. A potential advantage of such a strategy would be that insect resistance may be slow to develop, because the proximate cause of insect mortality would vary depending upon the pathogen infection that actually caused death of the pest insect.

Campoletis sonorensis parasitism disrupts humoral immunity and increases susceptibility of *H. virescens* larvae to opportunistic bacterial pathogens (Shelby *et al.*, 1998, 2000; Shelby and Webb, 1999). By their identity, the IV and BV *ankyrin* genes and the BV *PTP* genes suggest involvement of PDVs in direct regulation of signal transduction cascades in parasitized hosts. Signal transduction cascades could be a means through which PDVs regulate either host immunity or development. PTPs are involved in control of intracellular signaling cascades (Stoker and Dutta, 1998), and the presence of PTP-related genes in *Md*BV and *Gi*BV (Chen *et al.*, 2003b) implies virus-mediated control of PTP-regulated signal transduction in parasitized insects. Similarly, the presence Iκβ-related ORFs in IVs and BVs may be significant as insect immunological and developmental pathways are under NF-κβ mediated regulation and, therefore, potentially affected by these inhibitors of NF-κβ signaling cascades (Dushay *et al.*, 1996). The Iκβ-related ankyrin genes in PDVs may function to suppress NF-κβ signaling cascades as a means to alter development and humoral immunity in parasitized insects. At a minumum, further investigation of the emerging *PTP* and *ankyrin* gene families seems likely to expand our understanding of how PDV gene expression mediates lepidopteran host compatibility at the molecular level.

6.10.5.3. Host Range

The PDV-containing parasitoids are among the most successful groups both in terms of species diversity and sheer abundance of animals. One factor that may contribute to the success of these animals is the presence of PDVs which may provide a mutable set of genes that function as host range determinants for the parasitoid. This possibility has not been investigated in depth.

Kadash *et al.* (2003) recently examined the relatedness between three different bracovirus genomes in the genus *Microplitis* (*M. demolitor*, *M. mediator*, and *M. croceipes*), and assessed the ability of each bracovirus to protect the developing egg of an alternate *Microplitis* parasitoid. Cross-hybridization studies showed that the three BVs shared a high degree of homology in DNA sequences, but the three bracoviruses varied in their abilities to protect a parasitoid–egg of a different species in given host environments (*H. virescens* and *P. includens*) (Kadash *et al.*, 2003). Results of this study indicated that different evolutionary pressures acting on closely related parasitoids may be involved in the rapid divergence of BVs in braconid genera to allow wasps to rapidly adapt to different hosts environments. Webb and Cui (2000) documented a direct correlation between viral gene copy number and viral protein titers in parasitized hosts, and Cui *et al.* (2000) showed a link between gene expression patterns, gene function, and host range of *C. sonorensis* in relation to the VHv1.4 cys-motif protein. Such studies suggest that PDV genes do serve as host range determinants and are, therefore, potentially useful for insect control strategies designed to modify host range.

6.10.6. Polydnavirus Origins and Evolution

A long-standing question in the study of polydnaviruses is their evolutionary origin (Stoltz, 1993). One school of thought is that PDVs arose from a viral ancestor(s) that was associated with ichneumonoids, their hosts, or both. Evidence cited in favor of this scenario includes the observation that PDVs morphologically resemble other recognized families of viruses that infect insects. For example, IVs morphologically resemble ascoviruses that are also known to be horizontally transmitted to lepidopteran hosts by parasitoids (Bigot *et al.*, 1997; Whitfield and Asgari, 2003). Weak homology between ascovirus and some IV capsid proteins is also reported (Federici and Bigot, 2003). BV virions resemble some baculoviruses and nudiviruses (Stoltz and Vinson, 1979a; Federici and Bigot, 2003). Other similarities between PDVs and known DNA viruses include: (1) virions contain nucleic acid; (2) virions are infectious; and (3) replication and packaging of PDVs in calyx cells produce what appears to be virogenic stroma. On the other hand, the encapsidated genome of PDVs lacks several genes required for replication in the lepidopteran host. As discussed above (see Section 6.10.2), PDV genomes also have features more commonly associated with eukaryotes than viruses, such as large amounts of noncoding sequence, introns, and

multigene families. This has led some investigators to suggest that PDVs are no longer viruses at all but wasp secretions or novel organelles for delivering wasp genes to hosts (Federici and Bigot, 2003).

We would suggest the differences between these alternatives are largely semantic and that the ancient association between PDVs and parasitoids may well prevent the origin of these viruses from ever being determined with certainty. To put into context the difficulty of ferreting the origin of PDVs, it is instructive to consider the evolution of viruses more generally. The origin of viruses as biological entities can never be known with certainty, but all virus families that exist today likely arose from elements derived from some combination of both free-living organisms ("virus" progenitor) and host cells (Holland and Domingo, 1998). It is also clear that viruses can emerge and evolve by a variety of mechanisms including mutation, recombination, and reassortment. Recombination can create new viruses by capturing genes or sets of genes from either host cells or other viruses. Mutations, insertions, deletions, and rearrangement of genomes have also been well-described for many viruses in diverse families.

Genome sequence comparisons within virus families have yielded supportable phylogenetic relationships but also some important notes of caution. For example, the Baculoviridae is probably the best studied family of insect viruses, yet phylogenies for this group based on individual gene sequences have consistently produced conflicting results (Herniou *et al.*, 2003). This inconsistency could reflect unequal rates of gene evolution or real differences in the phylogeny of individual genes due to recombination events, duplications, and gene losses (Herniou *et al.*, 2001). The importance of the latter becomes clear when one considers that among 13 fully sequenced baculoviruses, 282 genes were specific to one virus, 243 genes had at least one homolog, and only 30 genes were shared by all genomes (Herniou *et al.*, 2003). Analysis of these shared genes in combination with gene order produced a well-supported phylogenetic tree for the Baculoviridae that now appears to consist of four major groups (Herniou *et al.*, 2003). Nonetheless, the pitfalls of anything short of such a broad analysis are clear.

No family level phylogeny exists for viruses as it is clear that there is no single origin for viruses (Domingo *et al.*, 1999; van Regenmortel *et al.*, 2000). For instance, there is no obvious way one can relate viruses of the size and complexity of Poxviridae (linear dsDNA, 130–375 kb, 150–300 genes) which infect insects and many other animals with Geminiviridae (circular ssDNA, 2.7–5.4 kb, 3–7 genes) that also infect insects as well as plants. Even comparisons among, for example, dsDNA virus families have yielded vague phylogenetic results. The main message to come from attempts at such broader phylogenetic studies is that virus evolution appears to be modular with recombinational arrangement of interchangeable genetic components occurring in different virus groups (Holland and Domingo, 1998). Numerous examples exist for a given family of viruses sharing a core component with another family while having nothing else in common. Thus, certain animal viruses, like picornaviruses and alphaviruses, encode genes or modules related to plant viruses with which they do not share the same morphology, number of genome components, or even genome organization. Comparison of different "supergroups" of viruses also almost always produces different phylogenies depending on which gene or module one compares. In summary, discerning ancestry beyond close relatives (like baculoviruses) has thus far resulted in severe blurring of perceived relationships among viruses.

The implications for understanding the origins of PDVs are obvious given recent estimates indicating that PDV–ichneumonoid associations arose at least 74 million years ago (Whitfield, 2000). Any similarities between individual genes shared between PDVs and another virus family must be viewed cautiously. Furthermore, a lack of significant similarity between PDV genomes and known virus families does not mean that PDVs themselves are not derived from viruses or properly classified as viruses themselves. Genomic analysis of PDVs is still at an early stage and arguably comparative data remain too weak to make phylogenetically meaningful comparisons either within PDVs or with viruses from other families. Even so, our limited knowledge of PDV genomes already suggests strikingly poor conservation in the class II genes that are expressed in parasitized hosts among PDVs outside the same genus (BVs) or subfamily (IVs). More important, potentially, for phylogenetic comparisons will be the structural genes that encode proteins for PDV nucleocapsids, as one may assume that the conservation of virion structure may reflect conservation among genes encoding virion proteins. However, very few of these genes have been identified as many appear to be encoded by the genome of the wasp rather than the encapsidated virus. Thus it is concluded that sequence information is still too weak to make firm comparisons between PDVs and viruses in other families. Even with additional data such comparisons may still yield ambiguous results given experiences with several other viral taxa.

It is also worth noting that many viruses have features strikingly similar to plasmids, episomes, and other mobile DNA or RNA elements like transposons or retrotransposons. The only clear distinction between many such mobile elements and viruses is the maturation of the latter within capsids or envelopes that affect efficient transmission and target cell receptor specificity. This is well illustrated by viruses like bacteriophage Mu (which is both a virus and transposon) and retroviruses (which are retrotransposons containing a functional envelope gene). While some authors have suggested that true viruses should show evidence of an evolutionary history independent of that of its host (Strauss *et al*., 1996), unambiguously discerning such independence is becoming increasingly more difficult as our comparative knowledge of animal and plant genomes rises. An extreme example is provided by maize in which numerous retroelement families account for 50% or more of the genome, such that large regions of host and selfish parasitic DNA can no longer be distinguished at all (Voytas, 1996). Again, the message from these broader comparisons is that most viruses share genetic features with their hosts and other mobile elements. In our view the balance of traits PDVs possess, particularly the encapsidation of nucleic acid for infection of other cells, favors viewing these entities as viruses rather than a type of organelle. If we reject the importance of envelopment of nucleic acid for infection of other cells, one has to wonder what is left to distinguish viruses from other biological entities.

We are more optimistic about the use of comparative genomic data for understanding the evolution of IVs and BVs to one another. Comparative studies with other viruses suggest that virus lineages that remain closely associated with a given host coevolve (Doolittle *et al*., 1989; Domingo *et al*., 1999). For example, papillomavirus types rarely if ever crosses host species barriers which is reflected in their phylogeny, since papillomavirus isolates from primates, ungulates, rabbits, and birds are separated by large distances (Ong *et al*., 1993). Similarly, the intimate association between individual PDVs and wasp species suggest that virus phylogeny is likely to mirror wasp phylogeny. Limited comparisons testing cophylogeny between BVs and wasps in the genus *Cotesia* have found essentially perfect correspondence (Whitfield and Asgari, 2003). The caveat for such studies is that the high divergence in class II genes already found among, for example, BVs suggests these factors may be poor choices for constructing supportable phylogenies for braconid PDVs as a whole. Provided whole genomes are ultimately available, employing groups of shared genes and genome organization, as has been done with baculoviruses, is more likely to yield clearer results than trees constructed using single genes. In conclusion, discerning the evolutionary relationships within the BVs and IVs is a potentially achievable goal, but discerning higher order relationships between BVs and IVs or between PDVs and other animal viruses will be more difficult and may not be possible.

6.10.7. The Future for Polydnavirus Research

In this review our understanding of PDVs, their association with parasitoids, and their function in parasitism has been summarized. In looking to the future, certain avenues of research that should receive priority are being suggested. These studies break along two lines: (1) advancing our understanding of PDV evolutionary relationships; and (2) advancing our understanding of PDV gene function, and the relationship between function and genome organization. Furthering our understanding of evolutionary relationships will require first and foremost more comparative genomic data. As discussed above (see Sections 6.10.2 and 6.10.4), the representative genomes of a selected IVs from campoplegine ichneumonids and a selected microgastrine braconid BVs have been fully sequenced. A few other campoplegine and banchine IVs as well as BVs from cardiochiline and chelonine braconids are in progress. At minimum, similar data are needed from at least one species in other subfamilies of ichneumonoids hypothesized to carry PDVs. In addition, genomic data from multiple campoplegine and microgastrine braconids from a common genus are needed. Together, these data would allow us to determine the rate at which PDV genomes are evolving, the relationship within and between BVs and IVs, and whether a cophylogeny exists between parasitoids and the viruses they carry.

Since encapsidated PDV genomes lack many genes required for replication these viral genes must now reside in the nuclear genome of their wasp host. Identifying these structural genes will be critical to understanding how PDVs replicate and potentially their relationship to other viruses. Evidence for integration of *C. congregata* BV segments in tandem array within the wasp genome is strong and suggestive that an ancestral provirus accounts for the genomic clustering of BV segments (Belle *et al*., 2002). Comparable data on other BVs and IVs is also needed.

The second area of priority should relate to host biology and the function of PDVs in parasitism. From the perspective of host immunity, our

knowledge of how insects regulate inducible humoral responses like antimicrobial peptide synthesis greatly exceeds our knowledge of hemocyte-mediated defense responses. This deficiency is well-illustrated by the recently published genome for *Anopheles gambiae* (Holt *et al*., 2002) where many genes regulating humoral defense responses are identifiable by homology but few genes regulating cellular defense responses are (Christophides *et al*., 2002). Future advances in understanding how PDV virulence genes suppress the insect immune system will depend on enhancing our understanding of the signaling pathways and processes that regulate insect cellular immune responses. Our understanding at the molecular level of how biosynthesis and release of insect endocrine factors are regulated is similarly weak, and will need to be improved in order to understand how viral genes developmentally arrest host growth. Lastly, developing bioassay systems beyond the hosts that a given parasitoid normally attacks will likely be needed to fully understand the mode of action of PDV genes. Especially attractive are insect systems like *Dr. melanogaster, A. gambiae*, and the honeybee *Apis mellifera* for which complete genomes are available. Development of genomic lepidopteran models would also, obviously, be of tremendous value to the study of PDVs.

6.11 Entomopathogenic Fungi and their Role in Regulation of Insect Populations

M S Goettel, Agriculture and Agri-Food Canada, Lethbridge, AB, Canada
J Eilenberg, The Royal Veterinary and Agricultural University, Frederiksberg C, Denmark
T Glare, AgResearch, Canterbury, New Zealand

6.11.1. Introduction

Entomopathogenic fungi play an important role in the regulation of insect populations. There is a diverse array of fungal insect pathogenic species from within four different classes. Adaptations range from obligate pathogens of specific insect species to generalists capable of infecting many host species to species that are facultative pathogens. Fungal epizootics are common in some insect species, while others are rarely affected. The earliest studies with entomopathogenic fungi were carried out in the 1800s, and these concentrated on developing ways of managing diseases that were devastating the silkworm industry (Steinhaus, 1975). In fact, the germ theory was first demonstrated by Bassi (1835 as cited by Steinhaus, 1975) using silkworms and the muscardine fungus, which was later named *Beauveria bassiana* in his honor. Bassi's studies on the disease in silkworms enabled him to extrapolate his findings into the field of human diseases. The stimulus for the idea of using entomopathogens to manage pest insects came largely from the silkworm disease studies. However, early attempts in using fungi as microbial control agents of pest insects were soon overshadowed by the development of chemical insecticides. It was not until the late 1950s that attempts to use entomopathogenic fungi for insect pest management resurfaced. To date, there are many commercial products available worldwide, based on less than 10 fungal species

(Shah and Goettel, 1999; Copping, 2001), but the potential for the development of many more remains high.

In this article, an overview of entomopathogenic fungi and their current and potential role in the regulation of pest insect populations is provided, emphasizing as much as possible the developments over the last 20 years. Reviews dealing with entomopathogenic fungi and their development as microbial control agents include those of Ferron (1985), McCoy *et al.* (1988), Evans (1989), Ferron *et al.* (1991), Glare and Milner (1991), Roberts and Hajek (1992), Tanada and Kaya (1993), Hajek and St. Leger (1994), Boucias and Pendland (1998), Wraight and Carruthers (1999), and several chapters in Butt *et al.* (2001) and Upadhyay (2003). For methods and techniques used to study these pathogens, readers are referred to Butt and Goettel (2000), and the chapters in Lacey (1997) and Lacey and Kaya (2000).

6.11.2. Entomopathogenic Fungi

Insect pathogens have a long history of recognition despite the relatively recent understanding of microbial infections. Descriptions of entomopathogenic fungi can be found in drawings from several centuries ago. Japanese descriptions of silkworm infections by muscardine fungi (probably *Beauveria bassiana*) and *Cordyceps* spp. infections of a number of insects date from around the nineth century (Samson *et al.*, 1988). Perhaps because of their prominent and often brightly colored fruiting bodies, *Cordyceps* species feature in many of the earliest references and drawings of entomopathogenic fungi. Species of *Cordyceps* have also been of practical value in several countries. Maori, the native people of New Zealand, were known to use extracts of *Cordyceps robertsii* as a pigment for traditional face tattoos (moko), while the Chinese have used *Cordyceps* infected caterpillars as traditional medicines for many years. Other entomopathogenic fungi had been recorded by the late eighteenth and through the nineteenth century. Flies infected by entomophthoralean fungi, where the distinct halo formed by forcibly discharged primary conidia could clearly be seen with the naked eye, were, for example, observed by Goethe (1817–1822).

Classification of these interesting fungi began with *Cordyceps* and other obvious insect-infecting fungi. While Cooke (1892) listed four groups parasitic to insects (*Cordyceps*, Entomophthorales, Laboulbeniales, and opportunitistic fungi such as *Cladosporium* and *Penicillium*), interest in the diversity of these fungi did not really blossom until the 1970s. Currently, at least 90 genera and more than 700 species, representing all the major classifications of fungi, have been implicated in diseases of insects.

With the advent of molecular comparisons as a tool in classification, the distinction between protozoa and fungi has been revisited and revised. Fungal taxonomy is still in a state of flux. As presently delimited, the kingdom Fungi may constitute a monophyletic group that shares some characters with animals, such as chitinous structures, storage of glycogen, and mitochondrial UGA coding for tryptophan. The Chytridiomycetes possess the primitive character of a single, smooth, posteriorly inserted flagellum and are basal to the other fungi (Cavalier-Smith, 1987; Barr, 1992). It does not include the Oomycetes, which have been moved to the kingdom Chromista with some algae (Leipe *et al.*, 1994).

While some phylogenists have moved the classes between kingdoms, the entomopathogens remain within four major classes: the Oomycetes, Chytridiomycetes, Ascomycetes, and Zygomycetes. Some unusual insect pathogenic species are found in other fungal classes, but most can be found in the Ascomycetes and Zygomycetes. A distinction must be made between disease causing species that in many cases result in mortality of the insect and those that live on insects, usually without causing mortality. The latter group includes species of Laboulbeniomycetes, which can be obligate parasites on insects, but have little effect on the health of their hosts (Tanada and Kaya, 1993) and Basidiomycota such as *Septobasidum* and *Uredinella*.

One of the most confusing aspects of fungal taxonomy is the treatment of species only known by an asexual stage. Many such species have been classified in the Deuteromycota within the class Hyphomycetes, which is essentially a form-class. This has led to many species having both a name for the sexual (teleomorph) stage and the asexual (anamorph) stage with no link between the names. With the advent of molecular identification tools, it has been possible to link many anamorph and teleomorph stages, or to substantially predict the teleomorph genera for a species described only through an anamorph stage. Many common insect pathogenic species are currently classified in the Hyphomycetes, such as *B. bassiana* and *Metarhizium anisopliae*, but with modern technology, it can be demonstrated that their affinities are with the Ascomycete genus *Cordyceps*. Whether separate pleomorphic and anamorphic names are still required is a current topic of debate around the International Code of Botanical Nomenclature. As

molecular analysis has the ability to link anamorphic stages with appropriate teleomorphic genera, the use of a dual nomenclature system is probably superfluous, but may be hard to lose in the short term.

The main classes that contain entomopathogenic species are reviewed in the following sections. Examples of insects infected with entomopathogenic fungi are presented in **Figures 1–15**.

6.11.2.1. Phylum Oomycota

Oomycetes are characterized by cellulose containing coenocytic hyphae, biflagellate zoospores, and usually contain no chitin. Sexual reproduction can occur between gametangia (antheridia and oogonia) on the same or different hyphae. While a number of species are saprophytes and parasites of animals and plants, two genera contain species pathogenic to mosquito larvae. The best studied species is *Lagenidium giganteum* (Lagenidiales), a pathogen of mosquito larvae (Glare and Milner, 1991; Kerwin and Petersen, 1997). Other species of *Lagenidium* can cause infections in aquatic crustaceans, such as crabs (e.g., Hatai *et al*., 2000).

Leptolegnia spp. (Saprolegniales) have also been reported to be pathogenic to mosquitoes, chironomids, and several other Diptera. These species are thought to infect via a secondary zoospore formed after encystment of the primary zoospore derived from sporangia (Zattau and McInnis, 1987).

6.11.2.2. Phylum Chytridiomycota

Chrytridiomycetes are characterized by cell walls containing chitin and no cellulose. Posteriorly uniflagellate zoospores and gametes settle and grow into a thallus, which becomes either a resting spore or coenocytic hyphae. This group is considered basal to the fungal branch under SSU rRNA phylogenetic comparisons. The Blastocladiales genus *Coelomomyces* contains most of the common entomopathogenic Chytridiomycetes. There are over 70 entomopathogenic species described in the *Coelomomyces* (Lucarotti *et al*., 1985). These species have been described from Diptera (mainly mosquitoes) and Heteroptera. Several species have an obligate intermediate host, such as copepods. They are characterized by formation of both thick walled resistant sporangia and flagellate zoospores. Other entomopathogenic species are known from *Coelomycidium* (Blastocladiales) and *Myriophagus* (Chytridiales); the former is found on blackflies and mosquitoes, and the latter has been reported as a pathogen on dipterous pupae by Sparrow, 1939 and Karling, 1948 (in Samson *et al*., 1988).

6.11.2.3. Phylum Zygomycota

Traditionally, the Zygomycota are separated on the basis of often nonseptate, multinuclear hyphae, and production of zygospores by copulation between gametangia. However, molecular analyses have not found the Zygomycota to be monophyletic (Jensen

Figure 1 Larvae of the European wireworm, *Agriotus obscurus*, killed by *Metarhizium anisopliae*. The progression of the emergence of the fungus from the cadavers and subsequent development of fungal structures is seen from left to right, with the larva on the right completely covered by the green spores of the fungus. (Photo courtesy of T. Kabaluk.)

et al., 1998), and some groups, such as the Glomales, may be placed elsewhere eventually (e.g., Bruns *et al*., 1993). *Basidiobolus ranarum* and other *Basidiobolus* species, traditionally considered as Zygomycetes, have now been placed in the Chytridiomycetes, despite being nonflagellate (Nagahama *et al*., 1995).

Figure 2 Tick (*Ixodes ricinus*) killed by *Metarhizium anisopliae*. (Photo courtesy of C. Nielsen.)

Within the true Zygomycota, the class Trichomycetes contains species often associated with insects. While Sweeney (1981) described the species *Smittium morbosum* (Trichomycetes) as a pathogen of mosquitoes, most associations of the Trichomycetes are symbiotic or weakly parasitic rather than true pathogens (Beard and Adler, 2002; Cafaro, 2002). Some species of *Mucor* (Mucorales) are occasionally associated with insect mortality.

The majority of entomopathogenic species within Zygomycota are contained in one order, the Entomophthorales. More than 200 entomopathogenic Entomophthorales species have been recognized. They commonly cause spectacular epizootics and are characterized in all genera but one (*Massospora*), by the production of forcibly discharged primary conidia. Many species are capable of producing various types of secondary conidia from the primary conidia and, in some cases, infection is obligatorily through a secondary conidium. Many species are also capable of producing resting spores, long-lived zygospores or azygospores. These fungi are generally obligate pathogens in nature, and many species are presently difficult or impossible to culture on artificial media.

Until around the 1960s, most entomopathogenic Entomophthorales were contained within a single genus, *Entomophthora*, but several years of taxonomic revision have placed the species into several genera. The main genera containing entomopathogenic species are *Conidiobolus, Entomophaga, Entomophthora, Erynia, Furia*, *Massospora, Neozygites, Pandora, Strongwellsea*, and *Zoophthora*.

Figure 6 Alate termite (*Macrotermes* sp.) killed by *Cordycepioideus* sp. The fungus has only been found on alate termites. (Photo courtesy of J. Eilenberg.)

6.11.2.4. Ascomycota (and Deuteromycota)

Fungi from Ascomycota have septate and haploid mycelia and the sexual spores, ascospores, are produced in an ascus on a fruiting body, the ascomata. Typically, eight ascospores are produced in each ascus. No motile zoospores are produced. There has been continuing taxonomic confusion over classification of the teleomorphic (sexual) stages and the anamorphic (asexual) conidial stage when they are not produced by a single occurrence. *Cordyceps*, a genus containing many (>300) entomopathogenic species is probably the best known Ascomycete because the sexual and sometimes asexual stages are produced on highly visible stroma. The genus *Ascosphaera*, which is heterothallic and sexually dimorphic, contains species responsible for chalkbrood disease in bees. Unusually for entomopathogenic fungi, *Ascosphaera* spores are ingested by bee larvae and germinate in the gut (Gilliam and Vandenberg, 1990).

Many strains within Ascomycetes have apparently lost the ability to form the sexual stages, the teleomorph forms, and were classified in the form-class Hyphomycetes. Entomopathogenic species are known from over 40 genera, but the most important entomopathogenic species occur in *Aschersonia, Aspergillus, Beauveria, Culicinomyces, Gibellula, Hirsutella, Hymenostilbe, Lecanicillium* (formerly *Verticillium*), *Metarhizium, Nomuraea, Paecilomyces, Sorosporella*, and *Tolypocladium*.

Figure 7 Small Diptera (Chironomidae) killed by *Erynia conica*. The dead insect is covered by conidiophores from which conidia are discharged. (Photo courtesy of J. Eilenberg.)

Figure 9 Adult cantharid beetle (*Rhagonycha fulva*) infected with *Entomophthora muscae*. Conidia have been discharged from the abdomen and clusters of conidia are seen on the wings. (Photo courtesy of J. Eilenberg.)

Figure 8 Adult dipteran (*Ptychoptera contaminata*) killed by *Entomophaga* (= *Eryniopsis*) *ptychopterae*. No fungus growth is visible before incubation in a moist chamber. (Photo courtesy of J. Eilenberg.)

Figure 10 Small muscoid fly (*Coenosia testaceae*) infected with *Strongwellsea* sp. This fungus causes an abdominal hole in the host, while still alive. Conidia are projected from the hole and the infectious fly can disperse the disease. (Photo courtesy of J. Eilenberg.)

Most of these genera have been linked to one or several ascomycete genera. Such linkages can be demonstrated either biologically (an insect infected with an anamorph dies and a teleomorph is produced) or by using molecular tools showing the genetic relationship between anamorphs and teleomorphs (Huang *et al*., 2002; Liu *et al*., 2002). With the advent of molecular identification, many more links between anamorph and teleomorph stages will be made and, as discussed above, the need for the form-class Hyphomycetes will be unnecessary.

6.11.2.5. Basidiomycota

There are very few Basidiomycetes that have been implicated in insect pathogenesis. Some publications list the Septobasidiales genera *Septobasidium* and *Uredinella* as pathogenic to insects, but most

Figure 11 Colony of cereal aphids (*Sitobion avenae*). One individual (swollen, whitish-orange) is infected by *Pandora neoaphidis* and the discharged primary conidia may result in infection of the rest of the colony. (Photo courtesy of T. Steenberg.)

Figure 12 Ant infected with *Pandora formicae*. Before death, the ant climbs to the top of the canopy, turns the head downwards, and grasps the plant with its legs. The conidiophores then emerge and conidia are discharged, showering the understory, where presumably more hosts are present. (Photo courtesy of J. Eilenberg.)

Figure 13 Adult *Scatophaga stercoraria* killed by a member of the *Entomophthora muscae* complex. White bands of conidiophores emerge from the abdomen, which then produce forcibly discharged conidia. (Photo courtesy of A. Bruun Jensen.)

are considered symbiotic to insects, such as scales (Samson *et al.*, 1988).

6.11.2.6. Approaches to Classification

Traditionally, fungal taxonomy has been based on morphological, developmental, and physiological characteristics, from which the current structure of species, genera, and classes has emerged. While these characteristics worked very well for many years, the complexity of fungal life has led to use of some characteristics in classification that are not the result of coevolution, but parallel evolution of a common function. This has led to the incorrect placement of some species and genera in the phylogenetic scheme. In addition, the use of indirect methods, which evaluate phenotypic traits, have not been useful at

Figure 15 Earwig (*Forficula auricolaria*) infected with *Zoophthora forficulae*. The insect is completely covered with the fungus and is firmly attached to the vegetation by sticky rhizoids produced by the fungus. (Photo courtesy of J. Eilenberg.)

the subspecies level. Identification of specific isolates is necessary in biocontrol, both as a regulatory requirement and to advance understanding of ecology and epizootiology (see Section 6.11.4).

There have been many different approaches to classifying insect pathogenic fungi. In some cases, fungi have been defined functionally or ecologically, rather than phylogenetically, especially when techniques to directly determine phylogeny did not exist. The entomogenous fungi provide an example where the entomogenous habitat was seen as a defining criterion in many cases, whereas morphology and physiology formed the basis of many of the earlier efforts with other fungi. Early descriptions of *M. anisopliae* refer to *Entomophthora anisopliae* (Zimmermann *et al*., 1995), recognizing the relationship between two common entomogenous groups over dissimilarities in morphology and physiology. The mode and morphology of conidiation has been a main character used for classification.

In recent times, classification systems have attempted to take a more phylogenetic approach to systematics (e.g., Humber, 1984), but a true phylogenetic classification had not emerged for most organisms until the advent of molecular biology. Other approaches are still being explored. Chemotaxonomy has been attempted with some entomopathogenic groups such as *Beauveria*, utilizing the commercially available carbohydrate utilization strips system of API (i.e., API50CH) (Todorova *et al*., 1994; Rath *et al*., 1995). Isoenzymes have been investigated for their ability to discriminate between fungal strains (e.g., May *et al*., 1979; St. Leger *et al*., 1992b), but their power in phylogenetic classification is limited.

Molecular techniques that target RNA and DNA have been applied at every level of the taxonomic hierarchy. Many techniques have been applied, some of which directly sequence genes, and some of which represent differences in DNA sequence, such as random amplified polymorphic DNA (RAPD) and restriction fragment length polymorphism (RFLP) approaches. Pulse field gel electrophoresis (PFGE) allows the separation of DNA fragments as large as chromosomes and can be used for whole genome restriction digest comparisons. Chromosome length polymorphism was used by Viaud *et al*. (1996) to study nine isolates of *B. bassiana*. Mitochondrial DNA has been used to estimate intraspecies variation in *Lecanicillium* (= *Verticillium*) *lecanii* and *M. anisopliae* isolates (Typas *et al*., 1998). There are a number of reviews on the use of molecular characterization for entomogenous fungi (e.g., Clarkson, 1992; Driver and Milner, 1998).

With the development of molecular biology as a mainstream tool in classification, it became possible to test assumptions formed by studies based on morphology and other characteristics reliant on phylogenetic relationships. In macroevolution, the seven kingdoms are based largely on sequencing of small subunit ribosomal genes. While classifying fungi solely on the sequence of any gene is not wise, a general consensus is being reached over the evolutionary position of the fungi in respect to other groups based on rRNA gene sequences (e.g., Berbee and Taylor, 2001). Molecular analysis has shown that a number of species and genera classified as fungi, or in the kingdom Eumycota, are actually grouped with the Chromista. Many species have been placed in the fungi simply on the basis of hyphal growth, but are now being reconsidered.

The genera of entomopathogenic fungi are being reconsidered on the basis of sequencing of conserved genes and introns. Recent efforts to clarify classification of entomopathogenic fungi demonstrate the utility of molecular characterization at several levels. Zare *et al*. (2000), Gams and Zare (2001), Zare and Gams (2001) have redefined the genus *Verticillium* using rDNA sequencing, placing all insect pathogens in the genus *Lecanicillium*. Similarly, sequencing of large subunit rRNA gene revealed *Paecilomyces* may not be monophyletic (Obornik *et al*., 2001). Sequencing of the small subunit rDNA has also been used to examine phylogenetic relationships among the order Entomophthorales (Jensen *et al*., 1998). These molecular studies supported the use of spore discharge characteristics as an identifying characteristic for Entomophthorales.

Molecular studies have also been useful in positioning individual species, such as *Basidiobolus ranarum*, previously placed in the Zygomycota, as a nonflagellate species of chytrid (Nagahama *et al.*, 1995). The use of sequence level analysis also suggested reassigning of species such as *Eryniopsis ptychopterae* to *Entomophaga* (Hajek *et al.*, 2003).

As noted above, the use of DNA and RNA comparisons has never been more useful than when considering the fungal species that never reproduce sexually, because the characters of sexual reproduction are the basis for much of the traditional alignment of family, genera, and species. While the higher classification of fungi is in a state of flux, the form-class Hyphomycetes is likely to disappear in the near future, with DNA analysis making the need for a group for which a sexual stage is not known redundant. Linking of anamorphs and teleomorphs is now relatively straightforward. For example, sequencing of the ITS-5.8s region of nuclear RNA has recently been used to confirm a teleomorph, *Cordyceps bassiana*, of *Beauveria bassiana* (Huang *et al.*, 2002).

Strain characterization is a useful attribute, particularly for biocontrol, and in some cases, molecular techniques have assisted the placement of an important strain into species. The taxonomic position of *M. anisopliae* strain IMI 330189 used in the LUBILOSA program for locust control was confusing, as it was originally classified as *M. flavoviride* based on morphology of the conidia and some other features. Driver *et al.* (2000) used molecular techniques to revise the genus *Metarhizium* and demonstrate subspecific relationships among *M. anisopliae* and *M. flavoviride* strains, based largely on the sequence of the ITS-5.8s regions of rRNA. Sequencing of the ITS-5.8s region of *M. anisopliae* strain IMI 330189 revealed it to be a *M. anisopliae* subspecies, which they named *M. anisopliae* var. *acridum*. However, species cannot be erected on sequence data alone, and several of the subspecies "clades" identified by Driver *et al.* (2000) can only be delimited by sequence data at present.

The main drawback with molecular approaches to classification is the lack of agreement on standard techniques. This is not generally a problem for use in strain identification, but the choice of method does influence the relationships among species and genera. The use of rRNA sequences has become widespread, but as the studies of Rehner (2003) show, reliance on single region sequences may be misleading. Rehner (2003) used a multigene sequencing approach to clarify the taxonomic position of *Beauveria* species strains. This approach is a step beyond what is currently known about the molecular taxonomy of most entomopathogenic fungi and is likely to be a common approach in the future.

The contribution of molecular techniques to the development of entomopathogenic fungi has been enormous. The techniques have been used to clarify evolutionary relationships (e.g., Jensen *et al.*, 1998; Driver *et al.*, 2000) as well as allow development of theories of evolution around these, often obligate, pathogens. However, there are a number of difficulties with some current studies, such as incorrect typification and lack of holotypes (Samson, 1995). Few of the species have yet been studied in detail.

6.11.3. Biology and Pathogenesis

Survival of entomopathogenic fungi requires a delicate balance of interaction between the fungus, host, and the environment. In general, the life cycle of entomopathogenic fungi involves an infective spore stage, which germinates on the cuticle of the host, forming a germ tube that penetrates the cuticle and invades the hemocoel of the insect host (Hajek and St. Leger, 1994). The fungus then multiplies within the insect and kills it; death is due to toxin production by the fungus or multiplication to inhabit the entire insect. Under favorable environmental conditions, the fungus grows out of the cadaver, and forms conidiophores or analogous structures and sporulates. Alternatively, many species form some type of resting stage capable of surviving periods of adverse conditions before forming or releasing a type of spore. Spores need new hosts, so the fungus needs a strategy for dissemination. There are many variations and even exceptions to this generalized life cycle. However, the important point is that the environment and host are crucial to the survival and reproduction of the fungus.

6.11.3.1. Encounter with Host

The role of the host is both passive, in that it is the main nourishment for the fungus to produce reproductive structures in most cases, and active, in that the fungus needs to contact the host under suitable conditions. The role of environmental variables for terrestrial fungi is hard to overstate. For some fungi, such as conidia producing Hyphomycetes, germination, penetration, and sporulation can all require high humidity. Temperature is usually limiting, with infection occurring within a certain range. Hyphomycetes generally have temperature optima between 20 and 30 °C, while Entomophthorales, require 15–25 °C, suggesting that Entomophthorales are the more temperate fungi. Individual isolates within a single species can vary in temperature

optima. Similar temperatures are usually required for germination, sporulation, and discharge.

Some species are more dependent on high humidity than others. *Lecanicillium lecanii*, a hyphomycete, can require up to 16 h of 100% relative humidity (RH) at the leaf level in order to cause high mortality rates in whiteflies (Milner and Lutton, 1986). In other cases, humidity requirements appear lower, such as *Entomophthora muscae* infecting Diptera (Mullens and Rodriguez, 1985). However, it is often difficult to measure the actual humidity that the fungus is exposed to, due to microclimatic variability. Leaf transpiration may create adequate humidity at the leaf surface, which is difficult to measure (Vidal *et al*., 2003), allowing infection to occur even at low ambient humidity conditions (Fargues *et al*., 2003). Dew period can also be more important than ongoing high humidity (e.g., Milner and Lutton, 1986). Entomophthorales are often very dependent on >95% RH for sporulation and conidial germination, despite the occasional exception such as *E. muscae* (see Section 6.11.3.4).

Soil presents a range of abiotic and biotic factors that influences the life cycle of fungi. Moisture can be more constant and higher in the soil environment than on plants, but spore movement is more restricted than in the epigeal environments. The level of organic matter and pH can be important in the eventual infections levels, as well as in survival of propagules. In this way, soil is more similar to aquatic environments. In soil, other microbes and small invertebrates (e.g., springtails; Broza *et al*., 2001) can consume fungi directly, compete saprophytically, or be directly or indirectly antagonistic to the entomopathogens. It is not surprising that fungi are more effective in sterilized than unsterilized soils in the laboratory (e.g., Inglis *et al*., 1998). Microbes such as bacteria resident within insect hosts can compete within infected cadavers and, if the fungus does not have mechanisms to exclude these microbes, the fungus will be unable to colonize the cadaver sufficiently to allow sporulation.

Other abiotic conditions that influence encounters between the host and pathogens are wind and sunlight. Wind can assist spore dispersal but will also decrease humidity and remove free water in some cases. Sunlight and UV can be detrimental to the persistence of infectivity of most fungi. For example, Inglis *et al*. (1997a) found that the poor efficacy of *B. bassiana* against rangeland grasshoppers in a Canadian field trial was a result of conditions of temperature and light exposure, as the fungus was more virulent in greenhouses and shaded cages than in the open rangeland. However, there is significant variation in susceptibility to UV among different species and strains within species (Fargues *et al*., 1996).

Aquatic species of fungi are not subject to the influence of humidity, as they are generally infective only in water. Periodic drying of habitats is a constant problem, but most aquatic entomopathogens have strategies to survive drying. Similar to terrestrial environments, temperature can be a limiting factor. Chemical factors, such as salinity or organic pollutants in the water are also important.

Meteorological data do not always correlate with the occurrence of epizootics, partly because microclimatic conditions are not the same as macroclimatic conditions. There are still many gaps in our knowledge of the interaction between the pathogen, host, and environment, as demonstrated by the lack of prediction of epizootic and disease occurrence in most fungi.

6.11.3.2. Specificity and Host Range

Specificity of entomopathogenic fungi varies widely between genera, within genera, and even among strains of a species. The so-called muscardine fungi, *B. bassiana* and *M. anisopliae*, have well-documented broad host ranges, which include hundreds of insect species from several classes. Veen (1968) listed 204 insects naturally infected by *M. anisopliae*. In the intervening years, many more hosts have been reported and include species of Lepidoptera, Diptera, Coleoptera, Hymenoptera, and Homoptera. Coleoptera are particularly prevalent hosts for *M. anisopliae* with over 70 scarab species included in the list of Veen (1968). Broad host lists, such as for *M. anisopliae*, are often misleading, as individual strains of entomopathogenic fungi can vary in their specificity. In addition, definition and delimitation of species can be arbitrary in these often asexual fungi, as demonstrated by recent molecular analyses of *Metarhizium* (i.e., Driver *et al*., 2000) and *Beauveria* (Rehner, 2003; see Section 6.11.2.6). For biocontrol applications, the isolate is more important than the species as a unit, partly due to variation in virulence to hosts among strains. There are implications in host range for determining the nontarget safety of fungal based bioinsecticides (Goettel *et al*., 1990a; Vestergaard *et al*., 2003). Based on published host ranges of the species *B. bassiana* or *M. anisopliae* it would be very difficult to convince regulators of their environmental safety, but it is commonly recognized that strains of *B. bassiana* and *M. anisopliae* are more restricted in their hosts than the species. A single strain of any entomopathogenic fungus rarely attacks both beneficial and pest species.

Some entomopathogenic fungi have been recorded from as limited a host range as a single species of insect. In the Entomophthorales, several species are known from only one host, but it is difficult to know if this is a true reflection of host range or the result of limited study. Few species have been cultured and even fewer have been bioassayed against a number of insects to determine potential host range. *Zoophthora radicans* (Entomophthorales) has been described from over 80 insect species from Diptera, Coleoptera, Lepidoptera, and Homoptera, but there is clear indication that strains are restricted, generally, to some species in a single insect class (Milner and Mahon, 1985). The individual strains are generally more pathogenic to the insects more closely related to the original host, but there are many exceptions.

Other groups of entomopathogenic fungi are limited in host range. *Coelomomyces opifexi*, for example, is known from only two mosquito species and a copepod intermediator (Glare and Milner, 1991). The many species of *Cordyceps* represent both broad and narrow host range species (e.g., Kobayasi, 1941), but here, again, information is limited.

In many cases, entomopathogenic fungi will kill certain species only in special situations. *M. anisopliae* is rarely recorded naturally as a pathogen of mosquitoes, but in the laboratory, many strains are highly pathogenic to mosquito larvae (Daoust and Roberts, 1982), indicating that other factors than susceptibility are important in occurrence of disease in nature. In some cases, the fungus can only kill weakened or stressed hosts. Behavioral avoidance can also lead to nonsusceptibility in the field, when laboratory bioassays indicate susceptibility. For example, *Aspergillus flavus* can be isolated from many wasp (*Vespula* spp.) nests in New Zealand and is highly pathogenic in the laboratory to *Vespula* (Glare *et al*., 1996), but the hygienic behavior of wasps is such that infections in healthy nests are not seen. *Zoophthora phalloides* is a pathogen of aphids, but shows distinct preferences in the field for some species. Remaudiére *et al*. (1981) recorded 72% of *Myzus ascalonicus* infected with *Z. phalloides* on a single bush, but only 6% of *Myzus ornatus* on the same bush. Conversely, *Pandora neoaphidis* on the same bush infected 71% of *M. ornatus* and only 1% of *M. ascalonicus*. The difference in susceptibility is likely due in part to the mode of infection by the two fungal species, as much as to possible differences in resistance among the aphid species. *Zoophthora phalloides* infects via the sessile capilliconidia, making it more effective against mobile hosts, while *P. neoaphidis* uses forcibly discharged primary and secondary conidia, which are more effective when they land directly on a host. Unsurprisingly, *M. ascalonicus* is a more mobile aphid than *M. ornatus*.

These results highlight the difference between laboratory and field susceptibility. If results from laboratory assays are to be used to predict activity in the field, pertinent environmental and exposure parameters must be incorporated as much as possible in the bioassay design (Butt and Goettel, 2000). For instance, in the laboratory, most bioassays do not allow for avoidance of the pathogen through biological, ecological, or behavioral methods. In the field, an insect may never come in contact with sufficient inoculum to succumb to infection. An example is caterpillars and *E. maimaiga*, a pathogen of gypsy moth. Hajek *et al*. (1996) examined the field incidence of caterpillars infected with *E. maimaiga* where high gypsy moth infections were occurring. They found only two individual caterpillars (1 of 318 *Malacosoma disstria* and 1 of 96 *Catocala ilia*) of a total of 1511 larvae from 52 species belonging to seven lepidopteran families infected with *Entomophaga maimaiga*. In the laboratory, more species were found to be susceptible and high percentages of the few species found infected in the field were infected in the laboratory. Despite *E. maimaiga* being a pathogen of the Lymantriidae in the laboratory, species other than gypsy moth are unlikely to be infected in the field unless they spend periods of time near the leaf litter where the fungus is sporulating (Hajek *et al*., 2000). Similarly, differential infections of mosquito hosts can be linked to position in the water profile, as bottom feeding species are more likely to come in contact with settling inoculum than surface feeders (Sweeney, 1981).

In most entomopathogenic fungi, there is differential virulence towards life stages of insects that are susceptible. Unlike bacterial, viral, and protozoan pathogens, most fungi directly penetrate the cuticle and do not need to be ingested. Therefore, entomopathogenic fungi have the potential to be active against nonfeeding stages such as pupae. Aquatic species, such as *Lagenidium* and *Coelomomyces*, rarely attack adult stages, although they can persist in them (see Section 6.11.3.4). Hyphomycetes such as *Metarhizium* and *Beauveria* often infect both adult and larval stages. Keller and others have used the ability of *Beauveria brongniartii* to infect both larval and adult stages of the European cockchafer, *Melolontha melolontha*, to develop biopesticide strategies based on spraying adults in order to transfer inoculum to the larvae in the soil (Keller *et al*., 1989). Most fungi, even if they attack all

life stages, show variability in virulence between the stages. Even within the larval stage, there is usually variability in susceptibility. For example, mosquito larvae were more susceptible to *Culicinomyces clavisporus* at earlier instars than later ones (Panter and Russell, 1984), while the scarab *Costelytra zealandica* is more resistant to *M. anisopliae* at the second compared to the third instar (Glare, 1994), indicating there is no general rule regarding which developmental stage will be more susceptible.

The development of resistance to entomopathogenic fungi in insect populations has rarely been documented. When the pea aphid, *Acyrthosiphon pisum*, was introduced to Australia, it became resistant to the pathogen, *P. neoaphidis*. Soon after the development of resistance, the fungus developed strains that were fully pathogenic for pea aphid, indicating a rapid genetic capacity to overcome resistance (Milner, 1982, 1985).

Genotyping using various molecular methods is becoming increasingly common in the identification of entomopathogenic fungi (see Section 6.11.2.6). However, the methods used to date rarely demonstrate a link between genotype and host preference where sufficient strains have been examined to give a meaningful result. There are exceptions, such as *B. bassiana* pathogenic to *Ostrinia nubilalis* and *Sitona* weevils, where some homogeneity among isolates from these hosts was found (Viaud *et al.*, 1996; Maurer *et al.*, 1997). In most cases, the molecular methods do not target genetic regions involved in specificity, but are aimed at random, nonspecific regions, or regions involved in basic cellular processes, such as ribosomal and mitochondrial regions. This suggests host specificity evolves relatively rapidly. Targeting of genes involved directly in virulence related events may lead to better matching between molecular identification and host range.

6.11.3.2.1. Vertebrate safety Fungi in general are well known allergens that produce toxins and are capable of infecting vertebrates. Fungal epizootics may be responsible for drastic reductions in invertebrate populations, populations that may be an important food source for some vertebrates. Consequently, the actions of entomopathogenic fungi may compromise vertebrate health and well-being in several ways.

Fungi are an important source of human allergens. However, entomopathogenic fungi are not typical human allergens (Gumowski *et al.*, 1991), indicating that exposure to fungi generated from natural epizootics does not generally induce allergenic reactions. Allergy problems have been documented in workers frequently exposed to certain entomopathogenic fungi such as *B. bassiana* (Saik *et al.*, 1990) and crude extracts from *M. anisopliae* contain potent allergens (Ward *et al.*, 1998). However, there were no reports of human hypersensitivity during mass production of *B. bassiana* by the Mycotech Corporation involving more than 30 000 person-hours of exposure (Goettel and Jaronski, 1997). Screening for allergies in 145 Tate and Lyle (Reading, UK) employees exposed to *L. lecanii* during its manufacture and of 31 employees involved in its field testing in greenhouses, concluded that the fungus is not significantly allergenic, even to a worker population that was more highly allergic to other allergens than average (Eaton *et al.*, 1986). Since all fungi are potentially allergenic, it is unreasonable and impractical to expect a total absence of allergic potential in microbial insecticides based on fungal pathogens. However, certainly every effort should be made to avoid human exposure during manufacture and application.

For the most part, entomopathogenic fungi are not virulent towards vertebrates (Saik *et al.*, 1990; Siegel and Shadduck, 1990). However, there are some exceptions. Certain species of entomopathogens such as *Conidiobolus coronatus* or *A. flavus* are well-known pathogens of vertebrates and, because of this, they are generally not considered for development as commercial biopesticides. An exception may be *Paecilomyces lilacinus*. Although as a species, it is known to cause human and other vertebrate infections and is an important emerging nosocomial fungal pathogen (Goettel *et al.*, 2001), the strain P 251, isolated in the Philippines, has been successfully developed as a safe microbial nematicide by the Australian Technology Innovation Corporation (Copping, 2001). This is another example of how fungal pathogens must be judged at the strain level, and not at the species level.

Although there have been no reports of infections in vertebrates directly resulting from the use of fungal pathogens as microbial control agents, there are several documented cases of "chance" occurrences. For instance, several entomopathogenic Hyphomycetes have been recovered from captive cold-blooded vertebrates (Austwick, 1983; Gonzalez Cabo *et al.*, 1995), although it is generally believed that these animals have been severely stressed by chilling. Laboratory challenge assays demonstrated pathogenicity of *B. bassiana* to silverside fish embryos and fry (Genthner and Middaugh, 1992), and of *M. anisopliae* to grass shrimp embryos (Genthner *et al.*, 1997) and silverside fish embryos and fry (Genthner and Middaugh, 1995). There have been several cases of human infection by entomopathogenic fungi reported for species presently in use as microbial control agents, with one fatality in an

immunoincompetent child, but none of these have been implicated from the commercial use of specific strains (Goettel *et al.*, 2001; Vestergaard *et al.*, 2003). The most recently reported case concerns the deep tissue infection of an immunosuppressed female by a *Beauveria* sp. (Henke *et al.*, 2002). The isolate in question was unable to grow *in vitro* at 37 °C, which indicates that the inability to grow at this temperature *in vitro* is insufficient to rule out possible infection and growth in mammalian tissues. Interestingly, this isolate was more virulent against a test insect, the Colorado potato beetle, as compared to a well-known entomopathogenic strain of *B. bassiana*.

Entomopathogenic fungi produce an array of metabolites (see Section 6.11.3.3.1 below), many of which are toxic or carcinogenic to vertebrates (Strasser *et al.*, 2000; Vey *et al.*, 2001). However, any hazard to vertebrates would require exposure to significant levels of these metabolites. Current evidence suggests that, unless infected insects are actively pursued and ingested (e.g., insect cadavers infected with *B. bassiana* are widely consumed in China for medicinal purposes), the risk to vertebrates should be minimal. To date, no detrimental effects have been noted in vertebrates fed insect cadavers. For instance, ring-necked pheasant chicks given feed coated with *M. anisopliae* var. *acridum* (as *M. flavoviride*) spores or infected grasshoppers for 5 days showed no significant changes in weight, growth rate, behavior, or mortality rate as compared to controls fed noninoculated food or noninfected grasshoppers (Smits *et al.*, 1999). Strasser *et al.* (2000) speculate that entomopathogenic fungi should pose no obvious risk to humans because toxin quantities produced *in vivo* are usually far lower than those produced *in vitro* and, therefore, toxin levels should never rise to harmful levels in the environment.

Fungal epizootics may deplete an important food source for certain vertebrates. However, at the same time, depletion of a pest is the desired effect in the use of an entomopathogenic fungus in microbial control. The possible effects on vertebrates due to the depletion of a food resource as a result of fungal epizootics, either natural or induced, are poorly documented. However, for the most part, depletion of the target host is the desired effect and can be more or less regulated in an integrated pest management program where fungi are used in large amounts (also called inundation). However, special attention must be paid if exotic fungi are to be used in the classical sense of biocontrol (Goettel and Hajek, 2001).

Stringent regulatory requirements address vertebrate safety issues. Before any entomopathogenic fungus can be registered as a microbial control agent, it must first undergo stringent testing for potential harmful effects on vertebrates, including mammals (see Laird *et al.*, 1990; Siegel, 1997). In principle, no harmful agent should ever make it onto the market. However, with the increasing development of immunosuppressive therapy in medicine, the increase in iatrogenic factors and nosocomial diseases, and the advent of new infectious diseases such as AIDS, the list of opportunistic fungi causing deep mycoses is increasing (Chabasse, 1994), and this includes some entomopathogens. Entomopathogens must be carefully scrutinized, but at the same time, regulations must not become unjustly stringent so as to significantly deter registration of safe and useful products.

6.11.3.3. Mode of Action and Host Reactions

Entomopathogenic fungi kill the host by a variety of means, from starvation through multiplication in the host, to production of toxins. Given the pathogenic habit, it is hardly surprising that entomopathogenic fungi produce extracellular enzymes and toxins. Entomopathogenic fungi produce a variety of chitinases and proteases, which aid penetration of the host physical defenses.

The main barrier to infection of insects by entomopathogenic fungi is the cuticle. For the majority of fungi, the route of infection is directly through the cuticle, not after ingestion. The fungus, therefore, needs enzymatic and/or physical means to penetrate this thick, multilayered shell. The process of infection starts with the spore contacting the cuticle of a host. In many cases, the conidia are adhesive to the cuticle, or secrete adhesive mucus as the conidium swells during pregermination (Hajek and St. Leger, 1994). Capilliconidia, the infective sessile spores of some *Zoophthora*, have a drop of adhesive on the end of the spore to assist attachment to passing insects (Glare *et al.*, 1985). Zoospores of *Lagenidium* encyst on the host surface, ensuring attachment (Kerwin and Petersen, 1997).

The exact mechanisms used by each fungus for penetration of the host cuticle may differ, but there are general processes and structures involved. *Metarhizium anisopliae*, for example, develops a number of specific structures to assist the anchoring and penetration of germ tubes, which arise from conidia (St. Leger, 1993). Appressoria and infection pegs assist the penetration of germ tubes. Once the penetrative tube has passed through the layers of the cuticle and epidermis, the fungus can proliferate in the hemocoel. For some hyphomycete fungi, such as *M. anisopliae*, this is initially performed by blastospores, while for some Entomophthorales,

proliferation can be by wall-less protoplasts (e.g., Butt *et al*., 1981; Bidochka and Hajek, 1998).

Injection of entomopathogenic fungi directly into the hemolymph can demonstrate that the cuticle is a major barrier to infection. However, the insect also has cellular and humoral methods of defense against fungal invasion. For example, when Bidochka and Hajek (1998) injected *Entomophaga aulicae* into gypsy moth larvae, a nonpermissive host, there was no evidence of restricted fungal growth, fungus specific induction of plasma proteins, or hemoctye encapsulation, but higher levels of phenoloxidase and prophenoloxidase-activating trypsin activity were found up to 96 h postchallenge. Bidochka and Hajek (1998) suggested that surface components of protoplasts, such as glycoproteins, may be implicated in activation of zymogenic trypsins in the insect, which in turn activate the prophenoloxidase cascade as a nonpermissive response.

6.11.3.3.1. Toxin production Some entomopathogenic fungi produce toxins, some of which are insecticidal and may assist in pathogenesis. Others produce metabolites that are antimicrobial, either to restrict saprophytic competition or protect against antagonistic microorganisms. Toxic metabolites from entomopathogenic fungi have been reviewed extensively by Roberts (1981) and, more recently, by Vey *et al*. (2001). The safety aspects of fungal metabolites have become an important issue, with implications for risk assessments, and these were reviewed by Strasser *et al*. (2000; see also Section 6.11.3.2.1).

Among the fungal metabolites that assist pathogenicity are the destruxins of *Metarhizium* spp. First described in 1961 (Kodaira, 1961), these cyclodepsipeptides are toxic to a number of insects. Susceptibility varies considerably, with a 30-fold difference between silkworm larvae and *Galleria* (Roberts, 1981). While the basic structure of destruxins is based on five amino acids and α-hydroxy acid, a number of isomers and congeners have been described (Vey *et al*., 2001). Destruxins have also been described from *Aschersonia* sp. (Krassnoff and Gibson, 1996) and from some plant pathogenic fungi. As well as toxicity at high doses, some destruxins reduce growth and reproduction (e.g., Brousseau *et al*., 1996). There is possibly a relationship between the chemical structure of the various destruxins and activity, with some forms more active against certain insect species (Vey *et al*., 2001). Destruxins can also be repellent or act as an antifeedant (Robert and Riba, 1989; Amiri *et al*., 1999; Thomsen and Eilenberg, 2000). Production of destruxins by some species and strains has been linked to increased host range, suggesting a role in pathogenic determination (Amiri-Besheli *et al*., 2000). Synthetic analogs to destruxins have been tested against lepidopteran insects and also proved toxic, and thus are potentially useful as novel pesticides (Thomsen and Eilenberg, 2000).

Some strains of *Beauveria* spp. produce beauvericin, a depsipeptide metabolite, which has shown toxicity to a number of invertebrates (Hamill *et al*., 1969; Roberts, 1981). Beauvericin has also been isolated from *Paecilomyces fumosoroseus* mycelium and the plant pathogenic fungus *Fusarium* spp. Activity has been classified as moderate against insects (Vey *et al*., 2001) and is not effective against all insects (Champlin and Grula, 1979). *Beauveria bassiana* also produces beauverolides, isarolides, and bassianolides, all cyclotetradepsipeptides, the former of which has been shown to be toxic to cockroaches (Frappier *et al*., 1975; Suzuki *et al*., 1977). Bassianolides have been shown to have activity against silkworms (Kanaoka *et al*., 1978). A further two nonpeptide toxins, bassianin and tenellin, have been isolated from *Beauveria* spp. and shown to inhibit the erythrocyte membrane ATPases (Jeffs and Khachatourians, 1997), but little else is known.

Linear peptidic efrapeptins are produced by *Tolypocladium* species and have some insecticidal and miticidal effects (Matha *et al*., 1988; Krasnoff *et al*., 1991). The species of *Tolypocladium* produce efrapeptins in varying amounts (Bandani *et al*., 2000). Bandani and Butt (1999) reported antifeedant and growth inhibitory properties.

Hirsutellin A is produced by *Hirsutella thompsonii* and is not proteolytic, but is toxic to a range of insects including *Galleria mellonella*, the mosquito, *Aedes aegypti* (Mazet and Vey, 1995), and mites (Omoto and McCoy, 1998). It is produced during liquid fermentation, and the sequence and amino acid composition is unlike any other known protein (Mazet and Vey, 1995). Other fungal toxins known to have some insecticidal properties include *Aspergillus* spp. Several toxins have been isolated from cultures of *Aspergillus*, such as kojic acid (Beard and Walton, 1969) and some mosquitocidal toxins (Toscano and Reeves, 1973). The production of aflatoxins by some strains of *Aspergillus* restricts interest in the group as insect pathogens, as these compounds have carcinogenic and tumor producing properties as well as some insecticidal properties.

It has not been demonstrated whether all entomopathogenic fungi produce toxins in the disease process and, indeed, if toxins are required for virulence. Quesada-Moraga and Vey (2003) demonstrated that *B. bassiana* can be pathogenic to the

locust regardless of toxin production. Furthermore, *in vivo* passage through a host or repeated subculture on artificial medium had a variable effect on toxin production; virulence and toxicogenic activity of one isolate was dependent on the mycological media that the inoculum was produced on, whereas virulence and toxicogenic activity of another isolate was greatly increased after two passages through the host.

In some cases, toxins are suspected, but not conclusively demonstrated. Some of the lower fungi, such as *Coelomycidium, Coelomomyces*, and the Entomophthorales, may possess only weak toxins, if any at all. It is more likely that they overcome their hosts by utilizing the nutrients and invading vital tissues (Roberts, 1981). Culture filtrates from entomophthoralean fungi injected into greater wax moth larvae (*Galleria*) resulted in blackening similar to that found in fully infected larvae, suggesting that toxins were active, but none were identified (Roberts, 1981). A short-lived cell lytic factor is thought to be responsible for death in lepidopteran hosts infected with *E. aulicae* (Milne *et al*., 1994).

Antibiotics are produced by entomopathogenic fungi in order to exclude saprophytes and resident microbes that compete for nutrients in the cadavers. Oosporein, a red-colored dibenzoquinone, is produced by strains of *Beauveria* spp. and has antiviral and antibacterial properties. Oosporein was found to inhibit the herpes simplex virus-1 DNA polymerase (Terry *et al*., 1992) and is active against Gram-positive, but not Gram-negative, bacteria (references in Vey *et al*., 2001). Beauvericin has shown antibiotic activity against bacteria (Ovchinnikov *et al*., 1971), and destruxin E has antivirus activity against nucleopolyhedrovirus (Quiot *et al*., 1980). The antibiotic phomalactone has been described from *H. thompsonii* var. *synnematos* (Krasnoff and Gupta, 1994) and was inhibitory to the entomopathogenic fungi *Beauveria, Tolypocladium*, and *Metarhizium*. Members within the *Cordyceps* also produce a number of metabolites that may be weak toxins or antibiotics. *Cordyceps* infected caterpillars are used as a traditional medicine in parts of Asia, and this may be partly based on the production of cordycepin, a weak antibiotic, by *Cordyceps* Zabra *et al*. (1996) reported that metabolites from *Pandora neoaphidis* had antibacterial activity.

6.11.3.3.2. Behavioral responses There have been relatively few detailed studies on the behavioral responses by hosts as a result of infection by entomopathogenic fungi. In the early stages of infection, in many cases, there are no noticeable symptoms; however, several days prior to death, symptoms become evident and include reduced feeding, activity, and coordination. Other responses include increased feeding, behavioral fever, altered mating or oviposition preferences, and positive or negative photo- or geotropism. Most responses are seemingly adaptations that favor either the host or the pathogen, while others may be the result of depletion of the host's nutritional reserves and the process of dying.

Reduced feeding has been reported in several insects. Examples include grasshoppers and locusts infected with *M. anisopliae* var. *acridum* (Prior *et al*., 1992; Thomas *et al*., 1997; Arthurs and Thomas, 2000), gypsy moth larvae infected with *E. maimaiga* (Hajek, 1989), *Plutella xylostella* larvae infected with *Z. radicans* (Furlong *et al*., 1997), and larvae of the Colorado potato beetle infected with *B. bassiana* (Fargues *et al*., 1994). In contrast, no change in consumption of food has been reported in some insects, such as *Plathypena scabra* (Lepidoptera, Noctuidae) infected with *Nomuraea rileyi* (Thorvilson *et al*., 1985) and *Cerotoma arcuata* (Coleoptera; Chrysomelidae) infected with *B. bassiana* (Lord *et al*., 1987). Increased feeding has been reported in *Lygus hesperus* (Noma and Strickler, 2000) and Colorado potato beetles infected with *B. bassiana* (Fargues *et al*., 1994). With the Colorado potato beetle, however, phagostimulation occurred only within the first 24 h after inoculation. Thereafter, there was no significant effect on consumption until day 2, and after that, consumption decreased significantly, resulting in an overall reduction in food consumption.

Intuitively, one could surmise that increased feeding during early stages of infection might favor either the host or pathogen. The pathogen might be favored if such increased feeding increases resources provided to it, although spore production of *E. maimaiga* in starved postinoculated gypsy moth larvae equaled production on fed larvae, suggesting, at least for this system, that larval feeding during the period of pathogen incubation within the host is not necessary for fungal development (Hajek, 1989). However, it may favor the host if such feeding provides more resources to fight off the pathogen. Most probably, decreased feeding just prior to death is a result of an overall shutting down of metabolic functions as the host nears death.

Some insects respond to fungal infection by altering their thermoregulatory behavior and achieving a higher than normal body temperature by basking in the sun or orienting on warmer surfaces. This is called "behavioral fever" and has been shown to either significantly slow the progress of infection or at times even eliminate the disease. This

phemonenon has been observed in fungal infections of *E. muscae* in flies (Watson *et al.*, 1993; Kalsbeek *et al.*, 2001a) and of *B. bassiana* and *M. anisopliae* var. *acridum* in grasshoppers and locusts (Inglis *et al.*, 1996b, 1997a; Blanford *et al.*, 1998; Blanford and Thomas, 2001). Clearly, the higher temperatures achieved during thermoregulation and/or behavioral fever exceed the pathogen's thermal threshold and are consequently detrimental to its growth and proliferation (Carruthers *et al.*,1992; Inglis *et al.*, 1996a, 1997b; Ouedraogo *et al.*, 2003). However, the ability to thermoregulate is possible only when environmental conditions are favorable and, consequently, behavioral fever is often not possible or is interrupted. For instance, a higher death rate of caged *B. bassiana* inoculated grasshoppers occurred in shaded than in nonshaded areas (Inglis *et al.*, 1997a). Even though some insects such as acridids infected by *M. anisopliae* var. *acridum* cannot escape infection, behavioral fever acts to prolong survival; only infected desert locusts that were allowed to "fever" were capable of surviving to adulthood, mating, and producing viable offspring (Elliot *et al.*, 2002). In addition to slowing the growth of fungal propagules within the host, elevated temperatures may increase the host immunity by maintaining high hemocyte population levels (Ouedraogo *et al.*, 2003) and inducing hemolymphal proteins (Ouedraogo *et al.*, 2002).

Insects infected with an entomopathogenic fungus may also alter their behavior during mating and oviposition. Housefly males preferably seek out *E. muscae*-killed females in their attempts to copulate (Møller, 1993). These males may themselves become infected or they may transmit conidia to uninfected females during copulation (Watson *et al.*, 1993). This behavior favors the dissemination of the fungus. The response to and production of sex pheromones by *Z. radicans* infected male and female *P. xylostella* moths is inhibited, thereby disrupting mating (Reddy *et al.*, 1998). Female carrot flies infected with *E. schizophorae* (as *E. muscae)* were unable to recognize their host plants and oviposited their eggs haphazardly instead of their normal deposition near the food plants (Eilenberg, 1987). It was concluded that, even though infection did not alter fecundity or fertility, *E. muscae* infected flies do not contribute to the development of the carrot fly population, as their eggs have no chance of survival on a nonhost plant. It is unclear whether this behavior provides any benefit to either the host or the pathogen.

Fungal infections are often responsible for inducing aberrant behaviors at or near host death. The result of such behaviors often are of benefit to the pathogen. The most common of these is to cause the infected host to move to elevated positions just prior to death. This is most common in insects succumbing to entomophthoralean infections. For instance, just prior to death, grasshoppers infected with *Entomophaga grylli* climb to the top of the canopy where they die firmly grasping onto the plant substrate by their first two pairs of legs (Carruthers *et al.*, 1997). Flies infected with *E. muscae* exhibit highly stereotyped behavior, which is characterized by four events: last locomotory movement to an elevated position, the last extension of the proboscis to the substrate, the start of upward wing movement, and the end of upward wing movement (Krasnoff *et al.*, 1995). Consequently, the flies die in elevated positions, with the proboscis extended and attached to the substrate, the abdomen angled away from the substrate, and the wings raised above the thorax. Since conidia are forcibly discharged by entomophthoralean fungi, this behavior acts to help distribute the spores over a wider area, allowing the spores to shower on susceptible hosts below. **Figure 16** shows an example of disease

Figure 16 Field situation showing the transmission of *Entomophthora* sp. (a) An adult cadaver of *Rhagonycha fulva* (Coleoptera) killed by *Entomophthora* sp. hangs from a leaf, attached by its mandibles. (b) An uninfected individual is attracted and is likely to get inoculated by physical contact with the conidia present on the cadaver and the leaf. (Photo courtesy of J. Eilenberg.)

transmission between cantharid hosts due to the exposed position of the fungus killed specimen.

6.11.3.4. Spore Production on Host

Spores are the main source of reproduction in entomopathogenic fungi. Among the groups, a number of strategies have been adopted to maximize the chances of finding new hosts to infect, and many different types of spores and sporulation structures have evolved to adapt to different habitats. Host death is a necessary prerequisite for sporulation in most, but not all, entomopathogenic fungi. The entomophthoralean fungus *Strongwellsea castrans*, for example, sporulates from one or two abdominal holes in still living flies (Eilenberg *et al.*, 2000a). However, in the majority of cases, spores are produced after the host has died and the fungus has fully colonized the cadaver.

In the asexual Ascomycetes (largely still classified as Hyphomycetes), production of robust primary conidia in large quantities is the main strategy for reproduction. Conidial production is dependent upon the size of the cadaver and nutritional factors, as well as species and strain of the fungus. In general, infections of a preferred host will generate 10^7–10^9 conidia/cadaver for terrestrial hosts (e.g., Glare, 1987; Luz and Fargues, 1998). For the fungus *N. rileyi* infecting *Helicoverpa armigera* and *H. punctigera* caterpillars, there was an approximately five- to tenfold increase in the number of spores produced in cadavers between 2nd, 3rd, and 5–6th instars (Glare, 1987). Under similar environmental conditions, conidial numbers appear to be mainly dependent upon the surface area of the host (Kish and Allen, 1976).

Most species from the Entomophthorales can forcibly discharge the primary spores, ejecting them away from the cadaver, and hopefully towards new hosts. Furthermore, many species then produce secondary conidia from the primary conidia, the spores of which are also forcibly discharged, and in some cases, capilliconidia are produced, which are detached from the capilli. Capilliconidia are sessile spores formed on top of a long capillary tube and represent a different strategy for infecting hosts, where new hosts encounter the spore when moving about. In some species, capilliconidia are the primary infective spore, e.g., *Z. phalloides* (Glare *et al.*, 1985) and *Neozygites floridana* (Nemoto and Aoki, 1975). Capilliconidia of some species can survive for days at reduced humidities (Uziel and Kenneth, 1991). **Figure 17** demonstrates how conidia may germinate and produce conidia of higher orders in the species *Entomophaga ptychopterae*.

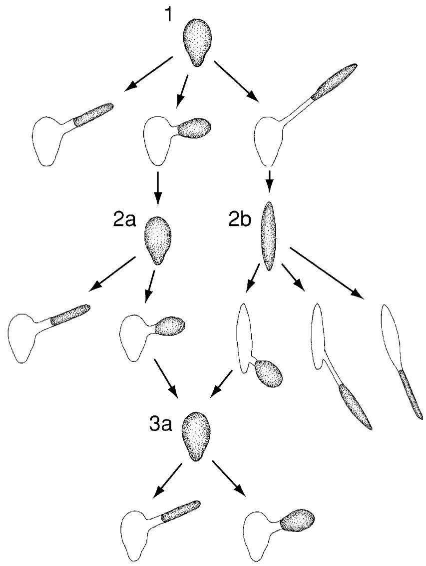

Figure 17 Conidia formation and germination in *Entomophaga* (formerly *Eryniopsis) ptychopterae*. A discharged primary conidium (1) can germinate with a germ tube or produce a secondary conidium of two different types: type 2a, which is similar in shape to the primary conidium or type 2b, which is narrow, ellipsoid, elongated, and produced on long conidiophores. Each type of secondary conidia can germinate with a germ tube or produce a tertiary conidium similar to the primary one (3a). This conidium can germinate with a germ tube or produce a quarternary conidium similar to the primary conidium. In addition, a type 2b secondary conidium can produce a tertiary conidium similar to a secondary conidium type 2b.

Production of primary and secondary spores by entomophthoralean fungi is generally very dependent on environmental conditions, as high humidity (even free water in some cases) is required for spore production (e.g., Steinkraus and Slaymaker, 1994). *Zoophthora phalloides* will only sporulate on aphid hosts at 100% RH and peak spore discharge takes place between 10 and 20°C (Glare *et al.*, 1986). This species produces up to 30 000 conidia per aphid cadaver. In the gypsy moth pathogen *E. maimaiga*, primary conidial production can be as high as 2.6×10^6 conidia per 5th instar cadaver (Shimazu and Soper, 1986). Not all entomophthoralean fungi depend on conditions of high humidity; for example, *Entomophthora muscae* can sporulate at just 50% RH (Kramer, 1980).

Inoculum density can influence eventual spore production on the cadavers. The aquatic *Culicinomyces clavisporus* produced less spores when the host was inoculated with higher doses of the pathogen (Cooper and Sweeney, 1986), and this is often the case for entomophthoralean fungi. This may be due to lack of complete colonization of the host by the fungus, or death due to the release of toxins rather than infection and multiplication.

Entomopathogenic fungi active in aquatic environments usually produce fewer spores than those infecting terrestrial insects. The mosquito pathogen *C. clavisporus* produces around 10^4 conidia/cadaver (Cooper and Sweeney, 1986). *Culicinomyces* produces nonmotile, true conidia, as do other Hyphomycetes. Other aquatic insect pathogenic fungi belong to fungal groups that can produce both motile and nonmotile spores. The oomycete *L. giganteum* produces both motile, biflagellate zoospores and sexually produced oospores (Kerwin and Petersen, 1997). The zoospores are released from both zoosporangial vesicles and oospores. Up to 20 000 sporangia can develop in a mosquito larval host, each releasing zoospores (Couch and Romney, 1973). Oospore production has been demonstrated to require sterols (Kerwin and Washino, 1983). These resistant and long-lived spores are produced within host cadavers. Another group of mosquito pathogens, *Coelomomyces* spp. (Chytridiomycetes) also has two infective stages. Resistant sporangia from mosquitoes release motile haploid zoospores, while the biflagellate diploid zygotes form within or after release from the obligate secondary host, usually a copepod (Lucarotti *et al*., 1985). The zygotes and zoospores are similar. Sporangia in infected mosquitoes can number from 100 to 15 000, releasing up to 5000 motile zoospores from each sporangium (Pillai and O'Loughlin, 1972).

Fluctuating conditions of temperature or humidity interrupt maximum spore production for most fungi. In addition, light and dark cycle influence the sporulation of some entomopathogens, but not others. At least nine entomophthoralean fungi cause host mortality in diurnal rhythms (Milner *et al*., 1984; Mullens, 1985; Tyrrell, 1987; Eilenberg, unpublished data), triggered by the onset of light (dawn) (Milner *et al*., 1984). This timing of host death seems important to allow the fungus to maximize the early morning dew period for sporulation. Conidial discharge of *Z. radicans* demonstrates circadian rhythms under alternating light and dark regimes, with more conidia discharged in the dark (Yamamoto and Aoki, 1983). *Erynia/Pandora neoaphidis* produced around 500 000 primary conidia from infected aphids under ideal conditions, but changing from high to lower humidities and back often stopped, or at least severely reduced, the number of conidia produced (Glare and Milner, 1991).

Resting stages represent a different strategy for entomopathogenic fungi. While primary spores are produced in large quantities by members of the Entomophthorales, they last for only a few days; however, resting spores can survive for months to even years. This allows them to survive periods of unfavorable conditions and cause infections the next season through production of germ conidia. Resting spores are produced within infected cadavers. Factors that influence the production of resting spores include developmental stage of the host, temperature, humidity, and inoculum density (e.g., Shimazu, 1979; Glare *et al*., 1989). With *Z. radicans*, which infects aphids, there is evidence of cytoplasmic based genetic elements involved in resting spore production, with more resting spores produced when aphids are inoculated with dual strains (Glare *et al*., 1989). The ability to produce resting spores varies with individual isolates. With *E. maimaiga* infecting gypsy moth, the primary determinant of resting spore production was larval instar, with infections of later instars producing the most resting spores (Hajek and Shimazu, 1996).

6.11.3.5. Transmission and Dispersal

Dispersal of infective propagules is a crucial component of survival, and entomopathogenic fungi use different strategies to maximize the chances of encountering new hosts. For Hyphomycetes and some other groups that produce copious numbers of spores, wind, rain, and invertebrates play a role in transmission. Generally, wind is a major aid for the distribution of conidia. The minimum airspeed required for dislodgement of *N. rileyi* was calculated to be 2.7 km h^{-1} (Garcia and Ignoffo, 1977).

Entomophthorales generally forcibly discharge the primary conidia, increasing the distribution of these short-lived conidia. Distribution can also be aided by the type of spore formed, with both the forcibly discharged and sessile capilliconidia produced by some Entomophthorales. The aphid pathogen *Neozygites fresenii* discharges about 3000 primary spores per cadaver, and Steinkraus *et al.* (1999) detected up to 90 000 primary conidia per cubic meter of air during the nighttime in a Louisiana cotton crop, indicating how successful forcible dispersal aided by air movement can be. However, for *N. fresenii*, most infections come from the capilliconidia, which are more resistant to the environment than primary conidia. With *Z. phalloides*, it has been demonstrated how aphids collect capilliconidia on their legs when walking across leaf surfaces, making this spore type ideal for infecting low-density mobile hosts (Glare *et al*., 1985).

Another mechanism to assist dispersal is through growth of hyphae out of a cadaver. The *Cordyceps* spp. and some of their anamorphs produce extensive stroma, which can grow more than 30 cm (e.g., Evans, 1982) and produce sexual and/or asexual spores at the end. Even common asexual species

such as *B. bassiana* sometimes grow several centimeters from the infected cadaver in soil. Movement of spores in the soil environment is much more limited than distribution in water or air. However, there is some movement of spores in soil, whether down the soil profile by water movement, or through distribution by invertebrates.

Insect behavior can assist dispersal. Some fungus mediated behavioral changes have been recorded, such as "summit disease" where infected grasshoppers climb to the top of plants to die (see Section 6.11.3.3.2). This may aid spore dispersal, but it has also been suggested that it is a mechanism by which the host reduces infection through increased exposure to UV. Movement of insects such as scavengers (e.g., collembolans; Dromph, 2001), natural enemies (e.g., coccinellid predators or parasitoids; Roy and Pell, 2000; see also Section 6.11.3.6), and pollinators (e.g., honeybees; Butt *et al.*, 1998) can act to disperse fungal inoculum. In some situations, insects may actually be attracted to diseased cadavers. For instance, adult *Rhagonycha fulva* have been observed to visit cohort cadavers (**Figure 16**). Use of insects to disseminate beneficial microbial control agents is further discussed by Vega *et al.* (2000).

Insect behavior can also lead to avoidance of infection. There is evidence that some insects actively avoid spores of entomopathogenic fungi. Scarab larvae were found to move away from soil containing *M. anisopliae* mycelia, but not from conidia (Villani *et al.*, 1999). The same species laid eggs preferentially in areas where mycelia were present, presumably because the mycelia respiration mimics plant root growth. Social insects are particularly adept at behavioral methods to avoid disease. For instance, termites have been shown to avoid conidia of *M. anisopliae* (Milner and Staples, 1996), and the common vespid wasps and honeybees use hygienic behavior to eject diseased individuals from the nest to reduce disease transmission (Gilliam *et al.*, 1983; Harcourt, unpublished data).

Some fungi use the host to aid dispersal directly. The fungus *S. castrans* sporulates from live hosts (**Figure 18**), thereby increasing distribution. Transmission in this species is also assisted by collembola, which can colonize the abdominal holes where the conidia are produced (Griffiths, 1985).

The production of resting spores is a major factor in transmission of many fungi, allowing the fungus to avoid unfavorable environmental conditions or lack of host. Resting spores do not synchronically germinate for most species of the Entomophthorales, increasing the temporal distribution of inoculum and the chances the fungus will eventually encounter new hosts. These spores can be long lived.

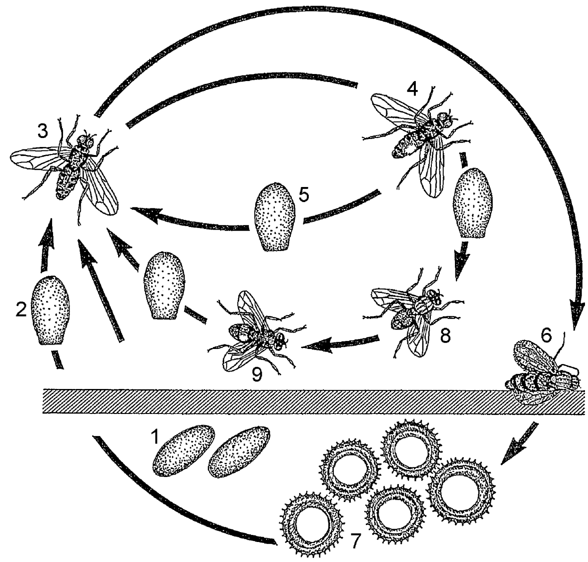

Figure 18 Life cycle of *Strongwelsea castrans*. (1) Pupae of *D. radicum* overwinter in the soil. (2) During spring, it is assumed that infective conidia of *S. castrans* are produced and discharged from resting spores in the soil. (3) Adult *D. radicum* emerge from pupae during spring and become infected by the conidia; one to two abdominal holes appear in the insect as a result of infection. (4) Conidia are forcibly discharged from the abdominal holes up to approximately 30 μm while the fly is still alive. (5) Discharged conidia, eventually after replicative conidiation, infect other adult *D. radicum*. Several successive infection cycles can take place during one season in the host population. (6) After midsummer, some *S. castrans* infected *D. radicum* develop resting spores instead of conidia. Following an incubation period, flies filled with resting spores die and drop to the soil surface. (7) Thick-walled resting spores survive in the soil layers during winter. (8) An alternative dipteran host gets infected. (9) A hole develops and primary conidia are discharged.

Persistence of *E. maimaiga* resting spores was found to be up to 6 years in forest soils (Weseloh and Andreadis, 1997), while the infection of the 17-year cicada by *Massospora* apparently depends upon resting spore germination over the full time frame (Soper *et al.*, 1976).

Transmission in many terrestrial fungi is dependent upon high humidity, with moisture required for sporulation and germination of conidia. It is not surprising that fungi have evolved to take advantage of the early morning dew through timing of host death. Timing death to occur just prior to dusk allows many entomophthoraleans to sporulate during the humidity of early morning. Despite the active discharge, conidia of Entomophthorales rarely reach above crop canopies and for *Pandora neoaphidis*, did not travel more than 1 m, even with wind assistance (Glare and Milner, 1991).

The ability to attack multiple life stages is important in disease transmission. Winged insects can be responsible for the spread of disease, especially

between populations and regions. Movement between sites for aquatic fungi, such as mosquito pathogens, is likely to be through adults, whether the adults are infected or just carrying spores. For instance, *Coelomomyces* infected adult female mosquitoes mate and take blood normally, but oviposit sporangia instead of eggs (Lucarotti, 1987). Small mammals and birds may also spread infective spores after ingesting diseased cadavers (Christensen *et al.*, 1977). Transmission between adults and larvae has been demonstrated for some Hyphomycetes, such as the beech-boring beetles of *Platypus* (Coleoptera) inoculated with *B. bassiana* (Glare *et al.*, 2002) and diamondback moth with *Z. radicans* (Pell *et al.*, 2001).

In aquatic environments, motile spores, such as the zoospores of *L. giganteum* and *Coelomomyces* spp., are able to move through the water in search of hosts. Even the resting stage, oospores and sporangia, produce zoospores, combining motility with long-term survival. Zoospores are the main dispersal stage for *L. giganteum* and are actively attracted to a chemotactic agent emitted by mosquito larvae (Domnas, 1981). *Coelomomyces* spp. zoospores may also be attracted to larvae in water (Kerwin, 1983; Federici and Lucarotti, 1986). Zoospores can travel up to 10 cm in still water (Jaronski, 1982) and many meters in natural systems, but cannot overcome physical barriers to move between discontinuous systems. This is not the only method entomopathogenic species employ to infect hosts in aquatic environments. The aquatic *Culicinomyces* infect hosts using sessile spores, which can persist in water for up to 8 days before settling (Sweeney, 1985).

Lastly, the intentional introduction of fungi as biocontrol agents can be a significant means of dispersal in some fungi, and is discussed in more detail in Section 6.11.6.

6.11.3.6. Interactions between Pathogens and Other Natural Enemies

Most insects have a variety of diverse natural enemies, which include predators, parasitoids, and numerous pathogens. Many of these compete for the same resource and, inevitably, with each other. Insects can become coinfected by two or more pathogens or by a combination of parasitoid and pathogen(s). Predators or parasitoids can prey upon pathogen infected hosts. Fungi may infect nontarget insects, including natural enemies, and natural enemies can also act to disperse fungal inoculum. The outcome of all of these interactions can be either nil, antagonistic, additive, or synergistic. For the most part, interactions between fungal entomopathogens and other natural enemies is positive (Roy and Pell, 2000).

The same insect population can be attacked by several species of fungi. Studies on aphids, like cereal aphids (*Diuraphis noxia, Rhopalosiphon padi, Sitobion avenae*, and others) and their fungal pathogens from Entomophthorales (*Conidiobolus obscurus*, *Entomophthora planchoniana, P. neoaphidis*, and others), have often documented this situation at the population level (Keller and Suter, 1980; Dedryver, 1981; Feng *et al.*, 1990). Each fungus species will contribute to the overall mortality in the aphid population, but may differ in their prevalence. For example, some studies documented that in cereal systems, *P. neoaphidis* was the most common species in 2 out of 4 years, while *E. planchoniana* was the most common in the other 2 years (Eilenberg *et al.*, unpublished data). In carrot flies, *Entomophthora schizophorae* is normally the only common fungal species, but one year in August, *Conidiobolus pseudapiculatus* was the most common species (Eilenberg, 1988; Eilenberg and Philipsen, 1988).

Different fungal species can affect different host stages in the same host population. For instance, the chrysomelid beetle, *Coleomera lanio*, is susceptible to *B. bassiana* and *M. anisopliae*, but the former infects larvae, pupae, and adults while the latter infects only pupae (Silveira *et al.*, 2002).

The same host specimen can be naturally infected by two fungi simultaneously, but it seems that this normally occurs at lower rates than would be expected from a statistical point of view. In laboratory studies, Inglis *et al.* (1999a) studied the effects of temperature on the competitive infection and colonization of grasshoppers coinoculated with *B. bassiana* and *M. anisopliae* var. *acridum*. They found that coapplication of the two fungi did not significantly affect the prevalence of mortality, but that in some instances, total fungal populations in the hemocoel of coinoculated grasshoppers were smaller than those in grasshoppers treated with each fungus alone, indicating a degree of interspecies antagonism. More *B. bassiana* than *M. anisopliae* was recovered from coinoculated grasshoppers incubated at a constant temperature of 25 °C, but as the amplitude of temperature differences increased, more *M. anisopliae* than *B. bassiana* was recovered, indicating that temperature influenced their competitiveness within the host cadaver. In contrast, using an avirulent strain of *B. bassiana* and a virulent strain of *M. anisopliae* var. *acridum*, and the desert locust as a host, Thomas *et al.* (2003) were able to demonstrate that even an avirulent pathogen can alter the virulence and reproduction of a second, highly virulent pathogen. Locusts preinoculated with the avirulent fungus prior to inoculation with

the virulent fungus exhibited a reduction in survival time and a significant decrease in sporulation of the virulent fungus compared to individuals inoculated with the virulent fungus alone.

Insect pathogenic fungi may also interact with other types of insect pathogens. Eilenberg *et al.* (2000a) documented that the fungus *S. castrans* and the microsporidium *Cystosporogenes deliaradicae* occurred commonly together in adult *Delia radicum*. In the same study, the bacterium *Bacillus thuringiensis* was also found sporulating in the abdomen in two fungus infected hosts, but serotyping and toxicity tests proved that the bacterial isolates belonged to serotypes that were avirulent to the host. As mentioned above, avirulent insect pathogens may play an important role in host–pathogen dynamics for the virulent insect pathogens. Another example of coinfection is found in the gypsy moth, *L. dispar*, which is naturally infected by the fungus *E. maimaiga* and the nuclear polyhedrosis virus LdNPV. Both pathogens are highly virulent and laboratory studies demonstrated that, depending on dosage and timing, there was sometimes an apparent synergistic interaction between the two pathogens, thereby significantly increasing overall mortality (Malakar *et al.*, 1999).

Insect pathogenic fungi can interact with parasitoids (Goettel *et al.*, 1990a). The two types of natural enemies may compete for the host's tissues and can, therefore, be regarded as antagonistic to one another. For instance, none of the parasitoids *Cotesia plutellae* and *Diadegma semiclausum* discriminated between healthy and *Zoophthora radicans* infected host *P. xylostella* larvae in oviposition experiments, although such infection always resulted in the death of the immature parasitoids (Furlong and Pell, 2000). The fungus also infects *D. semiclausum*, and can thus in several ways be regarded as potentially antagonistic in field situations. In contrast, some parasitoids are able to discriminate between healthy and infected hosts, avoiding oviposition in infected cadavers (Goettel *et al.*, 1990a). The parasitoid *Aphidius ervi* initiated fewer attacks on colonies of the aphid *Acyrtosiphon padi* that were subjected to the fungus *P. neoaphidis* on the previous day than on uninoculated colonies (Pope *et al.*, 2002). Several aspects in the interactions between the parasitoid *Aphelinus asychis*, the pathogen *P. farinosus*, and the host *D. noxia* demonstrate the potential of synergistic or additive interactions: the parasitoid discriminates fungal infected hosts thereby avoiding ovipositing in them; parasitoids emerging from fungal inoculated host populations are healthy; and there is a possibility that the fungus may be transmitted by the parasitoids (Mesquita and Lacey, 2001).

Insect predators can, of course, be infected by insect pathogenic fungi. Some insect pathogenic fungi occur in both predator and prey insects in specific ecosystems, but infection levels in the predators are usually low (Vestergaard *et al.*, 2003). It is still unknown whether the genotypes of the fungal isolates occurring in the different insect populations are identical and, furthermore, whether transmission of infection between predator and prey population is of significant importance. Predators can be antagonistic to fungal pathogens simply by eating fungus killed cadavers or parts thereof, thereby reducing subsequent fungal sporulation and spread. Roy *et al.* (1998) documented this effect in their studies of the predator *Coccinella septempunctata*, the fungus *P. neoaphidis*, and the prey and host aphid *Acyrthosiphon pisum*. The same predator could, however, vector the fungal disease to uninfected hosts and thereby enhance fungal dissemination and epizootic potential; this effect was found to be enhanced due to the increased activity of the pea aphid, *A. pisum*, to avoid the predators, at the same time resulting in a higher uptake of inoculum of *P. neoaphidis* and consequently higher infection levels (Roy *et al.*, 1998, 2001).

6.11.4. Evaluation of and Monitoring Fate

Evaluation of use of entomopathogenic fungi in biological control is an extremely important, yet complex, task. The most obvious evaluation criterion is control of the pest population. In situations where measurement of pest population changes is not difficult, the success or failure of biocontrol can be seemingly straightforward. However, even in such situations, the sublethal effects, such as reduced feeding, fecundity, or crop damage, should not be overlooked. In many situations, the actual number of pests is unimportant compared to the damage they cause or disease they vector. In these cases, evaluation depends more on reducing damage or disease than the pest populations themselves, the ultimate evaluation criterion being crop quality or yield.

With changes in regulations and concerns over safety of introduced agents, more emphasis is being placed on monitoring the fate of fungi (and other biological agents) after release. Monitoring the fate of entomopathogenic fungi in the environment can be important in ecological studies, for commercial evaluations, for measuring establishment, and for regulation and safety. In particular, there is concern

and interest in the release and monitoring of genetically modified organisms in the environment, including entomopathogenic fungi. Bidochka (2001) identified three main benefits from monitoring the fate of fungi: (1) identification of the introduced agent in a biological impact assessment, (2) economic cost benefit assessment, and (3) valuable information on fungal epidemiology.

Despite many years of research into entomopathogenic fungi, there remains an inadequate understanding of epizootiology, due in part to lack of specific methods for tracking individual isolates in the environment. The fate of released fungi, the genetic structure of fungal populations, and how to measure these components has not been well explored.

There are several possible ways in which to study persistence of artificially augmented fungal inoculum levels, including leaf and soil washes, leaf impressions, differential staining, bioassay of field collected substrates, and monitoring of sentinel insects (Goettel *et al.*, 2000). Comparisons can be made to untreated areas. When there are no longer differences in population levels between treated and untreated areas, it can be concluded that the augmented fungus has returned to background levels. The number of fungal propagules in the environment has often been used as a measure of the potential success of biocontrol applications. Propagule loadings have been measured by colony counts on semiselective media, where the fungus can be cultured, or through spore traps for fungi that discharge their spores into the air, such as the Entomophthorales. However, these methods do not distinguish between applied and background strains.

Methods that have been used to study the fate of entomopathogenic fungi at the specific strain level include phenotypic markers, vegetative compatibility, mating types and, more recently, a plethora of molecular approaches, which allow specific tracking of individual strains in most environments. When strains can be cultured, studies have used markers such as colony appearance or antibiotic resistance, but these techniques suffer from genetic instability and alterations due to environmental factors. Other nonmolecular based markers have been investigated, such as commercially available carbohydrate utilization or enzyme production strips system of API (i.e., API50CH; APIZyms), but with limited success (St. Leger *et al.*, 1986; Todorova *et al.*, 1994; Rath *et al.*, 1995). These systems can be used to distinguish groups, but are unlikely to distinguish individual isolates in most cases. Therefore their usefulness in tracking released strains is usually minimal.

Vegetative compatibility groups (VCGs) are subspecific groups within the same fungal species from which isolates can fuse hyphae to form heterokaryons and, thus, exchange genetic information (the parasexual cycle). Couteaudier and Viaud (1997) demonstrated that compatibility groups, within *Beauveria* spp. in Europe, could be used to delimit genetically incompatible groups and aid monitoring.

Many entomopathogenic fungi cannot be cultured and the lack of simple methods for isolation and specific strain characterization has made it difficult to conduct ecological studies on fungal persistence. The most important advances in monitoring the fate of entomopathogenic fungi in the environment have come from the application of molecular biology techniques. Precursors to DNA techniques were the use of allozymes to identify strains, and use of enzyme-linked immunosorbent assay (ELISA) for tracking in the environment. Application of allozyme analysis to strain detection in the environment has been attempted, although single isolate identification amongst strains from a single host has not proved possible. For example, the allozymes of *Beauveria* and *Metarhizium* spp. have a high degree of variability, indicative that the species had maintained a large effective population size for a long time (St. Leger *et al.*, 1992b). In some cases, isoenzymes have not been useful in separating applied and background strains (e.g., Trzebitzky and Lochelt, 1994) or showed little correlation with virulence (Reineke and Zebitz, 1996), but Lin and Lin (1998) found esterase patterns of *Beauveria* isolates correlated with geographical distribution and host. Allozymes have also been used with the Entomophthorales. Silvie *et al.* (1990) used allozymes to study the fate of *P. neoaphidis* released for greenhouse aphid control. Milner and Mahon (1985) used similar techniques to distinguish between an introduced Israeli strain of *Z. radicans* for aphid control and endemic strains pathogenic to flies and caterpillars. Hajek *et al.* (1990) used allozymes to confirm that the gypsy moth pathogen causing epizootics in North America was *E. maimaiga*. In further studies using allozymes and RFLPs, they demonstrated that *E. maimaiga* and *E. aulicae*, two very similar species, were attacking different caterpillars in the same area (Hajek *et al.*, 1991b). ELISA was also developed for *E. maimaiga* based on allozymes, but was cross-reactive for *E. aulicae* (Hajek *et al.*, 1991a).

Application of DNA techniques is making major advances in monitoring the fate of entomopathogenic fungi in the environment. There are numerous studies that have demonstrated the power of molecular biology in strain, species, and genera separation

(see Section 6.11.2.5). These same techniques are useful when applied to monitoring fungal isolates in the environment. For example, Enkerli *et al.* (2001) used 10 microsatellite markers to characterize *B. brongniartii* and could use these markers to demonstrate that strains applied in Switzerland in 1983 were still active over 8 years later. Specific identification of *B. brongniartii*, based on polymerase chain reaction (PCR) primers designed to group 1 intron insertions in the 28s rRNA gene, was used to identify and monitor an introduced strain for control of the scarab pest, *Hoplochelus marginalis*, in the Reunion Islands (Neuvéglise *et al.*, 1997). Other techniques, such as chromosomal length polymorphisms, RAPDs, and RFLP have all been used to assist monitoring strains in the environment. Molecular approaches to phylogeography of insect pathogens are also developing. Using a molecular genetics approach, Bidochka *et al.* (2001) found that genotypes of *M. anisopliae* in Canada were more influenced by habitat than host.

An extension of the use of molecular techniques for distinguishing strains important in biological control is the insertion of sequences (tags) or genes which can be used to specifically assist monitoring. For example, insertion of a green fluorescent protein gene was used to allow detection and tracking of a genetically modified *M. anisopliae* (Hu and St. Leger, 2002).

Media based detection methods, such as selective agars, can determine the number of viable propagules in the environment, but generally cannot allow separation between applied and background strains. Molecular approaches can allow separation of strains, but while these molecular approaches are extremely powerful, most techniques do not provide information on the activity (viability) of the propagules detected. Even though fungi can be detected, it is not possible to say whether the detected fungus is able to infect hosts. Use of *Galleria* or other sentinel insects, such as in the soil baiting method (Zimmermann, 1986), can demonstrate virulence, but gives no quantification of propagules. A combination of methods is required to monitor applied fungi in the environment, to provide information on the number of viable propagules of the applied fungus present over time.

6.11.5. Epizootiology and Its Role in Suppressing Pest Populations

Entomopathogenic fungi are well known for their ability to rapidly decimate insect outbreaks through spectacular epizootics, and it is principally this property that has spurred interest in the use of fungi for pest management. The term "epizootic" is used to describe a situation where the proportion of infected individuals is high or at least higher than the enzootic condition, i.e., the disease condition that is usually of low prevalence and constantly present in a host population (Tanada and Kaya, 1993). Prevalence is defined as the number or proportion of infected individuals at a given point in time (Fuxa and Tanada, 1987). Natural epizootics caused by fungi are an important factor in regulating pest insect populations, often alleviating the need for other interventions, such as application of chemical pesticides. Here, some examples of fungi with a role in suppressing pest populations in epigeal, soil, and aquatic environments are provided.

6.11.5.1. Epigeal Environment

Epizootics often occur within the epigeal environment. Infection may spread rapidly directly from infected insects to uninfected insects, from spores on leaves to insects feeding on the leaves, and also via spores present in the air.

High prevalence is often found among aphids (e.g., Feng *et al.*, 1991; Hollingsworth *et al.*, 1995; Hatting *et al.*, 2000). Hollingsworth *et al.* (1995) monitored the fungus *N. fresenii* in populations of *Aphis gossypii* in cotton in Arkansas, USA. Epizootics were common and prevalences could reach 90%. Such prevalences were detrimental to the aphid populations, which actually began to decline when the prevalence reached 15%. Also, aphids living in cold environments suffer from fungus infections. Nielsen *et al.* (2001) sampled *Elatobium abietinum* on sitka spruce in Iceland. Both *Entomophthora planchoniana* and *N. fresenii* were present in the aphids and were responsible for epizootics during the autumn, when daily mean temperatures were below 15 °C. However, the effect on the host population was not documented during this study.

Another group of insects often found infected with fungal pathogens are dipterans. Steinkraus *et al.* (1993) studied the prevalence of *Entomophthora muscae* in populations of *Musca domestica* and found prevalences of up to ~75% towards the end of the season. In this case, as in other cases, the epizootic builds up during the season. In studies of *M. domestica* and *Entomophthora schizophorae*, Six and Mullens (1996) documented that maximum daily temperatures higher than 26–28 °C correlated with low prevalences.

Entomopthoralean fungi from the *Entomophaga grylli* species complex are important pathogens of acridids worldwide (Carruthers *et al.*, 1997). They commonly cause epizootics, particularly following periods of high humidity or rain. Such epizootics

have frequently led to dramatic reductions in acridid populations, saving farmers and ranchers millions of dollars. The epizootics are very noticeable, as thousands of cadavers can be seen adhering to the tops of vegetation (see Section 6.11.3.3.2).

The host density-dependent development of epizootics was documented in the *L. dispar* populations infected with *E. maimaiga*. This fungus has shown remarkable dispersal over a period of several years (or maybe even decades) in north-eastern USA (Hajek, 1997, 1998, 1999). An interesting adaptation to the host is seen, since first instar larvae produce infective conidia of the fungus while larger larvae produce resting spores for winter survival. The effect on the host population is significant and the fungus is responsible for decimating large populations of this destructive, introduced pest.

Recent examples of epizootics in other insect groups from the epigeal environment include *N. parvispora* on thrips (*Frankliniella occidentalis*) in Spain (Montserrat *et al*., 1998), *Zoophthora phytonomi* on weevils in alfalfa in the USA (Morris *et al*., 1996), and *Entomophthora leyteensis* on whiteflies in the Philippines (Villacarlos *et al*., 2003). It appears that epizootics occur worldwide and in all major insect orders.

6.11.5.2. Soil Environment

Due to the cryptic nature of insects inhabiting the soil environment, natural epizootics most probably occur much more often than reported. It appears that the main source of inoculum of several important Hyphomycetes is the soil and epizootics have often been observed among soil living stages of insects (Steenberg *et al*., 1995; Fuhrer *et al*., 2001). Using insects as baits, a number of studies have demonstrated the presence of spores from the genera *Beauveria, Metarhizium, Paecilomyces*, and *Tolypocladium* in soil (Klingen *et al*., 2002; Keller *et al*., 2003). Among Ascomycetes, *Cordyceps* spp. have often been observed on insect cadavers on the soil surface. A study in Colombia documented, for example, that species of *Cordyceps* were common in populations of ants (Sanjuan *et al*., 2001). The effect of *Cordyceps* infections on insect populations is in need of further investigation.

The biological role of the soil ecosystem for the insect pathogenic fungi is, however, not clarified. The soil may simply act as a reservoir for a population of spores, which then infect host insects, or the soil ecosystems can be involved in a more complex interaction with insect pathogenic fungi. For instance, *B. brongniartii* was found in localities where the host, *Melolontha melolontha*, was absent for approximately 40 years (Keller *et al*., 2003). Either the fungus can survive by using other hosts or by saprophytic growth, or the spores can survive for many years. Hu and St. Leger (2002) suggest that the rhizosphere is an important interphase between insects, insect pathogenic fungi, and plants. Insects not susceptible to certain fungi may act to disperse fungal inoculum. Broza *et al*. (2001) and Dromph (2001) both documented that collembolans can be involved in transmission of insect pathogenic fungi without being infected themselves.

The presence of inoculum in the upper soil surface layers is important for the initiation of epizootics in the epigeal environment during spring. Nielsen *et al*. (2003) demonstrated that inoculum of epigeal, entomophthoralean pathogens (*C. obscurus*, *P. neoaphidis*) of cereal aphids (*Sitobion avenae* and *R. padi*) was present in the soil surface in early spring. Aphids became infected by these fungi when crawling on the soil surface. The epizootic would then develop in the epigeal environment.

6.11.5.3. Aquatic Environment

The aquatic environment is very different from terrestrial environments. Most insect pathogenic fungi infecting aquatic species have motile spores, such as zoospores, which can be actively attracted to the host (see Section 6.11.3.4). In aquatic environments, disease can be influenced by a range of abiotic and biotic factors, some of which are not experienced in other environments. For example, salinity, pH, organic and inorganic pollutants, and water movement can alter or stop infection. Salinity affects both *Coelomomyces* and *Lagenidium* infections. No *C. opifexi* infections were detected in salt water pools with over 20% salt, although the mosquito larval hosts could be detected in pools with twice that level of salt (Pillai, 1971). *Lagenidium giganteum* is even more susceptible to salinity with less than 0.05% salt levels in water required for high infection levels (Merriam and Axtell, 1982a). *Culicinomyces clavisporus* was more resistant to salt, infecting at 1.3% salt (Merriam and Axtell, 1982b). Temperature is also a major influence on disease and epizootiology, as with terrestrial fungi.

There has been substantial interest in some aquatic-active entomopathogenic fungi, mainly due to the pest status of mosquitoes and blackflies. However, many of these fungal species have complex life cycles unsuited to biocontrol, or have limited prevalence in most situations. *Coelomomyces* have an obligate intermediatory host (also referred to as an "alternate host"), often a copepod, between infecting mosquito larvae. This has both limited the occurrence of the pathogen, as well as its use in intentional introductions. Copepod abundance was

found to be the critical factor in epizootics caused by *C. punctatus* (Apperson *et al*., 1992). Pillai (1971) sampled over 400 pools in New Zealand and detected *C. opifexi* in only 21. When pools that had both mosquito and copepod hosts were intentionally inoculated, disease levels persisted for over 2 years, but disease incidence remained low (mean <16%). It seems that the pathogen remained in equilibrium with its hosts, even in a closed system of saltwater pools. There is evidence that *L. giganteum* persists better in high density than in low density populations, where the fungus may struggle to recycle.

Unlike the zoospore-infective species, the hyphomycete mosquito pathogen *C. clavisporus* is infective after ingestion. This reduces the need for a motile stage, as conidia present in the water are ingested, rather than needing to find and attach to the host. However, settling of conidia becomes a major factor in epizootiology. Applying high rates of conidia to ponds can kill up to 100% of mosquito larvae but there is no residual prevalence after 2 days (Sweeney, 1981). However, more recently, Seif and Shaarawi (2003) found that *C. clavisporus* was active for 5 days against mosquito larvae in brackish ponds in Egypt.

The ability to persist through times of habitat drying is a useful attribute for aquatic pathogens. *Lagenidium* and *Coelomomyces* both produce thick-walled resting stages (oospores and sporangia). *Lagenidium* can be unaffected by periodic drying (e.g., Fetter-Lasko and Washino, 1983).

Lagenidium giganteum and *C. clavisporus* have been the subject of development as biopesticides, which has resulted in epizootiological studies and inundative release. *Lagenidium giganteum* is now the basis of a commercially available mosquitocide. However, research on *C. clavisporus* peaked in the 1970–80s in Australia, and did not lead to a commercial product. Attempts at introducing *Coelomomyces* as a biocontrol agent in the classical sense into the Tokelau Islands provided inconclusive results (Laird, 1985).

6.11.6. Development as Inundative Microbial Control Agents

Inundation biological control is defined as

> The use of living organisms to control pests when control is achieved exclusively by the released organisms themselves
>
> Eilenberg *et al*. (2001)

It is attractive from the point of view that the effect on the target host is obtained with the released agent itself and is often regarded as *the* strategy in biological control with microorganisms. Terms like "biopesticide," "biological pesticide," or "mycopesticide" are frequently used to describe inundation biological control with fungi. These terms also reflect that this strategy is in many ways an "insecticidal approach" in that the inoculum has to be applied directly to the crop or host, often several times per season, which is attractive from a commercial point of view.

Inundation biological control is, however, not necessarily the most sustainable way to control pests, especially if the biological control agent is used simply as a replacement for chemical insecticides. Replacement of a chemical with a microbial control agent could result in the same type of problems associated with chemicals, namely development of populations resistant to the control agent, be it chemical or biological, as has occurred with the bacterial microbial agent *B. thuringiensis* (Tabashnik, 1994). Although no instances of the development of resistance to an entomopathogenic fungus have been documented to date, it must be realized that inundative use of entomopathogenic fungi has been limited and, therefore, the prerequisites for selection of a resistant population would, in most instances, not have been met as yet.

Many Hyphomycetes are well suited for the inundative strategy based on their relatively wider host ranges, ease of production, formulation and application, and a relatively long shelf life. Several species of fungi from Hyphomycetes have been developed commercially and are currently for sale worldwide (see Section 6.11.6.2 below).

Entomophthoralean fungi possess some characteristics that allow them to fit into the inundation biological control paradigm, while other characteristics suggest that these fungi would fail under these conditions (Pell *et al*., 2001). The generally high virulence of many species is a useful characteristic for this strategy, while the presence of replicative, infective but short-lived conidia hampers the development of "easy to use products." A further drawback is the fact that isolation *in vitro* is difficult and has been achieved only for very few species. Efficient mass production methods are mostly lacking as is knowledge on formulation.

In greenhouses, entomophthoralean fungi may have a better chance. The most thorough recent attempts were made by Shah *et al*. (2000). Experimental preparations based on alginate granules and mycelial mats of *P. neoaphidis* caused up to 36% infections in the potato aphid *Macrosiphon euphorbiae* after 14 days, although better results were obtained with *B. bassiana*.

In most temperate countries, greenhouses are the only place where inundative biological control of crops with entomophthoralean fungi could be recommended at present. Preparations of *P. neoaphidis* could be tested against aphids in greenhouses and may, due to some horizontal transmission effects afterwards, prove to have some advantages over other biological control agents used, including *Lecanicillium lecanii*. For some of the greenhouse pest–pathogen systems mentioned in Section 6.11.7, there could also be some prospects in inundation. Whatever the environment, a most promising release strategy could be a combination: an inundation with some immediate effect but including a significant inoculative effect.

6.11.6.1. Mass Production

The success of any commercial microbial control agent depends largely on the ability to produce adequate supplies of the agent to economically manage the target pest or pests. Entomopathogenic fungi produce different types of spores, depending on the growth environment. Aerial conidia are produced on the surface of cadavers, while blastospores, sometimes referred to as "hyphal bodies" or protoplasts, are produced in the host's hemocoel. Consequently, the fermentation medium and method will also dictate the type of spore that will be obtained. In submerged culture, primarily mycelia and blastospores are produced while aerial conidia are produced on the surface of liquid media or on solid substrates.

Efficient mass production methods are mostly lacking for entomophthoralean fungi as is knowledge on their formulation. Despite the development of methods for mass producing several species, to date, there are no commercialized products based on entomophthoralean fungi. Due to the short-lived nature of entomophthoralean conidia, attempts at mass production have targeted primarily mycelia or resting spores (Pell *et al*., 2001).

Many insect cadavers killed by fungi can be found in the environment in a dehydrated state; often, transfer of these cadavers to conditions of high humidity results in massive conidiogenesis and spore release (e.g., Tyrrell, 1988). This phenomenon has spurred the development of "dried mycelia" as a potential way of mass producing and using entomopathogenic fungi (McCabe and Soper, 1985). Mycelia are mass produced in deep fermentation, air dried in the presence of a sugar desiccant protectant, granulated, and stored dehydrated under low temperature. Upon rehydration, the fungus sporulates on the granule surface. This method is suitable both for entomophthoralean and hyphomycetous fungi. Despite some successful field demonstrations using dried mycelia against several insect pests (e.g., Pereira and Roberts, 1991; Krueger *et al*., 1992; Krueger and Roberts, 1997; Booth *et al*., 2000; Shah *et al*., 2000), this method has not yet been adopted commercially.

Some entomopathogenic fungi produce conidia or resting spores in submerged culture. Examples are resting spores of the entomophthoraleans, *Conidiobolus obscurus* (Latgé, 1980) and *E. maimaiga* (Kogan and Hajek, 2000), and conidia of the hyphomycetous fungi *Culicinomyces clavisporus* (Cooper and Sweeney, 1986) and *M. anisopliae* var. *acridum* (Jenkins and Prior, 1993). Submerged conidia of some species perform as well as aerially produced ones (e.g., *M. anisopliae* var. *acridum*; Jenkins and Thomas, 1996). For other species this is not so, e.g., submerged conidia of *C. clavisporus* performed worse than aerial conidia (Cooper and Sweeney, 1986). To date, there are no commercialized products based on conidia or resting spores produced in submerged culture.

Most Hyphomycetes produce blastospores in submerged culture, but for the most part, these are thin walled and short lived, and with few exceptions, are used primarily to produce starter batches for use in inoculation of aerial culture (see Section 6.11.6.2). In some cases, blastospores are more virulent than aerial conidia (e.g., Jackson *et al*., 1997; Lacey *et al*., 1999), and several commercial products consist of blastospores produced in submerged culture (e.g., *L. lecanii* and *P. fumosoroseus*; see below).

Solid state fermentation is used for production of aerial conidia of a number of commercially produced Hyphomycetes (see below). The solid substrates can be either nutritive, such as bran, cereals, or rice, or nonnutritive, such as vermiculite, clay, or sponge. Production of *B. bassiana* and *M. anisopliae* on rice is widely practiced in South America (Alves *et al*., 2003), Africa (Cherry *et al*., 1999), and China (Feng *et al*., 1994).

More details on the production of entomopathogenic fungi can be found in Bartlett and Jaronski (1988), Jenkins and Goettel (1997), Jenkins *et al*. (1998), and Wraight *et al*. (2001).

6.11.6.2. Commercialized Products

There are many commercial products available worldwide, most based on fungi from six to seven species from Hyphomycetes (Shah and Goettel, 1999; Copping, 2001; Wraight *et al*., 2001; Alves *et al*., 2003). Hyphomycetes are very well suited for commercialization due to their relatively wider host ranges, ease of production, shelf life, persistence, and ease of application.

6.11.6.2.1. *Beauveria bassiana* The most widely used species available commercially is *B. bassiana*. Products based on this species are available for use against a very wide variety of insect pests, from banana weevils (*Cosmopolites sordidus*) in Brazil (Alves *et al.*, 2003), pine caterpillars (*Dendrolimus* spp.) in China (Feng *et al.*, 1994), to the European corn borer, and greenhouse aphids in the Western world (Shah and Goettel, 1999; Copping, 2001). Formulations consist of aerially produced conidia produced as wettable powders or in emulsifiable oil.

The largest applications of *B. bassiana* have occurred in China, where an estimated 10 000 tons of conidia were produced annually for decades to control a wide range of forest and crop pests (Feng *et al.*, 1994). Most of these conidia were produced in state-owned, mechanized Chinese production facilities. However, with the recent transition from a state-planned and directed system to a market driven one, *B. bassiana* products have come to be considered as marginal and have not attracted the necessary attention from investors (Feng, 2003).

A solid culture process based on a packed bed of a proprietary starch granule has been developed to produce conidia that are marketed as Botanigard and Mycotrol in the USA and elsewhere (Bradley *et al.*, 1992). The products are used primarily to control aphids and whiteflies in commercial greenhouses. With host ranges that include over 700 species of arthropods (see Goettel *et al.*, 1990a), the market potential for more commercial products based on isolates of *B. bassiana* is large.

6.11.6.2.2. *Beauveria brongniartii* Products based on *B. brongniartii* are available against a wide variety of coleopteran, homopteran, lepidopteran, and dipteran pests in flowers, vegetables, oil palms, and other crops in Colombia (Alves *et al.*, 2003), against cerambicid beetles in Japan (Wraight *et al.*, 2001), and against the European cockchafer and other white grubs in Europe (Copping, 2001). Conidia are produced in solid-state fermentation either on barley kernels or clay granules. In Peru, the fungus has been widely used to control the Andean potato weevil (Alves *et al.*, 2003). The soil beneath potato storage facilities is treated with spores of the fungus prior to introduction of the potato tubers. Weevils become infected when the larvae drop to the soil to pupate.

6.11.6.2.3. *Lecanicillium lecanii* *Lecanicillium (= Verticillium) lecanii* is primarily marketed for control of greenhouse aphids, whiteflies, and thrips (Copping, 2001; Wraight *et al.*, 2001); however, products are also available in Colombia and Peru for control of lepidopteran, homopteran, and dipteran pests of flowers, vegetables, and other crops (Shah and Goettel, 1999; Alves *et al.*, 2003). Blastospores produced in submerged fermentation or conidia produced in solid-state fermentation are used in the various products. Previously, the requirement for very high humidity was a serious detriment in adopting this fungus for use in greenhouses, where high humidities also favor development of plant diseases. However, development of an improved formulation that decreases the humidity requirements of the fungus has alleviated much of this problem (Ravensberg, personal communication).

6.11.6.2.4. *Metarhizium anisopliae* (including var. *acridum*) Products based on *M. anisopliae* are available for a wide range of pests, including sugarcane spittle bugs (*Mahanarva* spp.) in Brazil (Alves *et al.*, 2003), red-headed cockchafer in Australia (Shah and Goettel, 1999), and termites in the USA (Copping, 2001). Products based on *M. anisopliae* var. *acridum* are available for control of grasshoppers and locusts in Africa (Lomer *et al.*, 2001) and Australia (Copping, 2001). Production systems vary, but most depend on culture in small bags or containers using rice as the substrate (Mendonca, 1992; Jenkins *et al.*, 1998). Such simple technologies may be more appropriate and economically feasible for smaller scale technologies, especially in developing countries, than larger, more sophisticated and capital intensive industrial scale production facilities (Swanson, 1997; Cherry *et al.*, 1999).

6.11.6.2.5. *Paecilomyces fumosoroseus* Formulations of *P. fumosoroseus* are marketed against whiteflies, thrips, spider mites, and aphids in Latin America, Europe, and North America (Copping, 2001; Alves *et al.*, 2003). Blastospores, produced in submerged culture, are dehydrated and formulated in a water dispersible bran granule or a water dispersible powder. The products are used primarily in greenhouse applications.

6.11.6.2.6. Others Numerous other products are currently available in many countries. Some examples include "*Entomophthora virulenta*" (= *Conidiobolus thromboides*) for control of whiteflies in Colombia (Alves *et al.*, 2003), *N. rileyi* for control of lepidopterans in Colombia (Shah and Goettel, 1999; Alves *et al.*, 2003), *P. lilacinus* for control of plant parasitic nematodes in Australia (Copping, 2001), and the Oomycete, *L. giganteum*, for control of mosquito larvae (Shah and Goettel, 1999; Copping, 2001).

Several products are based on microbial "cocktails." For instance, in Colombia, a product called

"Microbiol Completo" consists of a mixture of the fungi *B. bassiana*, *M. anisopliae*, *N. rileyi*, *P. fumosoroseus*, and the bacterium *Bacillus thuringiensis*. This mixture is marketed for use against a wide variety of pest lepidopterans, coleopterans, hemipterans, dipterans, and acari (Alves *et al*., 2003). Another cocktail, "Microbiol H.E.," contains a mixture of *B. bassiana*, *M. anisopliae*, *M. flavoviride*, *N. rileyi*, *P. fumosoroseus*, *P. lilacinus*, *V. lecanii*, and *Hirsutella thompsonii*, which includes activity against nematodes in addition to the pests listed under the Microbio Completo. Microbial cocktails not only increase host spectrum, but also may ensure activity under different environmental conditions. For instance, results from a field simulation study against grasshoppers suggested that *B. bassiana* itself would be more efficacious under cooler, cloudy conditions, although *M. anisopliae* var. *acridum* (as *flavoviride*) would be more efficacious under warmer, sunny conditions, while a cocktail of both fungi would be efficacious under both conditions (Inglis *et al*., 1997b).

6.11.6.3. Improvement of Efficacy

There are many factors that can affect the efficacy of biopesticides, such as slow speed of kill, moderate efficacy, poor storage characteristics, lack of field persistence after application, and expense (see Section 6.11.3; see also Inglis *et al*., 2001; Pell *et al*., 2001). Many of these factors can be overcome by strain selection, genetic improvement (St. Leger and Screen, 2001), formulation (Wraight *et al*., 2001), and application (Bateman and Chapple, 2001).

6.11.6.3.1. Strain selection Entomopathogenic fungal species are composed of often genetically heterogeneous collections of strains, which can have different properties on key characteristics, such as virulence to pest species. Natural variation between strains of any given species has long been used in the search for biocontrol fungi. The selection among strains for the more virulent, better environmental persistence, or some other important variable, is a constant theme in the literature. A common first step in the search for fungal control agents for any pest insect is to assay strains from a number of locations to select the most pathogenic (e.g., Vicentini *et al*., 2001; Shaw *et al*., 2002).

In addition to utilizing natural variation, there have been efforts to improve biocontrol fungi through selection. Improving virulence by passage through hosts has been attempted, sometimes with success. Ogarkov and Ogarkova (1999) reported an up to twofold increase in virulence of *B. bassiana* to *Trialeurodes vaporariorum* after passage through the host. *Lagenidium giganteum* increased virulence to two mosquito hosts by bi-weekly passage through another mosquito (Washino, 1981). Fargues and Robert (1983) restored lost virulence of *M. anisopliae* through serial passage through a scarab. These are all indicative of the potential for strain improvement through selection.

Improvement of other characteristics of entomopathogenic fungi have been investigated through selection. Increasing the endogenous reserves of conidia to enhance viability and desiccation tolerance was proposed by Hallsworth and Magan (1994). By growing cultures of *B. bassiana, M. anisopliae*, and *P. farinosus* under different conditions to obtain conidia with a modified polyol and trehalose content, conidia with increased intracellular levels of glycerol and erythritol were isolated. These conidia germinated more quickly and at lower water activity than unselected conidia (Hallsworth and Magan, 1995). Conidia with increased trehalose germinated more slowly but had better shelf life than unselected conidia.

More recently, there have been attempts to use biotechnological techniques, not just in direct genetic improvement of fungi, but to assist strain selection. As described in Sections 6.11.2.6 and 6.11.4, biochemical and molecular techniques have been used to identify specific strains of entomopathogenic fungi, allowing for more specific selection of strains following exposure to discriminatory conditions. For example, protoplast fusion has been used to combine characteristics of strains of *Beauveria* to improve the biocontrol potential. Fusion of a strain of *B. bassiana* from *Leptinotarsa decemlineata* with an insecticidal toxin-producing strain of *B. sulfurescens*, resulted in recovery of some di-auxotrophic mutants with enhanced activity against *L. decemlineata* and the caterpillar *O. nubilalis* (Couteaudier *et al*., 1996; Viaud *et al*., 1998). Molecular analysis demonstrated that the resulting mutants were mixtures of the two genotypes. Some of the resulting strains were classified as hypervirulent, as they killed the hosts more quickly than the parental strains. Virulence was stable after passage through the host, suggesting protoplast fusion may be an alternative method to direct genetic engineering for improving the biocontrol efficiency of entomopathogenic fungi (Viaud *et al*., 1998).

6.11.6.3.2. Genetic modification The use of genetic manipulation to overcome perceived limitations of entomopathogenic fungi for use as biocontrol agents is attractive. The research so far is limited when compared to other groups of organisms, but some interesting research has been done. The most

advanced research has been on the hyphomycete fungi *M. anisopliae* and *B. bassiana*.

Transformation systems have been developed for some entomopathogenic fungi. The first transformations of an entomopathogenic fungus were by Bernier *et al.* (1989) and Goettel *et al.* (1990b), who expressed a benomyl resistance gene in *M. anisopliae*. Electroporation and biolistics have also been used to transform *M. anisopliae* (St. Leger *et al.*, 1995). Polyethylene glycol (PEG) mediated transformation of protoplasts is another method for transformation of entomopathogenic fungi, as done with *P. fumosoroseus* and *P. lilacinus* (Inglis *et al.*, 1999b) using benomyl as the selective agent. Sandhu *et al.* (2001) developed a heterologous transformation system for *B. bassiana* and *M. anisopliae* based on the use of the *Aspergillus nidulan*s nitrate reductase gene (niaD), after EMS treatment of protoplasts and regeneration on chlorate medium.

Genetic modification of entomopathogenic fungi by direct manipulation has been led by St. Leger, and the area was recently reviewed by St. Leger and Screen (2001), covering both insect and plant pathogenic fungi. In the numerous publications, these researchers described the identification and cloning of protease genes, particularly the *pr1* cuticle degrading protease gene from *M. anisopliae* (St. Leger *et al.*, 1992a). Several other entomopathogenic Hyphomycetes (*A. flavus, B. bassiana, Paecilomyces farinosus, Tolypocladium niveum*, and *L. lecanii*) also have *pr1*-type enzymes (St. Leger *et al.*, 1991, 1992a). Efforts to produce more effective strains of fungi have included the overexpression of *pr1* by insertion of multiple copies, resulting in increased speed of kill of a host insect, although transformants had very poor sporulation ability (St. Leger, 2001). Modification of *pr1* gene expression in *M. anisopliae* resulted in melanization and cessation of feeding 25–30 h earlier than the wild-type disease in caterpillars (St. Leger *et al.*, 1996). The group has gone on to place the *pr1* gene under control of a constitutive promoter and included a green fluorescent protein encoding gene for tracking the fungi after field release (Hu and St. Leger, 2002). Genes involved in regulation of PR1 expression have also been identified from *M. anisopliae* (Screen *et al.*, 1997, 1998).

Chitinase, produced by many insect pathogenic fungi and implicated in pathogenesis, has also been the target of molecular studies. Several chitinase gene sequences from *Beauveria* and *Metarhizium* have been submitted to GenBank and described in publications (e.g., Bogo *et al.*, 1998). Overexpression of extracellular chitinase has also been demonstrated for *M. anisopliae* var. *acridum*, but did not alter virulence to the caterpillar, *M. sexta*, compared to the wild-type fungus (Screen *et al.*, 2001).

6.11.6.3.3. Formulation and application strategies There are a number of limitations that still affect the use of fungi. Formulation and application of fungal propagules has the potential to overcome some of these limitations. Jones and Burges (1998) defined four basic functions of formulation: (1) stabilization of the agent during production, distribution, and storage; (2) aiding the handling and application of the product to the target in the most appropriate manner and form; (3) protection of the agent from harmful environmental factors at the target site, thereby increasing persistence; and (4) enhancing efficacy of the agent at the target site by increasing activity, reproduction, contact, and interaction with the target pest.

Progress has been made in formulation science, and formulations for entomopathogens have been comprehensively reviewed by Burges (1998). Early formulations of entomopathogenic fungi often used just a weak detergent to get the hydrophobic spores into solution, without any efforts to use the formulations to improve efficacy. More recently, the use of oil as a formulation ingredient has been successfully used to overcome several problems. In the LUBILOSA program developing *M. anisopliae* var. *acridum* for control of locusts in Africa, the combination of oil formulations with ultra low volume (ULV) spraying has led to successful development of a biopesticide (Lomer *et al.*, 2001). Although it would seem impossible to use an entomopathogenic fungus requiring high humidity against locusts in the hot, dry conditions prevalent in much of their environment, studies have shown that ambient humidity may not be as critical as once thought (Fargues *et al.*, 1997; see also Section 6.11.3.1). Formulating *Metarhizium* conidia in nonevaporative diluents such as oils allowed the conidia to attach, spread (Inglis *et al.*, 1996a), and germinate on susceptible locusts, even at low ambient humidities (Bateman, 1997).

Formulation can also assist in extending shelf stability of fungal propagules generally desired by commercial producers. Spore survival after mass production varies greatly, depending on the species, but few entomopathogenic species of fungi can achieve the 1–2 years of shelf stability at formulation. Formulation in clay material is known to improve the shelf life of many conidial preparations (e.g., Shi, 1998). This appears to be due to the ability of clay to reduce the moisture content of the spores, as spores survive longer with less than 5% moisture (Wraight *et al.*, 2001). Moore *et al.* (1996) have

shown that survival of conidia of *M. anisopliae* was highest at low (<5%) relative humidity, and similar results have been found for other Hyphomycetes. Some oils can also maintain a shelf life of over 1 year for some Hyphomycetes, possibly due to maintenance of low spore moisture content.

Several groups have examined formulation of hyphal material from members of the Entomophthorales, which are more fragile than Hyphomycete conidia. McCabe and Soper (1985) patented a process of drying the mycelium of *Z. radicans* and coating it with sugar as a method for long-term storage and, more recently, Shah *et al.* (1999) demonstrated algination as a method for formulating *Pandora (Erynia) neoaphidis* mycelium. Formulations of dried mycelia of *M. anisopliae* and *B. bassiana* were developed by coating with a sugar solution before drying (Pereira and Roberts, 1990). Entomopathogenic fungi have also been formulated as granules (e.g., Reinecke *et al*., 1990) or, in some cases, applied without removal from the grains used as a production medium.

Persistence is a major issue with fungal biopesticides. One of the major factors affecting persistence is ultraviolet (UV) radiation, which rapidly degrades fungal spores. Use of various UV protectants in formulations has been tested, but with only limited success (Burges, 1998; Wraight *et al*., 2001). The most effective method to reduce UV degradation of spores has been to use application techniques that place the spores in the appropriate position to rapidly infect the host or to avoid UV, such as by applying subsurface. Subsurface application of entomopathogenic fungi has been used for *M. anisopliae* against scarabs (e.g., Logan *et al*., 2000) and other insect pests, but introducing large amounts of fungal inoculum into the soil and securing an even spread remains problematic. Methods that have been used include using seed drills for subsurface application of granules and hand application. The problems of spread of conidia after application to soil has led to the *Melolontha* researchers developing an area-wide approach based on augmentative applications of *B. brongniartii* for long-term suppression of pest populations (Hajek *et al*., 2001).

Compatibility between production, formulation, and application techniques is vital to successful use of microbial biopesticides. Application is a very specialized area of agricultural research, and has both its own technological and specific issues related to achieving adequate control, as well as coverage. Application technology can ensure infective propagules contact the target pest. Much of this technology is derived from our experience with chemical pesticides and may not be the most appropriate for use with fungal pathogens. Bateman and Chapple (2001) have recently reviewed spray application of mycopesticides in detail. Advances have been made with fungi, such as the use of ULV application technology. ULV has been used with the oil formulated *M. anisopliae* for locust control, as the droplets are resistant to evaporation (Lomer *et al*., 2001). Electrostatically charged ULV sprayers have been investigated for better coverage on leaf undersides (Sopp *et al*., 1989). Hydraulic spray systems have been used to apply water based formulations on crops, with air-blast and air-assist technologies primarily used for low-volume applications in fields and orchards. There are many variables to be considered in spray application, whether with ULV or with more conventional equipment. Droplet size is an important consideration, as there is a trade-off between small, more aerial droplets for better spread and large droplets, which contain more propagules and settle more rapidly. The size of the area to which fungal propagules are to be applied can alter the type of application equipment used. For large-scale applications, such as aerial applications, it is possible to use ULV applications of undiluted materials in some cases, whereas it can be difficult to get sufficient coverage on small areas using the undiluted sprays.

A number of novel application methods have been developed that do not rely on methods developed for chemical pesticide application technology. These methods, which rely on the behavior of the pest, may more closely mimic natural infection routes and have more chance of success in situations where conventional spray application is impossible, such as dispersed and highly mobile pests. “Lure and infect” uses an attractant to bring a susceptible insect to a trap containing a pathogen. After contamination in the trap, the insect leaves the trap and infects others, as demonstrated by the use of *Z. radicans* against diamondback moth. Furlong *et al.* (1995) showed that using pheromone lures to attract moths to traps containing sporulating *Z. radicans* can result in contamination and spread of the fungus through the target population. Autodissemination similarly uses trapping of adults in pathogen laced attractant traps then using those adults to disseminate the fungus into the population. This technique was successful in the Azores for introducing *M. anisopliae* to *Popillia japonica* populations (Klein and Lacey, 1999), but whether population suppression would occur depends on the control ability of the fungus. Pheromone impregnated pellets containing *B. bassiana* spores have also been tested against grain borers (Smith *et al*., 1999).

6.11.7. Development as Inoculative Microbial Control Agents

Inoculation biological control is defined as

> The intentional release of a living organism as a biological control agent with the expectation that it will multiply and control the pest for an extended period, but not that it will do so permanently.
>
> Eilenberg *et al.* (2001)

This is desirable because only a limited amount of inoculum (*in vivo* or *in vitro* acquired material) is released at each treatment. The inoculum is expected to proliferate and control the target pest over time, but additional releases would normally be needed in the future (e.g., next cropping season). Entomophthoralean fungi may fit very well in inoculation biological control because they have the ability to establish epizootics quickly in target pest populations, have a narrow host range, and are able to persist in the target insect population.

Inoculation biological control is being used in northeastern USA to initiate epizootics of *E. maimaiga* in populations of *L. dispar* (Hajek and Webb, 1999; Pell *et al.*, 2001). Resting spores are collected on sites with high populations of the target insect and high prevalence of the fungus, and then spread on soil in areas without the fungus, but with host infestation. Although the fungus is well established throughout the host's distribution area, the host continues to spread, and cadavers are distributed along the leading edge of this spread in an effort to halt the destruction caused by this introduced pest.

There are other possibilities for inoculative biological control using fungi, such as inoculation of a small amount of *B. brongniartii* to control soil dwelling beetles from Scarabaeidae (Eilenberg *et al.*, 2000b). Another possibility would be use of *E. muscae* and *S. castrans* against cabbage root flies (*D. radicum* and *D. floralis*). Moreover, indoor, inoculative releases to control *M. domestica* could be based on *in vivo* cultures of *E. muscae* or *E. schizophorae* (e.g., Kuramoto and Shimazu, 1997). Conidia are sufficiently persistent in the environment for this release (Kalsbeek *et al.*, 2001b). Indoor stables are favorable for studies on fungus dispersal in a confined environment.

Dissemination is essential for the success of inoculation biological control. Pell *et al.* (1993) and Furlong *et al.* (1995) demonstrated that autodissemination of *Z. radicans* was possible in field populations of the diamondback moth *P. xylostella* in Malaysia by using a pheromone trap to attract adult insects. After the adults left the trap, they dispersed the fungus to both larvae and adults, and larvae became infected. Further experiments of inoculative releases in England demonstrate that it is possible to induce epizootics in *P. xylostella* using *Z. radicans* (Pell and Wilding, 1994). Other examples are provided by Vega *et al.* (2000).

6.11.8. Use in Classical Biocontrol

Classical biological control is defined as

> The intentional introduction of an exotic biological control agent for permanent establishment and long-term pest control
>
> Eilenberg *et al.* (2001)

It is desirable from the point of view that limited inoculative releases of an organism will result in a long-lasting control of a pest (often an introduced pest species). Because the introduction of an exotic species has the potential of irreversible direct effects on nontarget species, or indirect effects through host depletion, it is important to gain as much information on the potential candidate's host range and epizootiology as possible prior to its introduction (Hajek and Butler, 2000; Hajek and Goettel, 2000; Goettel and Hajek, 2001; Goettel *et al.*, 2001).

There is great potential in the use of entomopathogenic fungi in classical biological control, especially against introduced pests. Fungi from Entomophthorales possess several characteristics favoring their use in classical biological control; they can establish epizootics quickly, they have mostly a narrow host range, and they persist in pest populations and in the environment. Unfortunately, in most cases, it is not known whether or not a given species is already present in a locality, and the tools needed for detailed studies of their spread after release (e.g., isolate specific characterization) are usually not fully developed (see Section 6.11.4).

As early as 1909, *E. maimaiga* infected gypsy moths, *L. dispar*, were collected in Japan and released in Boston, USA, in an attempt to control introduced *L. dispar*, but the fungus was not observed in local *L. dispar* populations for many years. It was, however, discovered in northeastern USA in 1989 and has now spread into many other areas within North America where *L. dispar* infestations were prevalent. It has not been ascertained if the fungus now commonly present is a result of the early release or if it was later accidentally imported (Hajek *et al.*, 1995; Pell *et al.*, 2001). A recent introduction of *E. maimaiga* into Bulgaria was successful (Pilarska *et al.*, 2000).

Another example of an establishment in a completely new environment was the release of an Israeli isolate of *Z. radicans* to control the clover

aphid *Therioaphis trifolii* in Australia. The experiments were limited in time and the area studied was small, yet it was shown that dispersal of the fungus up to at least 65 m took place within 2 months of release (Milner *et al.*, 1982). Another isolate of this same species was released in Illinois in 1984 to control the potato leafhopper, *Empoasca fabae* (McGuire *et al.*, 1987a). Epizootics of *Z. radicans* then occurred in *E. fabae* and contributed to regulation of the population, and there was evidence to suggest that one of the isolates might have become established (McGuire *et al.*, 1987b).

Neozygites floridana from South America has been considered for classical biological control of the cassava green mite (*Mononychellus tanajore*) in Africa (Elliot *et al.*, 2000). The data on dispersal in plots in Brazil indicated that the fungus would be capable of spread under African conditions and contribute to long-term control of the pest. However, it was concluded that *N. floridana* would not be capable of providing adequate control of the mite if used as the sole control agent. Releases of the Brazilian isolate were made in Benin in 1999 (Hountondji *et al.*, 2002). Postrelease monitoring revealed that the introduced isolate had become established, with infection prevalences of up to 36%, 48 weeks after initial introduction.

The use of fungi for classical biological control is at the present time a rather difficult issue. First, one must find a potential agent that does not already occur in the chosen environment. Then, laboratory studies are warranted to document that the proposed agent has potential for classical biological control. Finally, the authorities must be convinced that the agent for release and establishment poses no harm to the native fauna, and this is difficult, but not impossible, to accomplish (Hajek and Goettel, 2000; Goettel and Hajek, 2001). Today, the latter is difficult to achieve, due to the present attitude in society that more or less demands zero risk to biodiversity.

6.11.9. Role in Conservation Biocontrol

Conservation biological control (sometimes also called habitat manipulation) is defined as

> Modification of the environment or existing practices to protect and enhance specific natural enemies or other organisms to reduce the effect of pests
>
> Eilenberg *et al.* (2001)

It is probably the most attractive among all strategies for biological control, yet the least studied. No agents are released, but the farming systems and practice are modified in order to stimulate the naturally occurring predators, parasitoids, and insect pathogens, to regulate the pest insect populations below the damage threshold (Barbosa, 1998). Sufficient regulation by entomophthoralean fungi and other natural enemies may actually already exist for the vast number of crop herbivorous insect and mite species, which never do any damage because of low densities. The conservation strategy also fits well into modern sustainable agriculture, where actions to make direct use of the naturally occurring enemies of pests are taken into consideration, including increasing biodiversity and supporting a positive interaction between the crop, the flora, and fauna within the field and field margins, and landscape elements (Gurr and Wratten, 2000; Landis *et al.*, 2000). Fungi from the order Entomophthorales fit very well into this strategy (Pell *et al.*, 2001). They have the ability to establish natural epizootics depending on the host insect and a number of biotic and abiotic factors. A number of entomophthoralean species exist in each field, forest, private garden, greenhouse, stable and nature area. Certainly, this diversity of species (and isolates from each species) could be explored and exploited in conservation biological control.

Each system should be analyzed adequately. Studies on the epizootiology of *N. fresenii* in the cotton aphid, *Aphis gossypii*, in Arkansas have demonstrated that it is possible to monitor and to some extent predict the epizootic development of the fungus in the target insect population (Hollingsworth *et al.*, 1995; Steinkraus *et al.*, 1996; Pell *et al.*, 2001). The monitoring of the pest insect can therefore be supplemented with knowledge on the symptoms of fungal disease in the host, which would allow extension officers to modify their recommendations of intervention; e.g., if the pest population is high, but fungus infected, no pesticide treatment would be required as the pest population would soon succumb to the disease.

Habitat manipulation and modification of existing practices are often proposed as means to promote infections caused by entomopathogenic fungi (Pell *et al.*, 2001): more hedges, less spraying with chemicals (e.g., fungicides), and irrigation are all, at least theoretically, supportive to development of natural fungal epizootics among pest insects. It was recently shown that soil-occurring insect pathogenic fungi from Hyphomycetes are found in higher densities in organic grown fields compared to conventionally treated fields (Klingen *et al.*, 2002). To date, however, it has not been possible to document that a

specified practice will result in a sufficiently high infection level *every time* in field situations. Indoors it has been shown that intensive spraying with water supports the development of natural epizootics of *Erynia ithacensis* in fungus sciarid gnats (Huang *et al*., 1992), and such manipulation should be better studied and eventually adopted.

Among biotic factors influencing the success of entomopathogenic fungi are their interactions with other natural enemies. Such interactions may be positive, since predators and parasitoids may assist in the transmission of these fungi as passive vectors (see Sections 6.11.3.5 and 6.11.3.6). A better understanding of the interactions between entomopathogenic fungi and other natural enemies would allow us to use different biological control agents in different strategies. There is much potential for conservation biological control using entomopathogenic fungi, however, more studies are needed before we can take full advantage of this naturally occurring resource. Especially warranted are studies to clarify the importance of soil as a reservoir of inoculum and to determine whether crop rotation is supportive to infection of entomophthoralean fungi and other insect pathogenic fungi.

More information is needed to determine how landscape elements affect early initiation of epizootics. In both cases, the inclusion of studies of insect pathogens should be promoted strongly to complement the more detailed existing knowledge of interactions among predators, parasitoids, host and nonhost insects, cropping systems, and landscape elements. Despite the wish to make entomopathogenic fungi operational for conservation biological control, much work still remains. Compared with knowledge on predators and parasitoids, the knowledge on insect pathogens in natural systems is limited, and much observational and descriptive work is certainly still needed.

6.11.10. What Does the Future Hold?

Compared to other technologies, development of entomopathogenic fungi as inundative, inoculative, and classical microbial control agents is still in its infancy. Inundative application of mass produced spores has long been seen as an attractive alternative to the classical use of fungi for control. A number of fungal based biopesticides are now being produced. But, despite the number of "products" based on entomopathogenic fungi currently commercially produced for pest control throughout the world, the market share is still well below the potential suggested by their role in natural insect control. Although great strides have been made in improving methods of production, formulation, and application, a great many improvements are still possible. Production of species "cocktails," especially combining microbials from different classes or even with chemical or botanical antagonists is only just beginning. To date, all commercial products based on entomopathogenic fungi have been developed from wild-type field strains. In many cases, these products are developed with the insecticidal paradigm in mind, that is, strains with the widest host range are formulated to be applied by conventional equipment. These products are often difficult to market to clientele that are used to conventional chemical insecticides and expect tank mixing possibilities with either herbicides or fungicides (and this is often not compatible), a rapid kill (fungi are usually slower acting), and a broad spectrum of activity (even fungi with the broadest host spectrum have reduced spectra as compared to most chemicals in present use).

With only a few studies attempting genetic engineering on entomopathogenic fungi, it is hard to determine when or not modification of fungi will increase their efficacy in biocontrol. The current regulatory environment in many countries makes such research expensive, and public acceptability without demonstrated consumer (rather than farmer) gains may be some time off. Strain improvement through guided selection strategies is more likely to find acceptance in the short term.

In addition to development of entomopathogenic fungi for use in inundative applications, we see great potential in their use in conservation and classical biological control. Whatever strategies are contemplated, they should be considered with the intention not just of replacing chemical pesticides with entomopathogenic fungi, but contributing to the development of sustainable agriculture, horticulture, and forestry as well as the preservation of biodiversity and nature. With increasing public and political pressure to implement integrated pest management strategies, it is inevitable that use of entomopathogenic fungi will play an increasingly important role (Lacey and Goettel, 1995).

6.12 Pheromones: Function and Use in Insect Control

T C Baker and J J Heath, Pennsylvania State University, University Park, PA, USA

6.12.1. Introduction

6.12.1.1. Basic and Applied Research on Pheromones

During the 45 years since the identification of the first pheromone by Butenandt *et al.* (1959), insect pheromones have achieved significant stature in agricultural and urban pest management systems worldwide. If a pest species is known to use a sex pheromone to communicate, one of the most important initial efforts in trying to establish a workable pest management strategy is to explore that pheromone system to try to develop a useful synthetic pheromone attractant.

Since the mid-1960s, basic research has advanced our understanding of the biochemical, neurophysiological, and behavioral underpinnings of insect pheromone communication systems to a degree that none of us in the field could have years ago imagined. However, these advances have to this point not played a significant role in the development of useful and commercially successful applied pheromone tools for pest management. Basic pheromone research has provided valuable after-the-fact insight into why certain pest management applications of pheromones may be working better than others. This insight is now ready to be transformed into predictive knowledge that can, and should, be used to improve existing applied pheromone technologies and to create new ones.

The applied pheromone technologies and products currently in use were developed by applied entomologists using repeated trial-and-error field trials that have shown what works and what does not work. Improved pheromone dispenser technologies resulted from engineering and manufacturing advances that were made mainly by research and development teams at commercial companies. Chemical ecology techniques, which are at the heart of any initial investigations aimed at isolating

and identifying pheromones, have advanced in sophistication and sensitivity over the years, and have played an essential role in identifying several thousand pheromone components. Most pheromone identifications, however, have been initiated by a need for pest management tools and not for basic exploration of communication systems.

Basic research on insect pheromone olfaction has provided knowledge about animal olfaction that arguably has been as valuable as similar lines of research performed on vertebrates (Hildebrand and Sheppard, 1997). This research has been illuminating and exhilarating; now, many of the new insights that have emerged need to be reconnected with efforts toward application.

There are many reasons why insects have received such intense focus for research on pheromones. Certainly a major reason, apart from the simplicity and accessibility of their behavioral, olfactory, and pheromone production systems, is that so many insect species are pests. Also, society's awareness of the overuse of insecticides and the environmental damage they were imparting accelerated during the mid-1960s, and along with it emerged a hope that pheromones might be a safe and effective alternative to insecticides. It is important in this chapter to bring awareness to readers of the successful commercial use and grower acceptance of pheromone-based products. Many who have had the privilege to perform basic pheromone research realize that to a large degree we have been able to do so because of the exciting promise that pheromones presented to society early on that they might replace existing insecticides.

The purpose of this chapter is, however, not to merely summarize the many commercial successes that pheromones have had or to note the inroads they have made into being accepted as reliable tools for population suppression of key pests. Rather, it is to bring together some of the basic knowledge about insect behavior and olfaction from the past 30-plus years of knowledge the authors have gained from the successful field uses of pheromones over the same period. A few new ideas are also suggested for increasing the efficacy and economic competitiveness of pheromones in some pest management arenas.

Successful use of pheromones in insect control depends upon successfully controlling insect behavior through the emission of synthetic pheromone blends. The behaviors that are most amenable to manipulation are those that involve long-distance attraction. There is more power over the target insects with long-range attraction because human control over the behavior reaches far out into the field from every pheromone emission source. Thus, our focus is mainly on sex pheromones in this chapter. It is evident that basic and applied research on sex pheromones historically has involved mainly two groups, the Lepidoptera and Coleoptera, and therefore dwelt mostly on these two taxa. Although this emphasis is necessary, many of the principles developed from research on these two insect orders should be transferable to the pheromone systems of other groups.

6.12.2. Brief Overview of Insect Sex Pheromone Communication Systems

Sex pheromones in insects include a variety of molecules from large, but volatile, aliphatic molecules to small cyclic monoterpenoids (**Figure 1**). Although the vapor pressures of many of these compounds are very low (**Table 1**), many behavioral and electrophysiological experiments over the years have shown that insects do indeed smell these compounds even at extremely low concentrations (Kaissling, 1974, 1987, 1990; Priesner *et al*., 1986; Szöcs *et al*., 1989; Cowles *et al*., 1996; Minor and Kaissling, 2003). Much of the information to follow has come more or less directly from an excellent recent book edited by Hardie and Minks (1999) that reviews nonlepidopteran pheromones.

6.12.2.1. Lepidoptera

Lepidopteran pheromones were the first to be widely studied and include a huge collection of mostly female-based pheromones. Female moths typically produce long-range, fatty acid-derived molecules (e.g., (**11**) in **Figure 1**) that function over long distances, whereas male moths tend to produce close-range courtship compounds that are often very similar in structure to plant secondary metabolites (e.g., (**3**) in **Figure 1**) (Baker, 1989a; Birch *et al*., 1990). In contrast to moths, butterflies tend to use color and motion cues more than pheromones to find mates. Butterfly pheromones are generally restricted to close-range or contact pheromones (Baker, 1989a). Moth pheromones have been cataloged in The Pherolist, a free database.

The majority of moth pheromones identified thus far are blends of 10- to 18-carbon-long straight-chain primary alcohols, acetates, or aldehydes. However, one interesting second major class of moth pheromone components is found in noctuids, geometrids, arctiids, and lymantriids comprises polyene hydrocarbons and epoxides (e.g., (**10**) and (**13**) in **Figure 1**) (review: Millar, 2000). For the majority of moth species, after synthesis of the fatty acyl chain to either 16 or 18 carbons in length, these pheromone

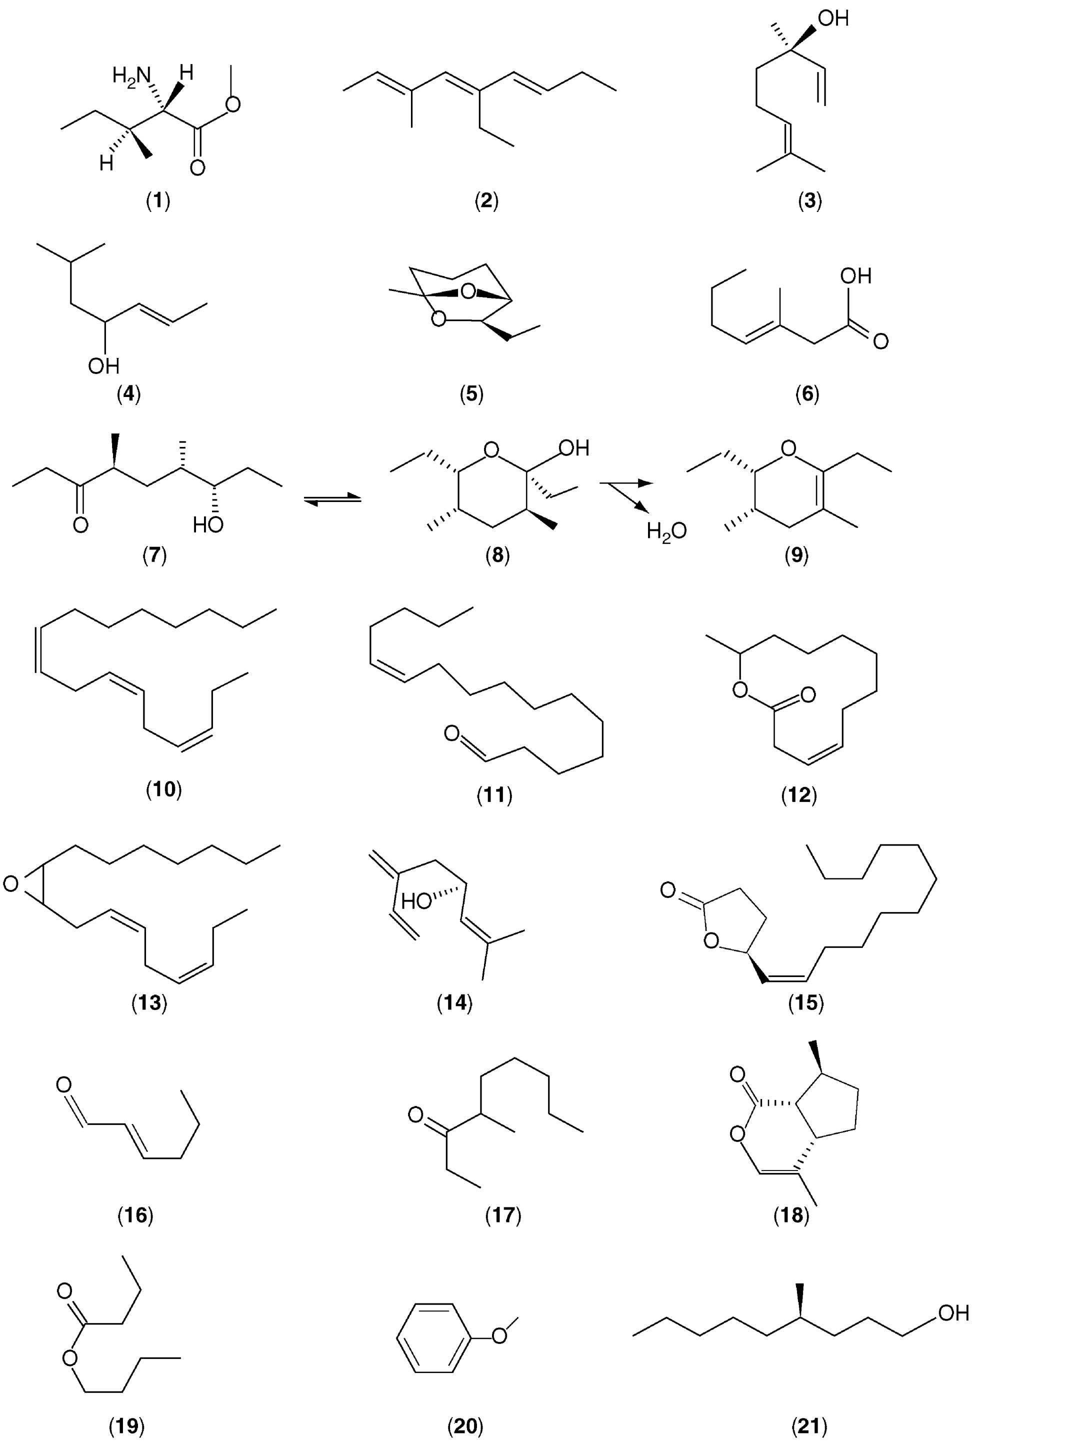

Figure 1 Pheromone component structures for various insects of the orders Lepidoptera, Trichoptera, Coleoptera, and Hemiptera. (**1**), L-isoleucine methyl ester; (**2**), (2*E*,4*E*,6*E*)-5-ethyl-3-methyl-2,4,6-nonatriene; (**3**), *R*-linalool; (**4**), (2*E*,4*S*)-6-methyl-4-heptenol; (**5**), (1*R*,5*S*,7*R*)-*exo*-brevicomin; (**6**), (*E*)-3-methyl-3-heptenoic acid; (**7**), (4*S*,6*S*,7*S*)-serricornin; (**8**), serricornin (cyclic); (**9**), anhydroserricornin; (**10**), (*Z*,*Z*,*Z*)-3,6,9-heptadecatriene; (**11**), (*Z*)-11-hexadecenal; (**12**), (*Z*)-3-dodecen-11-olide; (**13**), (*Z*,*Z*)-3,6-*cis*-9,10-epoxyheptadecadiene; (**14**), (*S*)-(+)-ipsdienol; (**15**), (*S*,*Z*)-5-(+)-(1-decenyl)oxacyclopentan-2-one; (**16**), (*E*)-2-hexenal; (**17**), 4-methylnonan-3-one; (**18**), (+)-(4a*S*,7*S*,7a*R*)-nepetalactone; (**19**), butyl butyrate; (**20**), anisole; (**21**), (*R*)-4-methyl-1-nonanol.

Table 1 Vapor pressures of some insect pheromone components; vapor pressures of some plant-related volatiles are also listed

Name[a]	*Vapor pressure at 25°C*[b]	*Registry number*[c]	*Insect order*

[a]Abbreviated chemical names, e.g., ''(*E*,*Z*)-3,13, 18:OH'' is shortened form of (*E*,*Z*)-3,13-octadecadien-1-ol. Ac, acetate; OH, alcohol; Ald, aldehyde.
[b]Vapor pressures were taken from Scifinder Scholar.
[c]Registry numbers are given to allow searching for additional properties in chemical abstract services.

component precursors begin to achieve some species–specific structural differences that are imparted by one or more desaturases that place double bonds at specific locations in the fatty acyl chain (Tillman *et al*., 1999; Roelofs and Rooney, 2003). The desaturation step is, depending on the species, either preceded or followed by β-oxidation to reduce the chain length of the molecule. Merely reversing the two-step sequence in which these two enzyme systems work creates most of the major differences in pheromone component structures in moths (Roelofs and Rooney, 2003). Final species–specific structural differences result from the final biosynthetic step, conversion of the fatty acyl molecule to its active functional group by reductases and oxidases.

A key neuropeptide named pheromone biosynthesis activating neuropeptide (PBAN) has been found in females of all pheromone-producing moth species thus far. PBAN stimulates both the behavioral release of pheromone (i.e., calling behavior) and the biosynthesis of the pheromone components (Nation, 2002). A receptor for PBAN has recently been characterized in *Helicoverpa zea* by Choi *et al*. (2003) and is a membrane-bound heptahelical G protein-coupled receptor (i.e., a seven-transmembrane GPCR). The PBANs of most species are extremely similar in structure, and injection of one species' PBAN into the female of a second species often causes enhanced pheromone production in the injected female, even across families (Raina and Menn, 1987).

6.12.2.2. Trichoptera

Trichopterans are closely related to Lepidoptera. In fact, on a family level phylogeny they form a monophyletic group with the lepidopterans; that is, they are the sister group to Lepidoptera (Ross, 1964). Trichopteran pheromones, like their lepidopteran counterparts, are produced by females and attract males from a distance. However, the limited number of trichopteran sex pheromone components that have been identified do not share the most common features of their lepidopteran counterparts. Trichopteran pheromone components are, however, similar in structure to those of some primitive lepidopterans of the family Eriocraniidae (Zhu *et al*., 1995; Kozlov *et al*., 1996). In only three species have putative pheromones been shown to have behavioral activity in the trichopterans (Löfstedt *et al*., 1994; Bjostad *et al*., 1996) and all three are produced by the paired set of sternal glands that secrete their products onto the fifth abdominal sclerite through a dorsolateral opening on each side of the sclerite (Ivanov and Melnitsky, 1999). Bjostad *et al*. (1996) identified 6-methylnonan-3-one (similar to (**17**) in **Figure 1**) as the major component of the sex pheromone of *Hesperophylax occidentalis*, and Löfstedt *et al*. (1994) found nonan-2-one and heptan-2-one to be the major components of the sex pheromones of *Hydropsyche angustipennis* and *Rhyacophila fasciata*, respectively.

Although nothing is known yet about the behavioral impact of the differences in pheromone

chirality that these trichopteran pheromone components have, chirality has been shown to be important to the activity of receptor neurons in individual olfactory sensilla (Larsson and Hansson, 1998). In some species these compounds had been implicated as being defensive secretions (see references in Ivanov and Melnitsky, 1999), but the first behavioral studies definitively demonstrated their roles as sex pheromones (Wood and Resh, 1984; Resh and Wood, 1985). No information is available regarding biosynthesis of these pheromones or endocrine regulation. Work on this group may not proceed as quickly as it has in others because trichopterans are not agricultural pests. However, they are important indicators of environmental quality (Brigham and Sadorf, 2001) and monitoring their presence with pheromone traps may be more convenient and efficient than stream sampling.

6.12.2.3. Coleoptera

Coleopteran pheromones have mainly been identified for scarabs (Scarabaeidae) (Leal, 1999), sap beetles (Nitidulidae) (Bartelt, 1999a), scolytids (Scolytidae) (Schlyter and Birgersson, 1999), weevils (Curculionidae) (Bartelt, 1999b), and stored-product beetles (Anobiidae, Dermestidae, Bruchidae, Tenebrionidae, Bostrichidae, Cucujidae, and Silvanidae) (Plarre and Vanderwel, 1999). Recently, much of the literature regarding beetle pheromones and all other insect pheromones has been compiled into one site (Pherobase). This site is likely the most extensive database of pheromones of insects currently freely available.

6.12.2.3.1. Scarabaeidae Scarab pheromone components are generally of four types: fatty acid-derived lactones ((**15**), **Figure 1**); straight-chain unsaturated aldehydes, alcohols, ketones, and esters (similar to 16, but with nine carbon atoms; **Figure 1**); terpenoids ((**3**), **Figure 1**); amino acid derivatives ((**1**), **Figure 1**); or phenolics ((**20**), **Figure 1**). They are produced by either unicellular epidermal glands on the posterior ventral sclerites or by an everted soft tissue sac on the last few segments of the abdomen, similar to the glands of higher lepidopterans. There seems to be an interesting segregation of chemistry among these two gland types that is also manifested at the subfamily level. The everted soft tissue sacs produce mainly terpenoids or amino acid-derived compounds and are associated with the Melolonthinae, whereas the unicellular glands produce the fatty acid derived compounds and are mainly associated with the Rutelinae (Leal, 1999). Not all the Melolonthinae use eversible glands; females in the genus *Macrodactylus* have never been observed everting a gland from the tip of their abdomens (Heath *et al.*, 2002). The lack of obvious calling behavior as well as the lack of cuticular pores in this genus may present a unique opportunity to study the evolution of sex pheromones in melolonthine beetles. In some scarabs the pheromone seems to be synergized by the presence of plant volatiles. For example, the Japanese beetle pheromone (Tumlinson *et al.*, 1977) ((**15**), **Figure 1**) captures twice as many beetles when selected plant compounds are blended and coemitted with it (Klein *et al.*, 1981).

6.12.2.3.2. Nitidulidae Sap beetle (Nitidulidae) pheromones are mainly known as a result of a series of studies conducted by Bartelt and colleagues (Bartelt, 1999a) on species in the genus *Carpophilus*. The pheromones, which attract both sexes, are produced by male glandular cells in the posterior of the abdomen that secrete their contents into tracheal tubes. The chemical structures of the pheromone molecules are of polyunsaturated, multibranched hydrocarbons ((**2**), **Figure 1**). Seventy-five times more *Carpophilus hemipterus* beetles are attracted to the blend of pheromone plus food odor than to either pheromone or food odor alone (Bartelt *et al.*, 1994). In fact, a high level of attraction synergism between food and pheromone odors exists throughout the genus *Carpophilus* (Bartelt, 1999a). These pheromone components seem to be biosynthesized through the use of acetate, propionate, and butyrate acyl units (Petroski *et al.*, 1994; Bartelt and Weisleder, 1996). The initial condensation reaction seems to differ significantly from the typical fatty acid synthesis with malonyl CoA (Petroski *et al.*, 1994). In some methyl-branched pheromones, the branched units are derived ultimately from amino acids (Tillman *et al.*, 1999). Possible hormonal and neurohormonal mechanisms regulating initiation and termination of biosynthesis remain unexplored at present.

6.12.2.3.3. Curculionidae A significant number of weevil (Curculionidae) pheromones have been identified (review: Bartelt, 1999b), and many of these have contributed to highly successful integrated pest management (IPM) of weevil pest species through their effectiveness in mass trapping (see Section 6.12.5.3.1). The majority of the known systems involved are male-emitted and the pheromones are often strong enough to attract both sexes from tens of meters away (Bartelt, 1999b and references therein). The structures of the pheromone molecules seem very diverse. However, they share a common mode of action in that, as in the *Carpophilus* sap beetles, the attraction of weevils by the pheromone is synergized by coemission of plant compounds. For example, all six palm weevil pheromones of

Rhynchophorus spp., (e.g., (**4**), **Figure 1**), are synergized by the presence of plant material such as sugarcane stalks (Oehlschlager *et al.*, 1993). In the Andean potato weevil, *Premnotrypes suturicallus*, a severe pest in the Peruvian Andes, field-collected *P. suturicallus* females must be actively feeding on a host plant to attract males (J.J. Heath *et al.*, unpublished data). It is not well known how or where weevil pheromones are produced, but there is evidence from *R. palmarum* males that they are synthesized in glands in the prothorax and exuded from the mouth (Sánchez *et al.*, 1996). Studies on the mechanisms of biosynthesis and regulation are also lacking.

6.12.2.3.4. Scolytidae Bark beetles (Scolytidae) pheromones were among the earliest studied and identified in insects (Silverstein *et al.*, 1966, 1968; Kinzer *et al.*, 1969; Bedard *et al.*, 1970). They were also, along with lepidopterous pheromones, the group of pheromones that showed the most promise in large-scale field tests to be effective in suppressing or manipulating populations of the devastating pests present in this family (Bedard and Wood, 1981; Lanier, 1981).

Recent work on this group (review: Schlyter and Birgersson, 1999) has not completely resolved a long-standing discussion of whether bark beetle pheromones are biosynthesized *de novo* or are just slightly modified (detoxified) host compounds. In at least two genera, *Tomicus* and *Dendroctonus*, it is the females that locate a host tree, begin boring galleries for oviposition, and in the process produce a long-distance pheromone that results from detoxified host compounds and host resin constituents. *Dendroctonus ponderosae* females release (−)-trans-verbenol, which attracts males. Once males arrive they produce (+)-*exo*-brevicomin ((**5**), **Figure 1**), which acts as an aggregation pheromone (i.e., both sexes are attracted). *Tomicus minor* females use a similar system.

Females of *Dendroctonus brevicomis*, alternatively, start producing (+)-*exo*-brevicomin as the first-arriving beetles burrow into the host tree to initiate galleries. Once they have reached the phloem tissue a resin containing myrcene, a hydrocarbon similar in structure to linalool ((**3**), **Figure 1**), begins to flow. The blend of these two compounds is attractive to males. Once males arrive they begin producing (−)-frontalin. This three-component blend is now attractive to both males and females. It has also been shown that myrcene is converted to (+)-ipsdienol ((**14**), **Figure 1**) simply by passing myrcene-laden air over *Ips paraconfusus* (Byers, 1995 and references therein). Male *D. brevicomis* and many other *Ips* spp. also produce (+)-ipsdienol, which has an antagonistic effect in field studies with *D. brevicomis* (Bertram and Paine, 1994).

Regardless of whether bark beetle pheromones are synthesized entirely *de novo* or their the mode of production involves the beetle making relatively small modifications of existing plant-derived compounds, one feature remains common throughout the bark beetles: pheromone-based attraction is synergized by coemission of plant volatiles. This is true for species in the well-studied genera *Dendroctonus*, *Ips*, and *Scolytus* as well as for species in other genera such as *Conophthorus coniperda* in which pioneering females produce 2*R*,5*S*-pityol while burrowing into the tree. Attraction is synergized by α-pinene and other monoterpenes (Schlyter and Birgersson, 1999).

6.12.2.3.5. Stored-product beetle pests Stored-product pests, including the families Anobiidae, Dermestidae, Bruchidae, Tenebrionidae, Bostrichidae, Cucujidae, and Silvanidae, have an interesting array of pheromones aptly reviewed by Plarre and Vanderwel (1999). These include both female-produced pheromones that only attract males, and also male-produced aggregation pheromones. Anobiid females produce cyclic compounds that can rapidly interconvert between different forms. For example, the acyclic form of serricornin ((**7**), **Figure 1**) is in equilibrium with the cyclic form ((**8**), **Figure 1**), which can then lose water to form anhydroserricornin ((**9**), **Figure 1**) (Mori *et al.*, 1984). Dermestid females produce unsaturated fatty acids and derivatives thereof that serve as pheromone components in this group (Silverstein *et al.*, 1967). The dermestid pheromone components are similar to those of moths ((**11**), **Figure 1**). Bruchid females emit short-chain, branched, unsaturated acids as their pheromone components that attract males ((**6**), **Figure 1**).

In most of the species of stored-product beetle pests, pheromones are produced by glands on or between abdominal segments. The genus *Tribolium* may be an exception. The male-produced aggregation pheromone, 4,8-dimethyldecanal (Plarre and Vanderwel, 1999 and references therein), in *T. castaneum* is apparently produced in glands located on the ventral side of the prothoracic femurs (Faustini *et al.*, 1981). The production of the *Tenebrio molitor* female-produced pheromone, (*R*)-4-methyl-1-nonanol ((**21**), **Figure 1**), is regulated by juvenile hormone III (Menon, 1976). The bostrychids use branched esters very similar in structure to the pheromones of some heteroptera (e.g., (**19**) in **Figure 1**). Cucujidae and Silvanidae use macrocyclic lactones likely produced by fatty acid biosynthesis ((**12**), **Figure 1**).

6.12.2.4. Homoptera

Knowledge of homopteran sex attractant pheromones comes from two agriculturally important groups, the scale insects and the aphids. Most of the species of aphids studied thus far use a blend of nepetalactone and nepetalactol compounds as their sex pheromone (Pickett *et al*., 1992; Hardie *et al*., 1994). For instance, the sex pheromone of the aphid *Aphis fabae* is a 29 : 1 blend of (+)-(4a*S*,7*S*,7a*R*)-nepetalactone and (−)-(1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (Pickett *et al*., 1992). These are monoterpenoids in the cyclopentanoid series ((**18**), **Figure 1**) and are produced by females in glands on the tibiae of the hind legs (Pettersson, 1971; Hardie *et al*., 1999). Although the nepetalactones and related compounds are found in plants of the genus *Nepeta*, biosynthesis and regulation are not well understood in either kingdom (Hardie *et al*., 1999). There is considerable research effort at present being made to explore the pheromone systems of an increasing number of aphid species for use in pest management. There is usually only one sexually communicating generation, and so this generation represents a vulnerable target for aphid control via pheromones. If mating and hence egg-laying by the sexually reproducing females could be disrupted with pheromones, there could possibly be significant population suppression effects.

One other aspect of aphid pheromone communication is their use of alarm pheromones. Interestingly, the main component of most aphid alarm pheromones is the branched chain sesquiterpene (*E*)-β-farnesene, whereas the alarm pheromone for the spotted alfalfa aphid is the cyclic sesquiterpene (−)-germacrene-A (Hardie *et al*., 1999). Dawson *et al*. (1987) found that (*E*)-β-farnesene, the alarm pheromone of the turnip aphid, *Lipaphis erysimi*, was not effective unless isothiocyanates were added to the blend, suggesting a host-plant volatile, context-dependent effect of (*E*)-β-farnesene.

6.12.2.5. Heteroptera

Heteropterans produce a wide array of compounds, often in unusually large quantities compared with pheromones of other groups of insects (reviews: Aldrich, 1995; McBrien and Millar, 1999). These compounds are produced by a number of different glands that can be found in at least six different parts of the body, including metathoracic glands, dorsal abdominal glands, sternal glands, unicellular glands, subrectal glands, and ventral abdominal glands (Aldrich, 1995). Metathoracic glands are mostly noted for their role in production of defensive secretions in adult bugs, but these glands are known to be sexually dimorphic and do produce pheromones in some species. The secretions from this paired set of glands most often contaminate pheromone extractions. Dorsal abdominal glands most often produce the defensive secretions of nymphs and then they disappear by adulthood. However, these have sometimes been shown to remain functional in adults where they then are involved in pheromone production. The sex pheromone systems of heteropterans are generally male-emitted, but there are a few examples of female-emitted systems. Aldrich (1995), in his comprehensive review of the diversity of heteropteran pheromones, has highlighted the need for focused research in this group that includes many important pest species as well as beneficial predatory species that are useful biological control agents.

Heteropteran pheromones tend to be either a blend of esters (e.g., butyl butyrate, (**19**), **Figure 1**) or an ester and a short-chain aldehyde or alcohol (Smith *et al*., 1991; Leal *et al*., 1996). These esters, aldehydes, and alcohols (e.g., (**16**) and (**19**) in **Figure 1**) are also often combined with a terpenoid ((**3**), **Figure 1**) to form a pheromone. For example, McBrien *et al*. (2002) showed that a conjugated triunsaturated methyl ester, when combined with one or more of three sesquiterpenes, was attractive to the stink bug *Thyanta pallidovirens*. There is little known about pheromone biosynthesis in this group, or of the hormones involved in the regulation of production in the Heteroptera.

6.12.3. Pheromone-Mediated Behavior

6.12.3.1. Research on Olfaction and Orientation

Two major basic lines of investigation have been taken to understand how pheromones cause insects to be “attracted” and arrive at the source. One has focused on orientation movements that are evoked by exposure to the correct pheromone blend for a particular species. By necessity, studies of insect pheromone-mediated orientation have been concerned with flight control, which ultimately needs to be understood with regard to how a flying insect stabilizes its flight in wind in all three possible planes of movement in space (David, 1982, 1986). The second major line has focused on studies of insect olfaction. It is the exposure to the correct blend of pheromone components, and not partial blends or suboptimal blend ratios, that most intensely turns on programs that change an insect’s movements and maximize attraction toward the source. Because the reception and integration of the pheromone blend’s quality modulates these programs, insect pheromone

olfaction has been an equally important and rewarding line of inquiry, and one that has received much funding support from federal funding agencies.

6.12.3.2. Understanding Pheromone-Mediated Orientation

6.12.3.2.1. Importance of the fine-scale structure of pheromone plumes to orientation behavior Wright (1958) recognized, in contrast to Bossert and Wilson's time-averaged "active space" depiction and modeling (Bossert and Wilson, 1963), that an odor plume is composed of strands of odor that issue from the surface of the odor source. The strands are sheared from the release surface and drift downwind where they become stretched, twisted, and more tortuous as they are ripped apart into substrands during their journey farther downwind (Murlis, 1986, 1997). These disjointed substrands interspersed with pockets of clean air comprise what we call the odor plume. However, it was not until intermittency of stimulation from the plume was shown to promote sustained upwind flight (Kennedy *et al*., 1980, 1981; Baker *et al*., 1985) and subsequently when moths were shown to have the ability to react fast enough during upwind flight to the subsecond changes in pheromone concentration (Baker and Haynes, 1987) that one began to understand that these individual pheromone strands and pockets of clean air are what are producing the sustained upwind flight behavior that is called attraction (Mafra-Neto and Cardé, 1994; Vickers and Baker, 1994). Thus, the major advance in basic understanding of insect pheromone-mediated behavior over the past 20 years is that with but one exception (Justus and Cardé, 2002), rapid increases in flux from individual plume strands and decreases from the clean air pockets between strands are essential to producing reiterative upwind surges that result in the attraction of male moths to pheromone sources.

Concerted attempts to apply this new knowledge have not yet been made, but this is an area of research that may offer the best chance for improving the efficacy and economic competitiveness of pheromones in pest control. Wyatt (1997) reviewed the advances in basic and applied pheromone research that had been made through the mid-1990s and provided a series of suggestions as to the types of research and extension efforts that should be undertaken to facilitate the more widespread commercial use of pheromones for direct control of insect pests. One objective of this chapter is to provide an updated snapshot of what has been learned from the continued successful commercial use of pheromones in recent years and also to review some recent advances in basic knowledge about the behavior and neurophysiology of insect olfaction to suggest new ways to improve and optimize the field use of insect pheromones for pest control. Biochemical and molecular aspects of insect olfaction are reviewed in depth by Vogt (see **Chapter 3.15**), and so attempt is not made to cover the many advances made in this important area.

The focus is mainly on sex pheromones because these have achieved the widest commercial utility. The treatment of the basic neuroethological mechanisms involved in olfaction and attraction is restricted mainly to the Lepidoptera, because research on this group has provided the most comprehensive and probably the most useful model by which to understand odor-mediated attraction of all insects. Based on current knowledge about olfactory pathways and flight responses of insects in other orders, there is no reason to suspect that the mechanisms of olfaction or in-flight orientation generally used by insects will be significantly different from those used by Lepidoptera.

6.12.3.2.2. Optomotor anemotaxis and self-steered counterturning: two indirect reactions to pheromone The insight and experience of John S. Kennedy began to free pheromone researchers of their preconceptions about attraction being a chemo-orientation process involving steering with regard to odor gradients (Kennedy and Marsh, 1974; Kennedy, 1977, 1983, 1986; Marsh *et al*., 1978; Kennedy *et al*., 1980, 1981). This allowed a better understanding of insects' responses to pheromones and other odors as being an *indirect* response to odor exposure that turns on steering programs with respect to *wind*, and *not* to odor. It was also discovered that a second indirect response is also turned on in moths by pheromone, an internally generated program of side-to-side oscillations that is switched on and takes place even in the absence of wind, persisting for many seconds after pheromone is removed (Baker and Kuenen, 1982; Kuenen and Baker, 1983).

Since those initial landmark studies by Kennedy's group it has been possible to learn more precisely how, when a flying insect encounters a series of odor strands of the right quality, these two programs are performed. In the wind-steering program, a visually mediated response called optomotor anemotaxis, the moth compensates for any off-line displacement due to wind direction, or for any changes in progress over the ground that arise due to changes in wind velocity. During pheromone stimulation, the optomotor anemotactic response keeps the insect heading and progressing more or less directly upwind. The other, nonanemotactic program (Baker and Kuenen,

1982; Kuenen and Baker, 1983) is a "counterturning" pattern of rapid left–right reversals of direction (Kennedy, 1983, 1986) which is performed concurrently with anemotaxis. Counterturning frequency increases upon contact with pheromone and coincides with more upwind-oriented optomotor anemotactic steering (Baker and Haynes, 1987). Counterturning frequency slows down upon loss of pheromone at the same time that the clean air causes the anemotactic program to allow more crosswind, transverse optical image flow, to result in slower-reversing, greater amplitude crosswind casting flight (Kennedy, 1983, 1986; Baker, 1985, 1989b, 1989c).

6.12.3.2.3. Altitude control Wind is the horizontal motion component of a moving air mass, and optomotor anemotaxis only explained steering with respect to wind to result in attraction (upwind displacement). A flying insect traversing pheromone plume strands also needs to navigate in a third dimension, i.e., with regard to its altitude. David (1982, 1986) provided experimental evidence that altitude control is accomplished via optomotor compensation for the apparent up or down movement of objects. He showed that these responses are performed by *Drosophila hydei* by changing their wing beat frequency to regulate the total flight forces that the wings generate when moving visual cues give them the sensation that they are rising or sinking. This vertical flight-force response system is intimately coupled with changes in body pitch angle that the insect performs in response to changes in the horizontal component of optomotor feedback that arise from changes in total flight force (e.g., wing beat frequency) (David, 1982, 1986). Studies of flight tracks of several moth species, which represent the total pheromone-mediated flight system involving both counterturning and anemotaxis, have shown that when a moth is casting widely following loss of pheromone, its vertical (up-and-down) excursions are correspondingly greater (VonKeyserlingk, 1984; Baker, 1989c). When the insect is surging upwind following repeated contact with pheromone strands, its vertical motion is much reduced as is its side-to-side movement (VonKeyserlingk, 1984; Baker, 1989c) due to high-frequency counterturning, with more thrust being generated to carry the insect upwind at a faster rate (David, 1986).

6.12.3.2.4. Subsecond reaction times of the two programmed responses to pheromone Intermittency of stimulation from the strands of pheromone and pockets of clean air that comprise a pheromone plume was shown to be required for at least two species of moths to promote sustained upwind flight of males (Kennedy *et al.*, 1980, 1981; Baker *et al.*, 1985). Soon after, it was found that male oriental fruit moths were able to react within 1/6 of a second to changes in pheromone concentration (Baker and Haynes, 1987). It was now possible to hypothesize that each encounter with an individual pheromone strand or pocket of clean air produces subsecond reactions in male moth behavior that, when reiterated during multiple encounters with strands and pockets of clean air in a plume, promote successful sustained upwind flight to the pheromone source (Baker and Haynes, 1987; Baker, 1990; Kaissling and Kramer, 1990).

The research progress resulting from many experiments aimed at understanding behavioral responses of moths to pheromone (reviews: Kennedy, 1983, 1986; Baker, 1985, 1986, 1989b; Willis and Arbas, 1991, 1997; Arbas, 1997; Baker and Vickers, 1997; Cardé and Mafra-Neto, 1997) brought the field to the point of being able to embrace a comprehensive understanding of how male moths locate sources of sex pheromone. A series of experiments using two different lepidopteran species from different families (Mafra-Neto and Cardé, 1994; Vickers and Baker, 1994) confirmed that the split-second reactions to individual odor strands are, in fact, the hypothesized upwind surges (Baker, 1990; Kaissling and Kramer, 1990) that are strung together during repeated contacts with strands in a natural plume to produce sustained upwind flight in response to pheromone. The intermittency provided by pheromone strands has been shown, in three of the four moth species that have been experimentally examined for this, to be essential to producing reiterative upwind surges that result in attraction of moths (Kennedy *et al.*, 1980, 1981; Baker *et al.*, 1985; Justus and Cardé, 2002).

The timescale over which the moths' reactions to pheromone strands and clean air occur is remarkably small. The behavioral responses to both the onset and loss of filaments can be as fast as 0.15 s (*Grapholita molesta*: Baker and Haynes, 1987), but usually are between 0.3 and 0.6 s (*Heliothis virescens*: Vickers and Baker, 1996, 1997; *Helicoverpa zea*: Quero *et al.*, 2001; and *Antheraea polyphemus*: Baker and Vogt, 1988). In studies of host-odor responses by flying female moths, only the latency of the casting flight response to loss of the odor has been measured, and its time course is similar to that of the latency for pheromone loss, 0.7 s (Haynes and Baker, 1989).

The speed of the reaction of moths to encounters with a pheromone strand or clean air pocket is not limited apparently by the speed of olfactory pathway processing; the same latency to a change in

movement occurs when visual cues related to wind-shift are experimentally generated instead of odor-loss cues (Baker and Vickers, 1994). The current evidence thus indicates that for responses to pheromone or host odor, the shape of the insect's flight track is determined by the frequency of encounters with filaments relative to encounters with pockets of clean air, and these encounters determine the relative proportions of upwind surging and casting, respectively (Baker, 1990; Kaissling and Kramer, 1990; Mafra-Neto and Cardé, 1994; Vickers and Baker, 1994; Kaissling 1997).

There is no evidence from other insect species in other orders that their in-flight response mechanisms to pheromone or other odors is different from that of moths. But further research examining the behavioral responses of other groups will be enlightening and essential to testing just how universally applicable these mechanisms are to insect odor-mediated flight.

6.12.3.2.5. Relevance of fast pheromone-strand reaction times to field attraction The rapid response to an odor filament is important because the strand has been shed from the odor source and, in higher velocity airflow, continues to travel in a more or less straight line away from the source (David *et al*., 1982; Elkinton and Cardé, 1987). This trajectory allows the responding insect to move in a straight line toward the source if it flies upwind when it smells the odor: the insect can locate the odor source by steering into and progressing upwind when it smells the correct odor. However, it is just as important for the insect to respond quickly to clean air as it is to an odor filament, because large-scale turbulence produces large swings in the wind direction that dictates along which lines the strands are flying away from the source (David *et al*., 1982). If the insect continues to move upwind into these wind-swing-produced large pockets of clean air for any length of time, it will more rapidly distance itself from the odor plume it has just lost contact with, as well as steer more off-line relative to the odor source (David *et al*., 1982; David and Kennedy, 1987; David and Birch, 1989; Baker, 1990).

A rapid cessation of upwind progress in response to odor loss, coupled with rapid and increasingly lengthy side-to-side oscillations in response to odor loss, allows the insect to increase its ability to regain contact quickly with the odor strands that have swung to one side or the other of its body. Because the insect has no way of telling to which side the odor has gone, this casting flight provides an unbiased response to one side of the wind line or the other in clean air, either of which could be the wrong side and result in failure to relocate the plume. The cessation of upwind progress during casting also prevents the insect from plunging too deeply and off-line from the source into a large pocket of clean air that is now moving off-line from the insect's previous toward-source line.

There is experimental evidence in which odor exposure to the insect or ground pattern movement is manipulated that odor-mediated optomotor anemotaxis is used by a variety of species besides Lepidoptera during odor-mediated upwind flight, including flies (*Drosophila*: David, 1982; *Tsetse*: Gibson and Brady, 1988, 1991). Similarities between male moths' reactions to gain and loss of sex pheromone odor and female moths' reactions to gain and loss of host volatile odor are striking (Haynes and Baker, 1989). Thus, knowledge about pheromone-mediated orientation mechanisms should help us better understand how to manipulate not only pheromone-mediated behavior of moths, but also odor-mediated behavior of male and female insects of all types, for better insect control.

6.12.3.3. Pheromone Blend Quality and Upwind Flight Behavior

The blend ratio of pheromone components for evoking optimal attraction and source contact by male insects is the one that most closely approximates the natural ratio emitted by females. Linn *et al*. (1986a) convincingly demonstrated for several species that males' behavioral thresholds for the optimal blend are lower than they are for partial blend compositions or suboptimal ratios. They also showed in the field that the optimal blend causes the initiation of upwind flight in more males from greater distances from the source than do blends comprised of suboptimal ratios or that from which some components are missing (Linn *et al*., 1986b), indicating that the threshold for upwind flight attraction to the optimal blend is lower than that for suboptimal or partial blends. As pointed out by Linn *et al*. (1986a, 1986b) and reiterated by Baker (1989b), these results showed that we must discard a previous view of how blends are used by males. The previous model proposed that there was a stepwise use by males during upwind flight of first one component in a female's blend when they are far downwind, and then two, three, and successively more components as they get closer to the source (Cardé *et al*., 1975; Nakamura, 1981; Bradshaw *et al*., 1983).

Recent studies have demonstrated that blend-quality reactions take place on a strand-by-strand basis, within fractions of a second. Vickers and Baker (1997) showed for *H. virescens* and Quero *et al*. (2001) using *H. zea*, that the duration and

length of males' upwind surging reactions to single strands of pheromone depend on their quality. Strands of the correct pheromone blend tainted with small amounts of heterospecific antagonist are poorer in intensity than are the surges to strands of the pure pheromone blend alone.

The blend of pheromone molecules must arrive simultaneously on the male's antenna, i.e., they must be perfectly blended in each strand, to have their optimal effect. This was demonstrated when male *H. virescens* were shown to be able to discriminate experimentally generated incompletely mixed strands of their major and minor pheromone components from strands that were completely mixed (Vickers and Baker, 1992). They can also discriminate experimentally generated strands of pheromone that are incompletely mixed with heterospecific antagonist from those in which each and every strand contains both antagonist and pheromone (Fadamiro and Baker, 1997; Baker *et al*., 1998a; Fadamiro *et al*., 1999a). This level of plume-strand quality temporal resolution was first suspected in other species using two natural and confluent plumes of pheromone and antagonist placed only tens of centimeters apart (Witzgall and Preisner, 1991; Liu and Haynes, 1992; Rumbo *et al*., 1993).

The propensity of insects to be attracted optimally to pheromone blends most closely approximating those emitted by the opposite sex is therefore attributable to their repeated strong surging reactions to individual strands. Thus, the higher quality surging that occurs in response to each strand of pheromone that is of optimal blend quality will, during repeated contact with natural strands in a pheromone plume, promote more sustained and intense upwind flight and displace a male farther upwind at a faster rate from greater distances downwind than will the surges in response to suboptimal blend strands. Presumably, the long-lasting casting response in a large pocket of clean air will also be of longer duration after contact with optimal blend-strands rather than suboptimal ones.

6.12.4. Pheromone Olfaction

6.12.4.1. Optimizing Flux Detection

It has become clear over the past 20 years that, as emphasized by Kaissling (1998), the insect olfactory system is designed to optimize flux detection and not to measure concentration. New understandings of the biochemical, neurophysiological, and molecular processes that contribute to the propagation of behavior after contact with airborne pheromone plumes show that the emphasis is on processing speed related to temporal resolution of the strand encounters. All the steps in the olfaction process work rapidly in succession to report pheromone strand encounters to higher centers (Vickers *et al*., 2001), from the biochemistry of transduction (see **Chapter 3.15**) to action potential propagation, to integration of the signal at the antennal lobe level, and finally to the output patterns sent to higher central nervous system (CNS) levels. Along at least some specialized pathways in this succession of synapses, the reporting of changes in flux is preserved and seems necessary to promote repeated neuronal excitation and quickly modulate behavior.

6.12.4.2. Elements of Pheromone Olfactory Pathways in Insects

The pheromone olfactory systems of insects are exemplified by that which exists in the Lepidoptera. Decades of research on moths has allowed knowledge about animal olfaction in general to be developed that rivals what is known in the vertebrates (Hildebrand and Shepard, 1997). Although the receptor organs used by different orders of insects to begin transducing pheromone molecules into action potentials vary in type, shape, and size (Kaissling, 1974, 1987; Steinbrecht, 1987, 1999), the integrative pheromone olfactory pathways after transduction that lead to motor output are strikingly similar to those in the Lepidoptera in the most well-studied groups such as cockroaches (e.g., Boeckh and Ernst, 1983; Boeckh *et al*., 1984). Thus, pheromone olfaction in the Lepidoptera at length to provide an overview of a typical insect pheromone olfaction system is discussed. A thorough review of all aspects of the pathways involved in insect olfaction is provided by many authors in Hansson (1999).

6.12.4.2.1. Olfactory receptor neurons and their perireceptor environments In the Lepidoptera, pheromone molecules in a plume-strand contact the thousands of extra-long receptor hairs (trichoid sensilla) on the antennae of male moths that are the primary pheromone receptor organs (Kaissling, 1974, 1987; Steinbrecht, 1987, 1999). In some families in the Coleoptera such as the Scarabaeidae, the pheromone-component-sensitive receptor neurons apparently reside in other types of olfactory receptor organs. The word "apparently" must be used here because it is virtually impossible to identify from which type of sensillum one is recording when using the tungsten-type electrodes that are requisite for recording from these tiny and often densely packed sensilla. For scolytid bark beetles, short trichoid or basiconic sensilla (short stubby hairs) have been implicated in sex pheromone reception (Dickens and Payne, 1978; Dickens, 1979). In

scarab beetles, coeloconic (pit-peg) and placoid (flat, plate-like) sensilla that are arrayed in various patterns on the lamellar hair surfaces are suspected to house the pheromone-sensitive receptor neurons (Mustaparta, 1984; Leal and Mchizuki, 1993; Kim and Leal, 2000; Ochieng *et al.*, 2002).

After landing on a hair's surface, the pheromone molecules enter the interior of the hair (or other types of sensilla in other groups) through pores and associated tubules and traverse a perireceptor gel comprised mainly of pheromone binding protein until they arrive at the membrane-bound pheromone receptor on the dendrite of an olfactory receptor neuron (ORN). Usually there are two, but sometimes three, pheromone-component-sensitive ORNs that are cocompartmentalized within one sensillum. For a thorough review of the biochemical events involving binding proteins, pheromone degrading enzymes, and the receptors themselves (see **Chapter 3.15**). A depolarization of the dendritic membrane of the ORN results if the pheromone component molecule has the correct geometry and electron distribution due to various double bonds and functional groups (e.g., acetate, alcohol, aldehyde, or ketone) to allow it to fit optimally into the protein pocket that is the receptor.

It is a point of debate as to whether the binding-protein-plus-pheromone-component molecule complex or the pheromone-component molecule itself binds to the "pheromone receptor" (see **Chapter 3.15**). A G protein coupled system cascade results in ion channel changes that result in dendritic depolarization and action potential generation down the axon to the brain.

This process is occurring simultaneously in the receptor hairs that contain ORNs that are specifically tuned to the other components of the pheromone blend. Often, as in the Tortricidae, the ORNs tuned to the minor pheromone components reside in the same hairs as those tuned to the major component (Akers and O'Connell, 1988). The minor components arrive on the antenna in the same plume-strands as the major component, and the pheromone components blended in each strand at particular ratios are immediately transduced to action potentials by their respective, component specifically tuned ORNs. The blend composition in each strand is therefore broken down into its component parts and the composition reported to neurons farther down the line by the differential activities of the different types of ORNs responding selectively to their own optimal ligands (Todd and Baker, 1999). The process is remarkable in that the across-antennal response of differentially tuned ORNs to each odor strand is basically a split-second gas chromatographic readout of the odor strand composition that is repeated two or three or more times a second as long as the insect remains in contact with the plume (Vickers *et al.*, 2001).

The differential responsiveness of the ORNs to compounds is imparted by the peculiar receptor site proteins on the dendrites and perhaps even by the selectivities of binding proteins that bathe the ORNs as a gel (Stengl *et al.*, 1999) (see **Chapter 3.15**). The result is that the ORNs respond optimally only to the molecules in the blend to which they are differentially tuned (and also to which the binding protein binds and delivers to the ORN's dendrite), even though the complete blend of compounds has adhered to and possibly entered the hair lumen with its own binding protein milieu. The abundance of each pheromone component in each strand is thus first represented in the relative activities of the neurons specifically tuned to them. The action-potential activities of these thousands of neurons responding to their specific portion of the two- or three-component blend then stream down in separate lines, apparently without cross-communication with other axons in the antennal nerve, to finally arrive at the macroglomerular complex (MGC) in the antennal lobe located at the base of the antenna (Matsumoto and Hildebrand, 1981; Christensen and Hildebrand, 1988; Christensen, 1989; Hildebrand and Shepard, 1997; Hansson and Christensen, 1999).

6.12.4.2.2. Glomeruli in the MGC The MGC comprises varying numbers of glomeruli, which are knots of neuropil made up primarily of axonal branches from antennal sensory neurons but also the fibers and arborizations of interneurons that synapse with them and with each other. The MGC is found only in males and receives information exclusively from sex-pheromone-sensitive antennal neurons (Matsumoto and Hildebrand, 1981; Boeckh and Ernst, 1983; Boeckh *et al.*, 1984; Hildebrand and Shepard, 1997). Antennal neurons that respond to plant- and flower-derived compounds terminate in what are termed ordinary glomeruli located more ventrally in the antennal lobes of both males and females (Hansson, 1995; Hildebrand and Shepard, 1997; Anton and Homberg, 1999; Hansson and Christensen, 1999).

Studies by Hansson *et al.* (1992) using activity-dependent uptake of cobalt to stain ORNs and following them to the MGC revealed that each MGC subcompartment in the antennal lobe of the turnip moth, *Agrotis segetum*, exclusively handles incoming information from the antenna about only one pheromone component or a known behavioral antagonist. Earlier, proof that there is an orderly and

reliable position of ordinary glomeruli in the insect brain from individual to individual was known from anatomical work on a moth and butterfly species (Rospars, 1983). However, it was the discovery that there are functionally, as well as spatially, distinct MGC subcompartments that receive pheromone-component-specific information from the antennal ORNs that was a breakthrough for understanding animal olfactory processing (Hansson *et al.*, 1991, 1992). Results using cobalt staining of ORNs on other moth species mirrored those of Hansson *et al.* (1992), Berg *et al.* (1995), Christensen *et al.* (1995a), Ochieng *et al.* (1995), Todd *et al.* (1995); review: Hansson *et al.* (1995).

Using a new technique involving calcium-sensitive dye developed by Galizia and colleagues for the honeybee, *Apis mellifera* (Galizia *et al.*, 1997, 1998, 1999; Sachse *et al.*, 1999) allowed for the dramatic visualization of the activities of populations of whole populations of lepidopteran ORNs projecting their pheromone-component-specific excitations to their target glomeruli (Galizia *et al.*, 2000; Carlsson *et al.*, 2002; Carlsson and Hansson, 2003). These studies confirmed, on an ORN population-wide stimulation basis, the results of cobalt staining of individual ORNs that showed projections of physiologically identified ORNs tuned to one pheromone component or antagonist projecting to a single glomerulus in the MGC. The interpretation of the calcium dye excitation as being due mostly to the predominance of signal being provided by calcium released in the glomeruli from the cholinergic ORN terminals was at first a matter of debate. But the correspondence of target glomeruli from calcium dye visualization (Galizia *et al.*, 2000; Carlsson and Hansson, 2003) with the target glomeruli to which individual cobalt-stained ORNs had been shown to project to (Ochieng *et al.*, 1995; Berg *et al.*, 1998) was confirmed.

The complete blend of odor in each pheromone plume-strand is represented by a particular balance of neuronal activity across the glomerular subcompartments of the MGC. Early researchers in olfaction and taste studies realized that odor quality discrimination must result from the ratios of activity being weighed across the many different types of receptor neurons (Boeckh, 1967), a phenomenon called "across-fiber patterning" (Dethier, 1972). With recent advances, we can, however, now understand that across-fiber patterning can be considered to be an across-glomerular pattern (Galizia *et al.*, 1998), as anticipated by Rospars (1983).

6.12.4.2.3. Across-glomerular pattern enhancement by local interneurons in the MGC The across-glomerular pattern of relative intensities is initially enhanced by the activities of the first level of interneurons that reach into these glomerular pools of pure, component-specific ORN activity. These first interneurons are called "local" interneurons (Matsumoto and Hildebrand, 1981; Boeckh and Ernst, 1983; Anton and Hansson, 1999; Anton and Homberg, 1999; Hansson and Christensen, 1999) because they spread locally across the antennal lobe like a net, sending no axons out of the antennal lobe. They interconnect the glomerular subcompartments within the MGC and also to ordinary glomeruli receiving input from ORNs about nonpheromone-related volatiles (Matsumoto and Hildebrand, 1981; Anton and Homberg, 1999).

The integrative, discrimination-enhancing ability of local interneurons is indicated by the fact that for most of them, their neurotransmitter is γ-aminobutyric acid (GABA), which imparts inhibition on neurons upon which they synapse (Anton and Homberg, 1999). A greater acetylcholinergic excitation of a local interneuron by antennal ORN synapses in one component-specific glomerulus will therefore impart a greater amount of GABA-ergic inhibition that spreads to the other, neighboring subcompartments (Anton and Homberg, 1999).

Research on the American cockroach (*Periplaneta americana*) MGC synaptic interconnections clearly indicates that inhibition also apparently can be imposed by local interneuron fibers onto the incoming signals from ORN axons, as well as onto projection interneurons and to other local interneurons within one glomerulus (Distler and Boeckh, 1996, 1997a, 1997b; Anton and Homberg, 1999). Whatever pattern across glomeruli that would have occurred due to the inputs to the antennal lobe glomeruli from the ORNs responding to the blend components might now be enhanced by lateral inhibition imparted by these local interneurons (Christensen *et al.*, 1993). Interestingly, the various local interneuron synapses occurring within and between glomeruli might result in some excitation exiting the antennal lobe via projection interneurons due to local interneuron-imposed disinhibition of previously inhibited interneurons (Christensen *et al.*, 1993, 1998a, 1998b; Anton and Homberg, 1999). The glomeruli from which excitatory projection interneuron output emerges can also apparently be shifted by the inhibitory–disinhibitory activities of local interneurons so that the output locations do not necessarily correspond to the input locations of ORNs (Anton and Hansson, 1994, 1999).

6.12.4.2.4. MGC projection interneurons In the male moth (and other insects), pheromone odor

blend information emerges from the MGC and travels downstream to locations deeper in the brain through a very small number of interneurons (Boeckh *et al.*, 1984). These are called projection interneurons, because they project out of the MGC and arborize with interneurons in higher brain centers. Unlike local interneurons, projection interneurons usually arborize only in one or a limited number of subcompartments in the MGC and generally travel to the far back of the brain where they synapse with neurons in the mushroom body (Christensen, 1989; Hildebrand and Shepard, 1997; Hansson and Christensen, 1999) before continuing on to synapse with other neurons in the extreme lateral portion of the protocerebrum. Protocerebral interneurons themselves can respond in enhanced manner to optimal blends (Kanzaki *et al.*, 1991; Kanzaki and Shibuya, 1992).

The interneuronal level in the MGC at which blends have been shown most frequently to be uniquely responded to is at the projection interneuron level (but see below how mixture interactions of ORNs might confound these interpretations). However, there are many projection interneurons that respond only when a particular individual component is present, regardless of whether it is part of a blend (Christensen, 1989; Christensen *et al.*, 1991, 1995b, 1996; Hansson *et al.*, 1991; Hildebrand and Shepard, 1997; Hansson and Christensen, 1999; Vickers and Christensen, 2003). But then again there are even slight differences in pheromone blend ratio, not just composition, that are responded to selectively by blend-sensitive interneurons within the antennal lobe (Wu *et al.*, 1996).

Blend-integrating responses carried by projection interneurons are known to be of at least two different types. One type involves an increased initial spike frequency plus a long-lasting excitation that occurs in response only to the presence of a blend of two components on the antenna and not to each component presented individually. Such blend-dependent excitation responses have now been discovered in antennal lobe interneurons of several species of moths, including *Manduca sexta*, *H. virescens*, and *H. zea* (Christensen, 1989; Christensen *et al.*, 1991; Hansson *et al.*, 1991; Berg *et al.*, 1998; Hansson and Christensen, 1999).

However, another very important type of blend-integrating response also is known from *M. sexta* and other moths, in which the presence of the blend on the antenna sharpens the onset and offset of the train of spikes emerging from these interneurons, resulting in a more highly phasic burst than would otherwise occur in response to either component alone. The temporal sharpening occurs due to a combination of inhibition from neuronal elements responding to one of the two pheromone components and excitation from those responding to the other (Christensen and Hildebrand, 1988; Christensen, 1989; Christensen *et al.*, 1991, 1998a, 1998b). This suggests that the blend uniquely sharpens the time courses of the plume-strand related successive trains of action potentials streaming toward the mushroom body and lateral protocerebrum. Thus two different types of blend-integrating information, based on the temporal aspects of the response – either highly phasic-sharpened, or more long-lasting and tonic – travel out through the projection interneurons to the brain.

As discussed above, it is just as behaviorally important for males to respond to the pockets of clean air between pheromone filaments as to the pheromone filaments themselves because clean wind no longer points toward the source, and the moth continuing upwind for too long upon flying into clean wind can find itself flying off-line from the source. The interneuronal pathways in the insect pheromone olfaction system do seem to provide ample ways to integrate and send highly phasic information related to pheromone filament contact all the way through to higher centers (Christensen and Hildebrand, 1988; Anton and Homberg, 1999; Vickers *et al.*, 2001; Vickers and Christensen, 2003). Therefore, the need to quickly turn off the excitation caused by a plume-strand to allow a male to change its behavior at the first hint of clean air is reflected in the highly irregular, plume-filament correlated responses of interneurons in the MGC of the antennal lobe when placed in natural pheromone plumes (Vickers *et al.*, 2001).

6.12.4.2.5. Mushroom body–antennal lobe-derived oscillations There is also evidence that inhibitory feedback loops between the mushroom body and the antennal lobe can cause oscillations to occur that may impose repetitive and very short time-windows within which the ratios of activities within glomeruli can be most accurately reported by the integrative circuits out of which projection interneuron excitation occurs (Laurent, 1996; Laurent *et al.*, 1996; Stopfer *et al.*, 1997, 1999). These oscillations have been demonstrated to facilitate discrimination of odor blend quality in the honeybee (Stopfer *et al.*, 1997).

6.12.4.2.6. Protocerebral interneuron activity The blend integration already occurring in the MGC does not mean that the sensation of blend cannot also be promoted by integration farther downstream by protocerebral interneurons (Kanzaki *et al.*, 1991; Kanzaki and Shibuya, 1992), or even by descending interneurons, which could weigh the

ratios of activity of component-specific projection interneurons and also integrate them with other inputs such as visual flow-field information (Olberg and Willis, 1990). Because ORNs are now known to be capable of responding to blends either through mixture suppression (Nikonov and Leal, 2002) (see Section 6.12.4.4) or mixture enhancement (O'Connell *et al*., 1986; Ochieng *et al*., 2002), the possibility cannot be ruled out that at least a portion of what seem to be blend-sensitive projection interneurons may merely be those same interneurons relaying an ORN-derived mixture response that originated farther upstream at the antennal level.

6.12.4.3. Pheromone-Sensitive ORNs as High-Fidelity Reporters of Plume-Strand Encounters

Based on the need for fast behavioral reaction times to individual strands of pheromone and pockets of clean air between the strands, the peripheral olfactory receptor neurons of flying insects should be built to report information to the brain about the odor blend such that it can rapidly discriminate odor quality on a strand-by-strand basis. At least some populations of ORNs, therefore, should be built to very rapidly detect and respond to the onset of each odor strand, and interneurons in the antennal lobe farther downstream should preserve and even enhance the reporting of the temporal aspects of the signal so as to be able to report this information to higher centers and then to motor neurons. But there also should be some kind of long-lasting response in the olfactory pathways that persists for many seconds after an encounter with a pheromone strand to promote sustained casting flight in clean air that will optimize an insect's chances of bridging the long clean-air gaps between odor strands that occur during large, sudden swings in wind direction. Another function of the fast response time of the ORNs would be to report sufficiently fine-grained information that the insect can discriminate a plume in which every filament contains a complete blend of odor from one in which the blend is partitioned into separate filaments (Baker *et al*., 1998a; Todd and Baker, 1999).

6.12.4.3.1. Importance of fast-phasic response for reporting changes in flux Insect sensory physiologists early on noted the phasic–tonic nature of the time course of typical ORN-generated action potential spike trains after stimulation with pheromone components (Kaissling, 1974, 1986, 1987). The phasic–tonic profile is characterized by the first portion of action potential output being a sharp burst that is shorter than, and does not correlate with, the longer-lasting stimulus (Kaissling, 1974, 1986, 1987). The remainder of the response is a tonic, residual low level of above-background firing that may not mirror the stimulus, especially at the highest dosages. The lack of correspondence of both the phasic and tonic portions of the receptor response have been shown not to be artifacts resulting from the techniques used to deliver the odorants (Kaissling, 1987).

Pheromone-sensitive ORNs do, however, display a wide variation in the phasic or tonic elements of their responses to pheromone components (Kaissling, 1974, 1986, 1987; Almaas *et al*., 1991; Berg *et al*., 1995; Berg and Mustaparta, 1995). There are examples of both highly phasic and highly tonic ORNs in the same species. For example, Berg *et al*. (1995) found that the receptors on male *H. virescens* antennae that were sensitive to (*Z*)-9-tetradecenal (*Z*9-14:Ald) responded in a more phasic manner than those sensitive to (*Z*)-11-tetradecenal (*Z*11-14:Ald). Rumbo (1983) and Rumbo and Kaissling (1989) found differences in the durations of response of antennal neurons tuned to different components of the sex pheromones of the light brown apple moth, *Epiphyas postvittana*, and *A. polyphemus*, respectively. The differences were usually related to the type of ORN, with the ORN tuned to the major component being the more phasic, and the ORN tuned to one of the minor components firing more tonically.

The propensity of insect olfactory receptor neurons to fire in a phasic versus a tonic pattern is related to their relative rates of adaptation and disadaptation (Kaissling, 1987). In general, phasic neurons are fast to disadapt and are able to track (respond to) the presence of pheromone that is repeatedly and rapidly pulsed at 10 Hz (Almaas *et al*., 1991) or even more than twice that (Bau *et al*., 2002). More tonically firing neurons are slower to disadapt, sometimes taking minutes or tens of minutes to do so, and cannot respond to a new pulse of pheromone during this time (Rumbo, 1983; Rumbo and Kaissling, 1989). Even for fast adapting–disadapting receptor neurons, disadaptation is not necessarily absolute, and the tracking response to rapidly repeated stimuli does not report accurate information about the concentration. The number of action potentials in response to each pulse, reflecting the concentration of odorant in each pulse, is significantly reduced under rapid stimulation, but the fidelity of response with regard to the temporal presence or absence of the pheromone is accurate. Thus, the sensitivity of a receptor unit in response to an odorant is not absolute and is subject to adaptation–disadaptation mechanics (Kaissling, 1986,

1987; Kaissling and Kramer, 1990). As emphasized by Kaissling (1998), it is the change in flux, which has a temporal element, and not concentration, which does not, that ORNs are specialized to report.

Contact with the strands of odorant within a natural plume is on a highly irregular basis in time, as shown both from the work of Murlis (1986, 1997) by using an idealized receptor (ion detector) and odor mimic (ionized air) as well as from the recordings of real odor plumes in the field and laboratory by using insect antennae or their ORNs as detectors (Baker *et al*., 1988; Haynes and Baker, 1989; Hansson and Baker, 1991; Vickers and Baker, 1994; Willis *et al*., 1994; Vickers *et al*., 2001; Bau *et al*., 2002). The adaptation–disadaption characteristics of receptors are concentration- and time-dependent (Kaissling, 1986, 1987; Almaas *et al*., 1991; Hansson and Baker, 1991; Berg *et al*., 1995), and these two aspects affect receptors' abilities to report to the CNS the presence of all of the strands of odorant that are contacted in a natural plume.

Murlis (1986, 1997) emphasized that a form of temporal averaging of the fine structure of an odor plume would occur when two equally concentrated strands contact the receptor too rapidly, resulting in the second strand evoking no action potentials from the already adapted ORN that had not recovered from responding to the first strand. Alternately, contact with a low-concentration strand could follow a high-concentration strand after an appropriately long time interval, but due to adaptation from the highly concentrated first strand, again evoke no action potentials. The adaptation–disadaptation related propensity of the ORN to adjust to both concentration and frequency thus ensures that the CNS receives high-fidelity inputs concerning plume-strand arrival over a wide dynamic range in turbulence-induced plume structures and reports them to higher centers (Vickers *et al*., 2001). The integrative mechanisms in the CNS (e.g., for odor-quality discrimination and enhancement of phasic inputs) (Christensen and Hildebrand, 1988; Christensen, 1989) thus is buffered from outside variance in the plume, and behavioral response likewise attains a higher fidelity over such wide-ranging differences in plume-strand flux.

Limits in the dynamic range of one type of pheromone-component-specific ORN to report the arrival of strands containing the component to which it is tuned compared with the capabilities of others tuned to other components has been shown to be important in natural pheromone plumes and has been correlated with changes in behavior (Baker *et al*., 1988; Hansson and Baker, 1991). Excessive concentrations of the three-component pheromone blend of *A. segetum* were shown to differentially impair the ability of only the (*Z*)-5-dodecenyl acetate (*Z*5-10:Ac) receptor neurons to disadapt and fire in response to repeated contact with filaments in a natural plume (Baker *et al*., 1988; Hansson and Baker, 1991). The competencies of neurons tuned to both *Z*7-12:Ac and *Z*9-14:Ac to fire in this very same plume were completely unaffected. Thus, the excessive plume concentration caused a distorted ratio of firing from the three receptor types, with now only two types firing when there should have been three. The responses of all three neuronal types to either a 10- or 100-fold lower pheromone-source loading were correlated with high levels of completed upwind flights to the source. Both *Z*7-12:Ac and *Z*9-14:Ac would be emitted at lower concentrations than *Z*5-10:Ac due to their lower volatility, and this would explain in part the ability of the receptors tuned to these two components to avoid becoming adapted to the very same frequency of filament contacts that produced adaptation of the *Z*5-10:Ac-tuned neuron (Hansson and Baker, 1991).

The importance of a phasic reporting of stimulus arrival by ORNs to the promotion of sustained upwind movement was further emphasized in experiments that directly manipulated the outputs of ORNs (Kaissling *et al*., 1989; Kramer, 1992). Kaissling *et al*. (1989) found that a hydrocarbon mimic of bombykol, the pheromone of the silkworm, *Bombyx mori*, caused highly tonic firing of the antennal receptor neurons tuned to bombykol that lasted several minutes, and that this tonic response was correlated with no upwind walking toward the source. Kaissling *et al*. (1989) then found that the plant-related compound linalool effectively hyperpolarized this neuron and prevented action potentials from occurring whenever it was puffed over the sensilla. When Kaissling *et al*. (1989) first stimulated the receptor neurons with the pheromone analog to induce high levels of tonic firing, and then interrupted the firing with intermittent puffs of linalool, they could create repeated, regular bursts of firing from the bombykol neurons that was indistinguishable from repeated puffs of bombykol itself. They reasoned that this highly artificial stimulus that does not contain the pheromone but mimics a reiterative pattern of phasic reporting of pheromone stimulation from the pheromone-sensitive neuron should be a behaviorally effective stimulus that should result in upwind walking by intact male moths. Kramer (1992) found that was indeed the case. High levels of upwind walking to the source occurred in response to this

unnatural stimulus and not to the uninterrupted tonic stimulus.

6.12.4.4. Mixture Interactions between ORNs Cocompartmentalized within Sensilla

There has been emerging evidence in recent years that insects can discriminate between two overlapping odor plumes due to the incomplete mixing of their intertwined strands (Witzgall and Preisner, 1991; Liu and Haynes, 1992; Vickers and Baker, 1992; Rumbo *et al.*, 1993; Baker *et al.*, 1998a). Wind-tunnel bioassays using experimentally generated, pulsed plumes have demonstrated that two pheromone-related odorants are not as effective when they are presented in staggered manner (in every other pulse) compared with when they are coincident in every pulse (Vickers and Baker, 1992; Fadamiro and Baker, 1997). *Helicoverpa zea* males demonstrate a startling ability to distinguish completely coincident strands of pheromone and heterospecific antagonist from those whose strands are separated by only 1 mm (Baker *et al.*, 1998a; Fadamiro *et al.*, 1999a). Baker *et al.* (1998a) and Todd and Baker (1999) pointed out that cocompartmentalization of the ORNs that are differentially tuned to these odorants (Cossé *et al.*, 1998) should optimize both the spatial and the temporal odor quality resolution ability of the animal and that on-site processing of mixtures within each sensillum would be the most likely mechanism to explain this high resolution of odor strand arrival.

Neurophysiological support for this hypothesis comes from a recent report by Nikonov and Leal (2002) in which the firing of pheromone-component-sensitive ORNs on the antennae of the Japanese beetle, *Popillia japonica*, was shown to be suppressed when a known behavioral antagonist was puffed in a perfect mixture simultaneously from a single odor cartridge across the antenna. They recorded from sensilla that always house two cocompartmentalized ORNs, one being tuned to the pheromone component and the other tuned to the antagonist (the opposite enantiomer of the pheromone component). Mixture suppression of firing by the pheromone component sensitive ORN was not observed, however, when the "mixture" of the two enantiomers consisted of simultaneous puffs from two different pipettes separated by only 1–2 mm, creating a time lag of only 1.5–3 ms (Nikonov and Leal, 2002). On-site processing of the mixture was thus found to occur in the Japanese beetle sex pheromone olfaction system and would result in reduced reporting of strands of odor containing both pheromone and antagonist to the antennal lobe.

Pheromone component sensitive ORNs on *H. zea* antennae exhibit distinct and significant responses to blends of the pheromone component mixed with certain plant volatiles (Ochieng and Baker, 2002). These plant volatiles mixed with the major *H. zea* pheromone component, (*Z*)-11-hexadecenal, enhance firing frequency during the phasic as well as tonic portions of the response of ORNs tuned to this component (Ochieng and Baker, 2002). The simultaneous arrival of the two odorants is necessary for the mixture-enhanced firing to occur (Ochieng and Baker, unpublished data). These results suggested the possibility that males' behavioral sensitivity and upwind flight response to pheromone might be elevated by the coemission of certain plant volatiles with the pheromone (Ochieng and Baker, 2002). However, a wide range of plant-related compounds as well as pheromone-related compounds mixed with (*Z*)-11-hexadenal are able to enhance firing of this ORN (Ochieng and Baker, unpublished data), and so it is unclear what role such an unspecific mixture response could play in the real world.

Until recently, little attention has been paid to the possibility of mixture interactions occurring at the ORN level, even with regard to their responses to combinations of sex pheromone components that are known to be behaviorally agonistic (O'Connell *et al.*, 1986; Akers and O'Connell, 1988). Likewise, a few sensory physiological studies have involved pheromone sensitive ORN responses to mixtures of pheromones and plant volatiles (Van der Pers and Den Otter, 1978; Van der Pers *et al.*, 1980). The knowledge that enhanced firing can occur on-site by primary olfactory receptor neurons in response to mixtures should provide a note of caution to researchers working at the antennal lobe level. It can no longer automatically be concluded that mixture interactions recorded from projection neurons are due entirely to blend integration occurring within the antennal lobe. Many of these "blend sensititive" interneurons may be merely relaying to higher centers the unprocessed, blend-enhanced activity that has already taken place far upstream, within the sensilla on the antennae (Todd and Baker, 1999).

6.12.4.5. Background Noise and Resolution of Odor Strands in Overlapping Plumes

Under natural field conditions, strands of pheromone are transported in air masses that are comprised also of complex mixtures of other volatile chemicals, including those originating from surrounding vegetation. Plant-related volatiles are an integral part of the pheromone systems of the majority of

beetle species that have been investigated thus far (Byers, 1995; Bartelt, 1999a, 1999b; Leal, 1999) (see Section 6.12.2.3). Also, plant-derived volatiles are used in the courtship pheromones of moths (Birch *et al.*, 1990; Landolt and Philips, 1997). The question of how mixtures of pheromone components or plant volatiles are reported by ORNs to higher centers is of increasing importance to understanding how insects' olfactory systems can discriminate pheromone plus plant odor plume strands and respond behaviorally to natural pheromone blend signals.

In moths, a few field-trapping studies have demonstrated that certain groups of plant volatiles added to sex pheromone can increase the capture of males, including *H. zea*, in sticky traps (Dickens *et al.*, 1990; Light *et al.*, 1993). However, it is not clear whether the enhancement of male attraction to the traps was due to separate enhanced responses of male moths to either the sex pheromone or the plant volatile portion, or to a response to the total blend that may in its entirety represent a unique odor quality.

The behavioral and evolutionary implications of fine-grained spatiotemporal resolution of odor strands first of all with respect to pheromone-related compounds such as pheromone components emitted by nonconspecific females that antagonize upwind flight have been considered (Baker *et al.*, 1998a; Fadamiro *et al.*, 1999a; Todd and Baker, 1999). Strands of heterospecific antagonistic pheromone components should antagonize upwind flight only if they occur as a complete mixture with conspecific pheromone in each and every strand, which would indicate that the strands originated from a single point source, i.e., a nonconspecific female. They should not be as effective in antagonizing upwind flight if they are not perfectly admixed in every filament, with some filaments containing only pure pheromone, others containing antagonist as well. But what about strands of plant volatiles, or more uniform clouds of plant volatile background odor?

If certain plant volatiles do play a role in modulating responses of males to female-emitted pheromone, it is not so clear what the olfactory system would be doing to optimize these responses. Plant odors in the field would seem to be ubiquitous and serve as a rather tonic fog of average chemical "noise" in which pheromone strands in a plume would travel and be detected by the male ORNs. However, there are many ways in which stronger point sources of plant volatiles can occur, the most obvious being flowers, fruits, and seeds (also corn silk) as strong point source plume generators. Other strong point sources can be generated by direct larval insect feeding damage to leaves (Turlings *et al.*, 1995; Alborn *et al.*, 1997; De Moraes *et al.*, 1998), and still other strong sources can be entire plants that have been induced to produce bursts of volatiles over the their entire surface by the systemic effect of insect saliva "elicitors" on the plants' biochemical machinery (Turlings *et al.*, 1995; Alborn *et al.*, 1997; De Moraes *et al.*, 1998).

There are many ways that any of these point source plumes of plant volatiles could be mixed with strands of pheromone from an adult insect. Some of these situations would see pheromone-plus-plant volatiles issuing as fully mixed strands from relatively strong point sources such as from bark beetle gallery holes, or from weevil feeding-wounding (J.J. Heath *et al.*, unpublished data). It would seem that the simultaneous emission of plant volatiles and pheromone from small, adult-generated point sources corresponds with the enhanced pheromone-plant-volatile attraction seen in the majority of studies of species of Scolytidae and Curculionidae. With moths, it is not as clear that there can be many situations where females can generate fully mixed strands of pheromone and plant volatiles from a small point source. One major difficulty here is that for most species in nature we do not know where females go to call. We do know that they will call from almost any surface, natural or unnatural, and in the presence of plant odors as well as in their absence. With no strong requirement having been observed for female moth calling in the presence of plant volatiles, it makes sense that only a very few studies have shown a significant enhancement of male attraction to pheromones by adding plant volatiles.

In natural situations, regardless of whether the calling female is sitting directly on a flower, fruit, or damaged leaf, it seems unlikely that perfectly mixed strands of pheromone plus plant volatiles having the same temporal flux dynamics will arrive simultaneously on males' antennae. Thus, it is questionable as to whether there is the same need in moths for fine-grained resolution of plant odor and pheromone odor strands as there might be in the Coleoptera, where plant-odor–pheromone mixture enhanced attraction is prevalent and strong point sources emitting plant volatiles plus pheromone are prevalent. But the tolerances of olfactory systems and behavioral responses for synchronous versus asynchronous plant-odor-plus-pheromone plume-strand arrival in different species' communication systems have not been explored. In future neuroethological studies of insect pheromone–plant-volatile mixture interactions, attention needs to be paid to the fine-grained resolution of odor strands and the natural plant-plus-pheromone odor

plume generation occurring for each species to understand how these communication systems may have been evolutionarily shaped.

6.12.4.6. Malleability of Receptor Tuning in Evolution of Sex Pheromones

That the relative abundance of differentially tuned ORNs on insect antennae can change over time is graphically illustrated by the findings of George and Nagy (1984), who found that after 20 years of rearing the same culture of oriental fruit moth, the number of sensilla trichodea housing pheromone ORNs on male antennae decreased to one-half of the original, wild-type number. In the noctuid moth species *A. segetum*, over a wide geographic range encompassing Europe and Africa, variation in the ratios of pheromone components emitted by females from different regions is mirrored by the ORN system of males (Löfstedt *et al.*, 1986; Hansson *et al.*, 1990). In *A. segetum*, the proportional abundance of ORNs tuned to *Z*5-10:Ac, *Z*7-12:Ac, and *Z*9-14:Ac is at least coarsely directly proportional to the proportions of these compounds found in gland extracts of females (Löfstedt *et al.*, 1986; Hansson *et al.*, 1990; Löfstedt, 1990). If the vapor pressures of the components were to be considered as well, the degree of correspondence between emitted proportions of components and the proportion of ORNs tuned to these components would certainly be even more highly correlated. Thus, there seems to be a good degree of ability of the ORNs of moths that are tuned to different components to change their abundance on insect antennae fairly quickly in ecological time. There is also evidence that ORN response profiles can be modified by factors from the brain, as suggested by the cross-species antennal transplant studies of Ochieng *et al.* (2003).

How this malleability is accomplished across a population of differentially tuned ORNs on antennae is unclear, but mutations in some insect olfactory communication systems have provided some insight. Mutations in the ORNs of *Drosophila* have been correlated with changes in olfactory mediated behavior (Carlson, 1996; deBryune *et al.*, 1997). These results and others in the area of the neurogenetics of olfaction are discussed thoroughly in the recent review chapter by Stocker and Rodriguez (1999). The *Drosophila* findings show that mutations affecting an ORN can involve the silencing of the ORN, in addition to the altering of the response spectra of other neurons (deBryune *et al.*, 1997). The changes in ORN response profiles were discovered after behavioral evidence in the mutants indicated that significant olfactory changes must have occurred.

Recently, it has been hypothesized that major shifts in moth pheromone blends might occur when previously unexpressed genes controlling pheromone component double bond position become expressed in some females in a population (Roelofs *et al.*, 2002). The new, altered blend might be attractive to a very few males in the population that have the capability of responding to both this new blend and the old blend, and through a process of asymmetric tracking over generations by males (Phelan, 1997), a new population of males and females communicating with this new blend would be formed (Baker, 2002; Roelofs *et al.*, 2002; Roelofs and Rooney, 2003). The degree to which pheromone-sensitive ORNs would be able to shift their tuning properties to correspond to and track, over generations, the new pheromone components is - important for such a shift in pheromone blend communication to occur.

It does seem that in some moth species that, compared with the rest of the species in their group, use unusual pheromone components (Löfstedt *et al.*, 1991; Löfstedt, 1993), the male pheromone-sensitive ORNs display correspondingly unusual response spectra (Löfstedt *et al.*, 1990). The examination of pheromone-sensitive ORN tuning properties within species as it relates to the ability to potentially accept odd pheromone molecules should be informative in future studies after the exciting findings of Roelofs *et al.* (2002). The degree to which pheromone blends can suddenly shift via expression of pseudogenes (Roelofs *et al.*, 2002) followed by asymmetric tracking by responding males (Phelan, 1997) can be first ascertained by studying the variation in pheromone-sensitive ORN tuning curves within, and then between, two or more targeted species within a group (Löfstedt *et al.*, 1990). Attention also needs to be paid to ORNs that are responsive to heterospecific antagonists, because these are the ones that may be involved in completing the asymmetric tracking process by preventing the continued attraction of broadly tuned males to females of the parent population over generations (Baker, 2002).

6.12.5. Use of Pheromones in Insect Control

6.12.5.1. Monitoring Established Populations

The most widespread and nearly ubiquitous use of pheromones has been for the monitoring of pest species' adult populations. Comprehensive IPM programs that were initiated in New York State and Michigan during the early 1970s were based

on good, species-specific monitoring traps for the complex of tortricid moth pests that impose direct and indirect damage to fruit. Tree fruit IPM was impacted positively, resulting in elimination of prophylactic calendar-date spray schedules and the introduction of timed applications of short-residual insecticides. During the mid-1970s to late 1980s, insecticide applications were reduced by more than 50% in New York State, Michigan, and the Pacific Northwest due to monitoring programs that improved decision-making about the need to spray insecticides (Madsen, 1981) as well as their timing. Such programs have become even more refined over the years, with concomitant further reductions in insecticide applications being documented (Agnello *et al*., 1994).

Monitoring of leafroller pests coupled with computer assisted degree-day models (Riedl and Croft, 1974; Riedl *et al*., 1976) allowed sprays to be timed for optimum efficacy against eggs and first instars on such key pests as the codling moth, *Cydia pomonella*, and oriental fruit moth. Spray-or-no-spray decisions based on abundance of adults in monitoring trap grids were also made possible by effective, standardized monitoring traps and deployment schemes developed against some pests such as the codling moth (Madsen, 1981). On other crops in the United States as well as around the world, pheromone monitoring traps have asserted themselves into IPM programs as essential elements to the success of these programs. Their use is such an integral and accepted part of IPM that we do not further review their use.

6.12.5.2. Detection and Survey Programs for "Exotic" Pests

Whereas we usually think of exotic pest species as being those originating from overseas, oftentimes the more distinct threat to agricultural crops comes from immigrating populations from one geographic area within a country into a different location. Pheromone traps have played a large role in detecting influxes of adult pest species from one region to another and also even from noncrop areas into crop areas. Survey programs involving grids of pheromone traps are used so routinely to report and track the yearly arrival of migrating adult populations of insects such as the black cutworm, *Agrotis ipsilon*, in the Midwest (Showers *et al*., 1989a, 1989b) or the spread of expanding populations such as the gypsy moth (Elkinton and Cardé, 1981) that it has become an essential part of our arsenal of tools for tracking and ameliorating pest movement related threats. A few examples of how pheromone trapping survey-detection systems have provided essential information that has aided in the suppression of migrating or expanding populations are reviewed.

6.12.5.2.1. Pink bollworm The pink bollworm, *Pectinophora gossypiella*, is a key worldwide pest of cotton. In the southern California desert valleys and in Mexico, its presence has altered IPM schemes since the 1960s, necessitating the application of 10–15 extra insecticide sprays per hectare per season. In the San Joaquin (Central) Valley in California, growers do not have to apply insecticides against this pest because it is not endemic, and therefore they enjoy much greater profit than their southern California counterparts. Indeed, many have attributed the near complete demise of cotton agriculture in southern California over the past two decades to the presence of the pink bollworm. The pink bollworm has not yet become established in the San Joaquin Valley, in large part due to an intensive grid of detection-survey traps that is deployed every year in a program run by the California Department of Food and Agriculture (CDFA) and supported by bale-tax "check-off" receipts from the grower group, the Cotton Pest Control Board.

Every summer, adult pink bollworms are blown into the Central Valley from Mexico and the southern California desert regions on tropical storm systems. The threat of these "blow-ins" mating and depositing eggs is huge; that they could survive and flourish to become established in the 284 000 ha of cotton grown in the valley is not disputed. The CDFA monitors an extensive grid of pheromone traps averaging approximately one trap per square mile, but extending at various densities throughout the Central Valley (Baker *et al*., 1990). When a male moth is discovered in a trap, an airdrop of sterile moths is implemented, with the plane being guided to the affected set of cotton fields, and the jettisoning of sterile moths from the plane all precisely recorded and verified by global positioning system computer-monitored tracking systems back at a home base. Sterile males are reared at the USDA–APHIS sterile pink bollworm moth-rearing facility in Phoenix. The sterile moths are dyed pink by the diet they ingest at the rearing facility, and so the many sterile males captured in the pheromone traps are easily distinguished from nondyed blow-ins. Quality control is also implemented by project leaders to confirm the vigilance of the many scouts who are employed each summer to check the traps. At predetermined and random times a nondyed male is placed in a trap and the discovery of this planted blow-in by the scout is awaited.

It is assumed that the presence of a nondyed male moth in a trap is indicative of females in the same area, and that the threat of an increasing endemic population of pink bollworms becoming established is real. The airdrops of sterile moths are aimed at creating a ratio of at least 60 : 1 pink:normal-colored (sterile : wild) male captures in the pheromone traps. This has proven to be an effective ratio for the sterile insect technique to eventually eliminate the nascent endemic population in location after location, year after year. When the 60 : 1 ratio cannot be attained, either by too many wild males present or too few sterile individuals being produced at a particular time by the sterile moth rearing facility, the CDFA then applies pheromone mating disruption. In the late 1980s, up to 2025 ha of cotton each year in the Central Valley received mating disruptant formulation applications in this context (Baker *et al.*, 1990). Monitoring and sanitation of this exotic pest under this program has provided a significant savings to growers and to the environment, allowing cotton to continue to be grown in central California with minimal insecticide load and maximum profits. The program is still operating successfully.

6.12.5.2.2. Boll weevil The boll weevil, *Anthonomus grandis*, has historically been one of the most economically damaging pests of agriculture in the United States. Its invasion into all of the southeastern states by 1917 from Mexico through Texas (Ridgway *et al.*, 1990) is widely considered to have caused the severe decline that occurred in cotton production in this region through the 1960s. Even now, it continues to be considered one of the major agricultural insect pests in the United States.

The identification of the male-emitted sex pheromone of the boll weevil by J.H. Tumlinson and colleagues in the late 1960s (Hardee *et al.*, 1967a, 1967b; Tumlinson *et al.*, 1968, 1969, 1970, 1971) resulted in the isolation and identification of a four-component pheromone (Tumlinson *et al.*, 1969, 1970, 1971). The components were identified as: (1*R*-*cis*)-1-methyl-2-(1-methylethenyl)cyclobutaneethanol; (*Z*)-2-(3,3-dimethylcyclohexylidene)ethanol; (*Z*)-(3,3-dimethylcyclohexylidene)acetaldehyde; and (*E*)-(3,3-dimethylcyclohexylidene)acetaldehyde. This blend was named (thankfully!) "grandlure." Numerous field trapping tests determined the requirement that all four components need to be present for optimal activity. The range of ratios that could be tolerated in achieving optimum trap capture of weevils was also determined (Coppedge *et al.*, 1973; Hardee *et al.*, 1974). An effective trap design was developed (Mitchell and Hardee, 1974) that allowed survey-detection and mass trapping studies to be initiated.

A program was subsequently initiated in Texas to begin large-scale efforts at suppressing boll weevil populations with stalk destruction, whose efficacy at reducing populations is monitored and confirmed by widespread deployment of pheromone traps (Ridgway *et al.*, 1990). However, the most widespread and effective use of the boll weevil pheromone traps has been in the highly successful population suppression program in the southeastern states. Initial trials were begun in the late 1970s in Virginia and northern North Carolina, consisting of surveillance and suppression through widespread pheromone trapping. Release of sterile boll weevils and also diapause control procedures (insecticide applications to kill adult weevils before cotton begins fruiting) were triggered if pheromone trap captures exceeded two to five weevils per trap (Ridgway *et al.*, 1990). Over the years of this program in this initial region, boll weevil capture levels declined to near-zero.

The success of the program in Virginia and northern North Carolina allowed the "boll weevil eradication" program to be expanded to the remainder of North Carolina and all of South Carolina in 1983. In 1987, the program was expanded further to include Georgia and parts of Alabama and Florida. The intensive dependence on pheromone traps as the key tool used in this program is indicated by the numbers of traps and lures used. In 1988 alone, approximately 590 000 traps were deployed and more than 8.25 million pheromone dispensers were used in these southeastern states (Ridgway *et al.*, 1990).

The pheromone traps served as a guide for application of insecticides, and this use of traps predominated during the initial years of the program when weevil densities and trap captures were high (**Table 2**). Beginning in year 2, if trap captures exceeded an average of 0.1 weevil per trap, insecticides were applied. However, if capture levels were lower than this, mass-trapping alone was considered adequate for population suppression (Ridgway, 1990). During the last 2 years of the second phase of the project, mass trapping was nearly exclusively used, due to the capture of so few weevils in most of the hectarage (**Table 2**). The effect of the program on weevil population densities over the first 4 years of the program was dramatic (**Table 2**). Whereas in the first year virtually no fields out of the 2800 fields sampled captured zero weevils, by year 4 more than 99.9% of the fields had zero captures. During the first year more than 95% of the fields had pheromone trap captures exceeding five weevils per trap, but by year 4 only 0.6% of the fields had trap captures exceeding this level (**Table 2**).

Table 2 Boll weevil captures in successive years of the expanded boll weevil eradication zones in North Carolina and South Carolina

Year	*Area (ha)*	*Number of fields*	*Percentage of fields capturing indicated numbers of weevils*		
			0	*1–5*	*>5*
1983					
North Carolina	6 600	800	0	1	99
South Carolina	21 240	2000	2	5	93
1984					
North Carolina	9 200	1000	21	35	44
South Carolina	32 000	2300	22	25	53
1985					
North Carolina	9 400	1000	90	7	3
South Carolina	37 000	4300	81	12	7
1986					
North Carolina	8 600	1000	>99.9	0	0
South Carolina	34 400	4200	97.3	2.3	0.4

The impact of the program was significant, in terms of allowing cotton production to once again expand and flourish, in terms of the reduction in insecticides applied per hectare (savings of \$69–74 ha^{-1} in Virginia, North Carolina, and South Carolina), and in terms of the increased yield value of the harvested cotton (increase of \$85 ha^{-1}) (Ridgway *et al*. 1990).

6.12.5.3. Mass Elimination of Insects from the Population by Using Pheromones

Early research in the applied uses of pheromones experimented with mass trapping (Roelofs *et al*., 1970). When experiments, mostly with adult moths, resulted in little or no suppression of populations, explanations as to the lack of effect focused on the fact that only males were being trapped, and various mathematical models were offered that showed the potential futility in using mass trapping with female-produced pheromones that attract and trap less than 95% of the males (Roelofs *et al*., 1970). It was, however, recognized that mass-trapping could be an effective method if good attractants for females could be identified (Lanier, 1990). Such attractants were already known for bark beetle species of the genus *Ips*, in which it is the males that locate the host trees, build galleries, and then emit pheromone to attract females. This male-produced sex pheromone also coincidentally attracts other (opportunistic) males, who fly to the trees on which any newly arriving females might be able to be mated with before they locate the male producing the pheromone (Borden, 1985).

Although this approach to using pheromones for direct control was largely ignored by many groups of pheromone researchers as a tenable population suppression method, Borden (1994) stated, "I contend that mass trapping has acquired an unjustifiably bad reputation." Borden, along with several other groups of bark beetle pheromone researchers were instrumental in exploring various forms of mass trapping to come up with successful demonstration plot programs for a variety of bark beetle pest species (Bedard and Wood, 1981; Borden and McLean, 1981; Lanier, 1981). Commercially successful programs then evolved from some of these programs.

Only a few moth sex pheromone researchers continued to explore another form of mass trapping (attract-and-kill) involving attracting only males to synthetic female sex pheromone sources laced with small amounts of insecticide (Charmillot *et al*., 1996; Charmillot and Hofer, 1997). This technique has begun to enjoy entry into the marketplace in recent years.

Finally, research and development of mass trapping systems for a variety of highly damaging tropical weevil species by using male-produced sex pheromones has resulted in highly successful commercial mass-trapping systems for suppressing populations of these species (Oehlschlager *et al*., 1992a, 1993, 1995, 2002). A few examples of the development of research successes into successful commercial products or governmental programs that have utilized various forms of mass trapping, including attract-and-kill will be discussed.

6.12.5.3.1. Mass trapping In the late 1970s populations of the spruce bark beetle, *Ips typographus*, were increasing yearly and threatening the very existence of the paper and lumber industries of Sweden and Norway. Because of the existence of a highly effective synthetic pheromone blend and the desperation of the industry, the governments of these two countries agreed to subsidize a mass-trapping program that would include virtually all the hectares of forest land affected or that could be affected by this pest. In 1979, more than 600 000 traps baited with the male-produced sex pheromone ("aggregation pheromone") were deployed in Norway, and more than 300 000 traps were deployed in Sweden, often with the help of local citizens who agreed to place them in the forests near their summer cottages in the northern areas of the countries. More than 4.5 billion beetles were trapped during the summer of 1979. The following year, the number of trees killed by *I. typographus* in Norway remained the same as during 1979 or was

slightly reduced, and the program was deemed highly successful because a large increase had been expected. In Sweden, there was a great reduction in the number of trees killed (Lie and Bakke, 1981). In both countries, this was the first year in many that tree mortality had not continued to increase. The forest industry was saved, and populations declined in the succeeding years. No replication or check plots could be used to assess this program due to the areawide (country-wide) deployment of the traps; however, this was not a scientific experiment, it was a desperate measure whose implementation correlated with the first nonincrease in the population in years.

The American palm weevil, *Rhynchophorus palmarum*, is a highly damaging pest of oil and coconut palms in the American tropics, and in Central and South America. A related species, *R. ferrugineus* is a major pest of oil and other palms in the Middle East. Larvae of *R. palmarum* cause direct damage when they bore into the trunks of the trees, but they also are a vector of red ring disease, which is caused by a nematode, *Rhadinaphelenchus cocophilus*. In the early 1990s, losses of trees either due to the weevil itself or to red ring disease (which necessitates removal of the infected trees) often routinely reached 15%. Due to the threat to the oil palm industry posed by this weevil in Costa Rica, experiments aimed at mass trapping the adult weevils were undertaken. An effective male-emitted sex pheromone (Rochat *et al*., 1991; Oehlschlager *et al*., 1992b) plus food attractant bait had been developed (Chinchilla and Oehlschlager, 1992; Oehlschlager *et al*., 1993) which attracts primarily females but also males, that are trapped in inexpensive bucket-type traps. The traps are baited with the pheromone, 2-methylhept-5-en-4-ol (Oehlschlager *et al*., 1992b) plus a stalk of sugarcane laced with carbofuran. Previous experiments had shown that neither sugarcane alone nor pheromone alone attracted significant numbers of weevils, whereas the combination attracted and trapped large numbers (Oehlschlager *et al*., 1992a, 1993).

In 1991 in a 30 ha stand of oil palms in a highly infested plantation in Costa Rica, 219 bucket traps baited with pheromone plus insecticide-laced sugarcane were placed at eye level on the trunks of oil palm trees in a 30 ha plot within the 1256 ha plantation. Over the course of the year, the number of weevils captured per trap per week declined from an initial 15 per trap to fewer than two per trap (Oehlschlager *et al*., 1995, 2002). In contrast, in the surrounding survey areas of the plantation, the number of weevils per trap per week increased from approximately 15 to an average of about 60 for the subsequent months, and ending at more than 20 per trap per week at sampling termination. Incidence of red ring disease in the mass trapping plot decreased in the year after initiation of the mass trapping, to level approximately only 20% of the previous levels and one-half that in the surrounding untreated stands (Oehlschlager *et al*., 1995, 2002).

Plantation-wide mass trapping was undertaken at the same time on two major oil palm plantations in Costa Rica, one comprising 6514 ha and the other comprising 8719 ha (Oehlschlager *et al*., 2002). Four-liter bucket traps baited as described above with pheromone plus insecticide-laced sugarcane stalks were deployed at chest level at a density of only one trap per 6.6 ha. The results in the two plantations were virtually identical (**Figure 2**). Before the mass trapping program was implemented, normal sanitation procedures involving removal of red ring disease-infected palms had failed to reduce the incidence of this disease. Once mass trapping was added to the system, after 1 year the incidence of diseased trees needing to be removed dropped by nearly 80%, from about 10 000 diseased trees removed to 2000 (Oehlschlager *et al*., 2002) (**Figure 2**). During that first year (1992–93) more than 200 000 weevils were trapped. In each successive year, the incidence of diseased trees declined until in 2001 only 50 diseased trees needed to be removed through sanitation (Oehlschlager *et al*., 2002) (**Figure 2**).

Subsequent commercial development of the *R. palmarum* mass trapping system has seen it be transformed into one of the most important pest management tools for weevil pests worldwide. Approximately 25 000 ha of palm plantings is estimated to be under *R. palmarum* mass trapping control yearly in Central and South America (A.C. Oehlschlager, personal communication). The density of traps now used is now only one trap per 7 ha. In addition to the ability of this male-based pheromone to attract females, and males, the reasons given for the success of mass trapping against *R. palmarum* (Oehlschlager *et al*., 2002) are first, that although the weevils cause great direct and indirect damage and induce tree mortality, they are present in relatively small numbers. Second, they have a long adult life, and so the capture of even low numbers steadily throughout the year can remove a large proportion of a generation and have a significant impact on population growth. Third, they are strong flyers, which allows the pheromone traps to be widely spaced (Oehlschlager *et al*., 2002).

These characteristics favoring success of mass trapping also seem to pertain to the other tropical

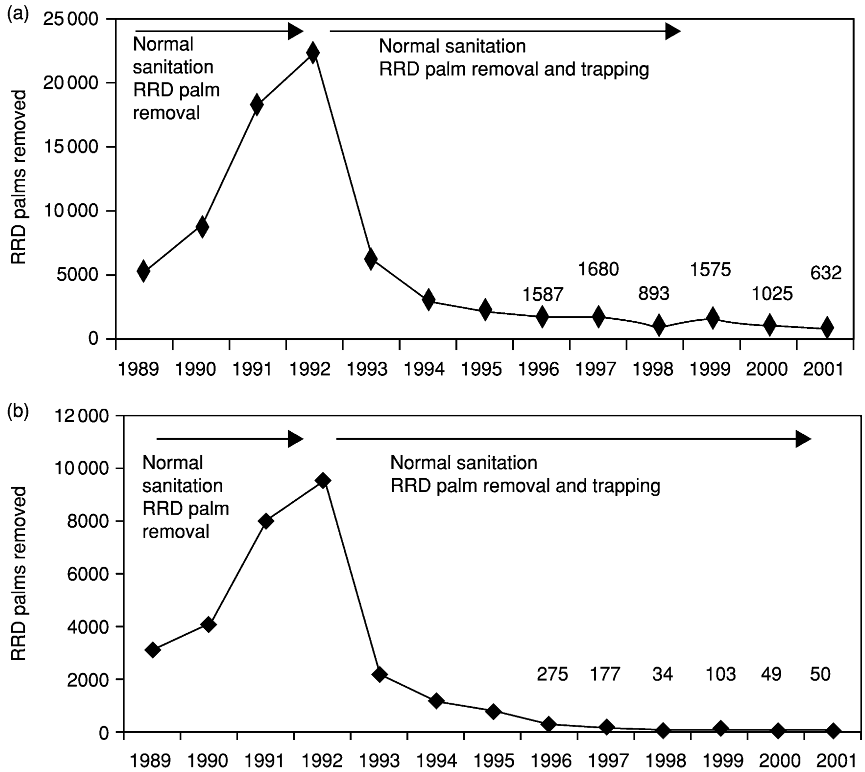

Figure 2 Incidence of red ring disease (RRD) vectored by the *Rynchophorus palmarum* weevil in oil palms in Costa Rica, before and after mass trapping of the weevils, as measured by the number of diseased trees that had to be removed each year from two plantations, (a) and (b), from 1989 to 2001. Plantation (a) comprised 6514 ha and plantation (b) totaled 8719 ha. From 1989 to 1992, before the implementation of mass trapping of the weevils, disease incidence steadily rose. During this period only normal sanitation and diseased palm tree removal were used to try to control the weevils. After 1992, when pheromone mass trapping was added to the program, the incidence of red ring disease declined dramatically. (Adapted from Oehlschlager, A.C., Chinchilla, C., Castillo, G., Gonzalez, L., **2002**. Control of red ring disease by mass trapping of *Rhynchophorus palmarum* (Coleoptera: Curculionidae). *Fla. Entomol. 85*, 507–513.)

pest weevil species. Other highly successful and effective commercial mass trapping systems using male-emitted sex pheromones are in place for these other species. For *R. ferrugineus*, more than 35 000 ha of palm plantings are treated with mass trapping every year in the Middle East. For another pest of palm, *Oryctes rhinoceros*, more than 50 000 ha yearly are under a mass trapping program in the Middle East (A.C. Oehlschlager, personal communication).

An estimated 10 000 ha of commercially grown bananas in the American tropics is under mass trapping programs every year against the banana weevil, *Cosmopolites sordidus* (A.C. Oehlschlager, personal communication). A simple and inexpensive pheromone trap plus this species' pheromone is used in only about four traps per hectare, but here the traps are placed on the ground because the weevils must walk into them to be captured in pit-fall manner. The traps are moved in a line week by week through the banana plantations to trap-out the weevils, and so the actual density of traps per hectare throughout the entire plantation that accomplishes weevil trap-out is extremely small.

Mass trapping also is being used extensively in palmito palm, which produces a delicacy, palm hearts. In palmito palm plantations, a combination lure for *R. palmarum* and the West Indian sugarcane weevil, *Metamasius hemipterus*, is used; the pheromones of the two species, 2-methylhept-5-en-4-ol and 2-methyl-4-heptanol (Perez *et al.*, 1997), do not interfere significantly with attraction and significantly lower the incidence of damage when placed in the same bucket traps at a density of four traps per hectare in this crop (Alpizar *et al.*, 2002). Hence, this "combination trap" kind of mass trapping program aimed at two species at once is now showing success at trapping and removing two damaging species of weevils from the population (Bulgarelli, 2002).

The ambrosia beetle, *Trypodendron lineatum*, is a worldwide pest in industrial timber processing areas, which, along with two other such beetles, *Gnathotrichus sulcatus* and *G. retusus*, causes degradation in lumber value that in the early 1990s was

estimated in to be more than $100 million per year in British Columbia (Lindgren and Fraser, 1994). This estimate ignores other losses, including export restrictions and modified harvesting and processing needed for the damaged timber. A major pheromone component of *T. lineatum*, 3,3,7-trimethyl-2, 9-dioxatricyclo [3.3.1.0^{4,7}] nonane ("lineatin"), had been isolated and identified from female frass in 1977 (MacConnell *et al*., 1977) and its field activity confirmed (Borden *et al*., 1979). The pheromone of *G. sulcatus* was identified from the volatiles of boring males as a 65 : 35 ratio of (*S*)-(+)- and (*R*)-(−)-6-methyl-5-hepten-2-ol (sulcatol) (Byrne *et al*., 1974), and the blend of both enantiomers was requisite to attraction (Borden *et al*., 1976). *Gnathotrichus retusus*, in contrast, was found to use only the (*S*)-(+)-enantiomer, which was identified from the dust of boring males (Borden *et al*., 1980a). Small amounts of the *R*-(−)-enantiomer in the blend were found to reduce attraction to the (*S*)-(+)-enantiomer (Borden *et al*., 1980a).

With the addition of host volatiles, synthetic versions of this female-emitted pheromone were highly effective at attracting males and females as well (Borden *et al*., 1980b). Research efforts towards developing a mass trapping program for keeping lumber yard operations sanitized from attack by all three ambrosia beetle species demonstrated the efficacy of this approach (Borden and McLean, 1981). Before the pheromone-based mass trapping program was available, many timber processing facility managers had used a trap-crop approach in protecting their yards, placing log piles in strategic locations around the yards and then collecting and destroying them (and the beetles) in pulp-chippers (Borden, 1990). The pheromone-based mass trapping IPM strategy evolved first from baiting log piles with pheromones, and then to enhancing beetle attraction to the piles, and finally to a pheromone-trap-only system that was made possible by the development of the easily used and highly effective multiple-funnel trap (Lindgren, 1983; Lindgren and Borden, 1983; Lindgren *et al*., 1983; Borden, 1990).

Several companies successfully marketed this ambrosia beetle mass trapping system, which is still in use commercially. One evaluation of the history of its use in one timber-sorting area on Vancouver Island showed that in more than 12 years, at least 16.5 million beetles had been captured, while keeping infestations to a minimum at an acceptable cost and economic benefit (Lindgren and Fraser, 1994). A key element to the companies' success, and the efficacy of the mass trapping programs, was that clients were required to purchase a service contract to accompany the sales of the traps and lures for the three species. This ensured that the appropriate vigilance and consistency in trap efficacy were maintained (Borden *et al*., 2001).

It is clear that the once-discounted technique of mass trapping using either male-produced or female-produce pheromones has become a newly appreciated, highly effective, environmentally friendly, and relatively inexpensive means of suppressing populations of certain pest species whose pheromone communication systems and bionomical characteristics make them susceptible to this approach. The next section dealing with attract-and-kill is yet another example of possible ways to gain control over pest populations with sex-attractant pheromones.

6.12.5.3.2. Attract-and-kill In the early 1980s many cotton growers in the southern California desert valleys who had been successfully using the hollow-fiber sex pheromone mating disruption system against the pink bollworm started experimenting with reducing the amount of active ingredient (a.i.) per acre, often by one-half or more, and adding small amounts of pyrethroid to the sticky glue in the tank mix that adheres the fibers to the cotton leaves when flung from the specialized aerial application mechanism (Baker *et al*., 1990). The apparent success of this technique in keeping damage low with reduced amounts of a.i. signaled the beginning of the concept of "attract-and-kill." Observations showed that males indeed were attracted all the way to the pyrethroid-impregnated stickum on the fibers (Haynes *et al*., 1986; Baker *et al*., 1990; Miller *et al*., 1990) and that they were killed or else rendered incapable of flying upwind to subsequent sources in the following days due to sublethal toxic effects (Haynes *et al*., 1986).

Pierre Charmillot and colleagues, after years of meticulous experiments in codling moth mating disruption with small apple orchards with irregular borders and high population hot spots (Charmillot, 1990), began experimenting with attract-and-kill in isolated apple orchard blocks (Charmillot *et al*., 1996; Charmillot and Hofer, 1997). In their studies, they used a formulation called Sirene CM (Ciba Corporation) that consisted of very small viscous gel droplets (0.05 ml) containing small amounts of permethrin (3 mg) and 0.08 mg of codling moth pheromone. Droplets were applied at between 1600 and 5000 drops ha^{-1} and after either one of the treatments, damage at harvest was 0.24%, 0.32%, 1.1%, and 1.14% in four orchards.

Two orchards that received a second year of attract-and-kill had negligible larval attack and very

low hibernating larval levels on the trunk (less than one larva per tree). These experiments showed that this technique is effective in keeping damage from this pest at acceptable levels using attract-and-kill alone. The technique works especially well in small (ca. 1 ha) blocks of apple that are not amenable to treatment with standard mating disruption formulations due to their large border-length-to-area characteristics. Proof that the attract-and-kill mechanism and not just mating disruption was the cause of the population suppression came from a second set of experiments in which the pheromone-impregnated droplets either did or did not contain small amounts of insecticide. The plots to which the insecticide-containing droplets were applied showed significantly reduced trap capture and tethered female mating reduction, whereas plots that received droplets containing pheromone without insecticide exhibited virtually no monitoring trap capture reduction and no reduction in tethered female mating (Charmillot *et al.*, 1996; Charmillot and Hofer, 1997).

One major conclusion that can be drawn from these successful studies using the codling moth is that it is possible to use mass trapping (attract-and-kill) against only males and achieve successful population suppression. The innovative bent of certain cotton growers and at least one determined codling moth researcher showed that the initial negative conclusions of early pheromone researchers concerning mass trapping of male moths were premature, or at least based on incompletely understood assumptions. At present, a commercially successful attract-and-kill product against the codling moth based on Charmillot's work and through substantial development efforts by CIBA Corporation is being marketed as "Last Call" in North America by IPM Technologies, Inc. Other attract-and-kill Sirene products using the pheromones of other species are being developed against other pests.

For attract-and-kill to work, obviously an optimally attractive pheromone blend formulation is required that will attract the males of the target species all the way to the source so that they contact the insecticide-laced matrix. This, and the need for so many droplets to be applied and retain their contact toxicity for a long period, are some of the exacting requirements necessary to be met for attract-and-kill to successfully take its place as a useful and successful pheromone-mediated population suppression tool.

6.12.5.4. Mating Disruption

6.12.5.4.1. Evolution of mating disruption technique Mating disruption is the technique by which pheromone is dispensed into a pest habitat in sufficient amounts to reduce the ability of males to find females, or vice versa. In the earliest days of mating disruption trials, it was thought that it was essential to dispense the pheromone such that a ubiquitous cloud of pheromone pervaded every cubic meter of habitat to disrupt mate-finding communication. Most trials concentrated on the use of microcapsules sprayed through conventional pesticide sprayers to achieve uniform coverage. Then, the first mating disruption formulation to be registered by the Environmental Protection Agency (EPA), the Conrel hollow fibers, was developed in 1978. It used hollow microfibers ca. 2 cm in length. These fibers were distributed over cotton fields by using airplanes equipped with specialized applicator technology. These dispensers, once they landed on and stuck to the cotton leaves, emitted volatilized pheromone by means of an open capillary tube technique and were effective when applied at an estimated density of one fiber m^{-2}. The evolution of dispensers into a yet stronger point source emission mode and further away from the original uniform fog mode occurred in the mid-1980s with the commercial appearance of the Shin-Etsu "ropes." These were made up of the pheromone of the target species residing in sealed polyethyelene tubes that were hand-applied in a twist-tie manner around plant stems. The reduction in the number of point sources per hectare from tens of thousands (fibers) to now only 1000 ha^{-1} was achieved with fewer but higher strength point sources with no loss of efficacy.

Still, researchers had not paid attention to the results of an important set of experiments conducted by Farkas *et al.* (1974), who followed up on initial intriguing results from Shorey *et al.* (1972) which showed that the number of point sources could be reduced to only a few per hectare if they were made to emit at very high rates so that the total amount of pheromone emitted per hectare remained at as high a rate as when many more, but weakly emitting, point sources were deployed. Some researchers started experimenting with this concept in the 1990s, and formulations using only 10–15 dispensers per hectare are now available commercially. The initial research on these involved the use of "active" emitters, which were machines that could be programmed to project aerosolized pheromone solution into the air and onto absorbent pads, which would then emit high amounts of pure pheromone of the target insect (Mafra-Neto and Baker, 1996a; Shorey and Gerber, 1996a, 1996b; Shorey *et al.*, 1996; Baker *et al.*, 1997; Fadamiro *et al.*, 1999b).

The initial concept was that the machines could be programmed to emit pheromone only during the

time of activity of the target (moth) insect pest's sexual activity. Efficacy in disrupting sex pheromone communication of a number of different species was clearly demonstrated (Mafra-Neto and Baker, 1996a; Shorey *et al.*, 1996; Shorey and Gerber, 1996a, 1996b; Baker *et al.*, 1997a, 1997b; Fadamiro *et al.*, 1998, 1999b). Then, it became evident that the emission of pheromone, whether from the pads or from surrounding foliage onto which the pheromone solution absorbed, was a constant, passive emission phenomenon. The MSTRS Technologies, Inc., dispensers that had previously been of the active-spray type using aerosolized pheromone evolved into high-release-rate passive-emitting dispensers. The MSTRS system is currently commercially available for use against several pest species, and dispensers are deployed at densities ranging from 10 to 20 ha^{-1}. One original machine-driven aerosolized dispenser system Suterra LLC's is also commercially available and in use against the coding moth.

6.12.5.4.2. Behavioral mechanisms involved in successful mating disruption A very few important studies have provided behavioral observations that have helped understand how moths' abilities to locate sources of female sex pheromone are diminished by the application of mating disruption dispensers. At least four mechanisms have been implicated when the disruptant used is an effective synthetic blend mimicking the natural blend (Bartell, 1982; Cardé, 1990; Cardé and Minks, 1995):

1. Attraction-competition, in which males are attracted some distance toward the disruptant dispensers and waste time flying around in response to these plumes.
2. Sensory adaptation or habituation, in which exposure to the synthetic disruption blend raises the threshold of response (lowers sensitivity) to subsequent plumes.
3. Camouflage of natural female pheromone plumes by the strong plume-strands emanating from the synthetic dispensers.
4. Advancement of the periodicity of activity of males such that they begin responding to the synthetic disruptant dispensers before females begin to call.

These mechanisms are not thought of as operating independently of one another, but rather most of the time they act in concert, depending on the dispenser type that is used and the environmental conditions (Cardé, 1990; Cardé and Minks, 1995).

There is evidence from many studies that what has now been more aptly termed "competition" (Cardé and Minks, 1995) but had previously been labeled "confusion" or "false trail-following," does in fact occur in mating disruption-treated fields, especially those receiving discrete point sources of dispensers such as hollow fibers or ropes. It is unknown, but it is regarded as unlikely, that male moths in fields treated with sprayable microcapsules, creating a nearly uniform fog of pheromone from the closely spaced, weak point source emitters, would be subject to the competition mechanism. The majority of species that have been tested for their responses to uniform clouds of pheromone quickly habituate when released in the pheromone fog, and cease upwind flight after only 1 or 2 s, reverting to cross-wind casting within the cloud (Kennedy *et al.*, 1980, 1981; Willis and Baker, 1984; Baker *et al.*, 1985; Justus and Cardé, 2002).

However, for disruptant formulations that use slightly more widely spaced and stronger point sources, attraction competition imposed by these sources on males should be more likely to come into play, and has been observed in the field (Miller *et al.*, 1990; Cardé *et al.*, 1993). The flight tracks of pink bollworm males have been recorded (Cardé *et al.*, 1997) in large wind tunnels placed over disruptant-treated cotton fields, as they flew upwind in response to the pheromone emitted by Shin-Etsu ropes that had been in the field for 7 days (as well as to those that had been in the field for only 24 h). Males that had been preexposed to the ropes within disruptant-treated fields for 24 h, as well as those males having had no preexposure, flew upwind to the rope dispensers, with the only difference being that the percentage of the 24 h preexposed males doing so was significantly reduced (Cardé *et al.*, 1997). The flight tracks of males flying upwind in response to the ropes appeared similar to the tracks of males flying upwind to much lower strength rubber septum monitoring trap lures, with the tracks of males flying to the ropes exhibiting a slower ground speed and more tortuous paths. The males were observed to land on or near (within 50 cm of) the rope dispensers and then become quiescent for long periods, implicating a second mechanism, habituation of the olfactory pathways, as having occurred after attraction competition.

Habituation is not an all-or-nothing phenomenon. The degree to which the olfactory pathways are habituated depends on the dose of pheromone applied during preexposure. Mafra-Neto and Baker (1996b) demonstrated, using a graded series of preexposure dosages of the pheromone of the almond moth, *Cadra cautella*, that lower habituating do-

sages reduced males' ability to respond subsequently to normal-strength pheromone plumes but that the usual percentage of these males could fly upwind and contact the source if stronger loadings of pheromone were used on the test lure. Thus, the degree of habituation depends on the concentration of the preexposure regime, as well as on the subsequent attractant lure, demonstrating that habituation behaves in a graded manner. The habituating concentration elevates the subsequent response threshold, and the highest habituating concentrations elevated the threshold of tested males to the greatest degree, requiring extremely strong attractant lure dosages to achieve any subsequent attraction whatsoever (Mafra-Neto and Baker, 1996b).

Habituation can occur without attraction-competition being evoked at all. Female pink bollworm produce and emit approximately a 50 : 50 ratio of (*Z,E*)-7,11-hexadecadienyl acetate and (*Z,Z*)-7,11-hexadecadienyl acetate (Hummel *et al*., 1973). The 1 : 1 ratio of the two isomers captures the most males in field trapping experiments, and neither the (*Z,Z*) nor the (*Z,E*) isomer alone traps significant numbers of males (Flint *et al*., 1979). The pure (*Z,Z*) isomer does not even elicit significant levels of upwind flight in laboratory wind tunnels (Linn and Roelofs, 1985). In a series of experiments, Flint and colleagues experimented with applying disruptant formulations, either Hercon laminated flakes or Shin-Etsu rope dispensers emitting only the pure (*Z,Z*) isomer (Flint and Merkle, 1983, 1984; Flint *et al*., 1988). Monitoring traps containing lures emitting a series of blend ratios from 0 : 100 to 100 : 0 of the two isomers were deployed throughout the disruptant-treated fields. Trap catch was totally shut down in the fields treated with the 50 : 50 ratio-emitting hollow fibers. Likewise, trap catch was also nearly totally suppressed by the pure (*Z,Z*) isomer-emitting dispensers. However, in these (*Z,Z*) isomer-treated fields there was a significant capture of males, albeit small, but the captures were significantly shifted to the monitoring traps emitting a 90 : 10 ratio of (*Z,Z*) to (*Z,E*). Males apparently were becoming habituated to the pure (*Z,Z*) isomer alone, and the monitoring lures emitting the highly enriched (*Z,Z*) to (*Z,E*) blend were now able to attract pink bollworm males as if the blend now was perceived as being more similar to 50 : 50 in these disrupant-treated fields.

Because the dispensers emitting the pure (*Z,Z*) isomer will not have been able to cause any attraction (and therefore no competition), the conclusion must be that sensory adaptation or habituation of the sensory pathways alone must be the mechanism acting to cause the near-elimination of trap capture in the (*Z,Z*) isomer treated disruption plots. Importantly, even though strong point source dispensers were used (especially the Shin-Etsu ropes), enough pheromone wafted through the fields from such sources that habituation alone without attraction significantly affected male behavior. Linn and Roelofs (1981) had demonstrated, using the oriental fruit moth, the ability of single components to exert a component-specific habituation on a particular sensory pathway specific for that component. The result was, as in the pink bollworm mating disruption experiments, that males that had been preexposed and habituated to only one (nonattractive) component were subsequently optimally attracted to multicomponent blends that needed to be enriched with excessive amounts of that component. The artificially enriched blend would now be perceived as the normal unenriched blend to which nonhabituated males are optimally attracted.

A third mechanism, "plume camouflage," has also been implicated as a mechanism involved in mating disruption (Cardé *et al*., 1993; Cardé and Minks, 1995). The amount of pheromone in the plumes from the disruption dispensers is thought either to overwhelm the strength of the signal from the female-equivalent source or possibly to dampen the amplitude of ups-and-downs in plume-strand flux over the antenna; the plume's fine-scale structure has been shown to be essential in eliciting reiterative upwind surges from strand to strand that promote sustained upwind flight (Mafra-Neto and Cardé, 1994; Vickers *et al*., 1994). Using their large field wind tunnels situated in cotton fields, Cardé *et al*. (1993) concluded that the reduced ability of male pink bollworms to fly upwind to and be trapped in monitoring traps in some of their experimental regimes in the tunnels was due to the ambient emitted amounts of pheromone from pheromone dispensers present in the fields that camouflaged the weaker plumes from the monitoring traps. As they pointed out (Cardé *et al*., 1997), it is difficult to prove that such a mechanism is working independently of habituation and also competition, but the measurements of pheromone concentration by means of field electroantennograms seemed to support their conclusions that camouflage was indicated as the most likely dominant mechanism in some special experimental regimes (Cardé *et al*., 1993). Camouflage using uniform clouds of pheromone does not seem sufficient for preventing upwind flight of moths in response to the intermittent flux provided by point source plumes (Kennedy *et al*., 1980, 1981; Willis and Baker, 1984; Schofield *et al*., 2003).

Finally, it has been well known since the early days of pheromone research that in a large number of moth species, the diel periodicity of male responsiveness to pheromone is broader than the female calling period (Cardé and Baker, 1984). For pink bollworm, this includes an advanced responsiveness of males to synthetic pheromone lures that precedes the normal time of sexual activity to females in the field (Breasley and Adams, 1994; Schouest and Miller, 1994). The observations of Cardé *et al.* (1997) in their large field wind tunnels also seemed to indicate that not only were freshly released males able to respond in a precocious burst of activity just after sunset but also males that had been exposed to field levels of mating disruptant for 24 h exhibited an advanced period of responsiveness compared with native males. Such behavior would work to the advantage of mating disruptant formulations, causing males to be exposed or to expose themselves through attraction competition with habituating amounts of pheromone before females would even begin calling.

Cardé and Minks (1995) and Cardé *et al.* (1997) suggested that combinations of mechanisms will likely be operating in concert to various degrees, depending on the dispersion of pheromone by a particular formulation, to reduce males' abilities to respond to pheromone plumes from their females. For example, when males are being "confused" and flying upwind in the plumes of synthetic pheromone emitted by hollow fibers (Haynes *et al.*, 1986; Miller *et al.*, 1990) or Shin-Etsu ropes (Cardé *et al.*, 1997), they are receiving high-concentration contacts with the strands of pheromone in those plumes, and habituation of the sensory pathways is occurring as a result of the male remaining in upwind flight and continuing to maintain contact with those strong pheromone strands.

This combination of attraction and habituation has been invoked as the mechanisms explaining why the very high concentration, low point source density dispensers such as the "puffers" and MSTRS dispensers work despite their very wide spacing (Baker *et al.*, 1998b). The very highly concentrated pheromone strands in a plume from a single such dispenser can be effective at great distances downwind, causing males that contact them to begin flying upwind while maintaining contact with the plume. As the males proceed upwind, they continue to "dose" themselves with highly concentrated pheromone strands, and at some point after a prolonged upwind flight to the source or near the source, the males become habituated to the pheromone and cease upwind flight, as has been observed for males flying upwind to the lower emission rate, less widely spaced Shin-Etsu ropes (Cardé *et al.*, 1997).

As formulations use increasingly widely spaced, high emission rate means of emitting pheromones, optimal attraction using the blends most closely approximating the natural female blend will become necessary to prolong the time a male spends locked onto the plume, dosing himself with high amounts of pheromone to become habituated. At the other extreme, sprayable microcapsule formulations will likely depend very little, if at all, on the attraction mechanism, relying almost exclusively on habituation or plume camouflage. Regardless of the type of formulation, it is expected that all should be able to take advantage of the advanced period of sexual responsiveness that males exhibit before females begin to emit pheromone.

6.12.5.4.3. Mechanisms by which mating disruption suppresses population growth It used to be assumed, and is still assumed by many people working in chemical communication, that successful mating disruption can only occur if the majority of females in a population are prevented from mating after the application of a mating disruption formulation. In reality, in all but a handful of the huge number of mating disruption field trials that have been conducted over the years, mating disruption itself has never been directly assessed. That is, the mating success of feral, freely flying females has rarely been evaluated. The use of tethered females or clipped-wing females placed on "mating tables" or at stations deployed throughout the disruption plot and then dissected for the presence (mated) or absence (unmated) of spermatophores does not assess what is really happening to feral females that have the ability to fly freely throughout the area. The tethered female technique gives the illusion of being a robust, real-world assessment of mating disruption efficacy, and although it is one of many good indicators, it is especially deficient when the insects distribute themselves unevenly within the habitat due to environmental factors such as heat, humidity, and wind. Unless the researcher knows ahead of time the locations where adults typically are most densely clumped and can tether the females there, the ability of the disruptant formulation to keep males from finding females will be overestimated.

The results of the few studies that have assessed the mating success of freely flying feral females are illuminating. For the highly successful and grower-accepted Shin-Etsu rope formulation used against the oriental fruit moth, Rice and Kirsch (1990) found that in plot after plot treated with mating

disruptant, females' abilities to mate at least once in disruption-treated plots was only suppressed at most 50% relative to check plots during a flight. Just as commonly, this ability was as little as 15–20% suppressed, despite the reduction of fruit damage in these plots to acceptable levels comparable with those when the standard insecticide regime was used (Rice and Kirsch, 1990). Thousands of females were captured in terpinyl acetate bait pails and analyzed for the presence or absence of spermatophores in their bursae copulatrices in both the disruptant treated plots and the check plots. This study was the first indication that for successful population suppression and damage reduction, it is not necessary to keep females unmated throughout their adult lives. Vickers *et al*. (1985) reported similar results for oriental fruit moth feral female mating success in Australian mating disruptant treated plots (23% mated females in mating disruption plots versus 90% in check plots).

Knight (1997) released six batches of 6000 sterilized codling moth females into disruption treated and check orchards and recaptured them in light traps or passive interception traps to dissect them and to look for the presence of male spermatophores to assess females' success at mating. The disruption formulation used was Isomate-C+, a Shin-Etsu rope-type dispenser system that had already been showing success at suppressing populations of codling moths in the Pacific Northwest. Again, as for the oriental fruit moth, after several days, more than 40% of codling moth females from the disruptant treated plots contained spermatophores, showing that they had mated, despite the application of this highly successful formulation. However, Knight (1997) noticed that females took longer to reach this level of mating success (4 days) in the disruption plots than they did in the check plots (1 day), and introduced the concept that perhaps successful population suppression through the application of mating disruptants requires only that the formulation delay mating, not suppress it entirely. Laboratory studies that prevented codling moth females from gaining their first mating by from 1 to 10 days showed that females whose first mating was delayed by as little as 3 days had reduced fertility and fecundity compared with those who had gained their first mating by day 1 or 2. When female first mating was delayed by 8 to 10 days, the number of fertile eggs laid was only 20% of that of females that had mated on day 1 or 2 (Knight, 1997).

The delayed mating concept was again implicated in studies on European corn borer *Ostrinia nubilalis* mating disruption (Fadamiro *et al*., 1999b). In these studies, analyses were made of the bursae copulatrices of more than 2400 feral females that were captured by hand-netting during the daylight hours as they were flushed from their grassy aggregation areas. The data showed that during each of the two summer flights, 100% of the females eventually became mated despite the application of high release rate, low point source density dispensers (Fadamiro *et al*., 1999b). What was interesting was that at the beginning of the first flight ca. 50% of the females remained virgin in the mating disruption plots, but the mating success of females in these plots eventually reached 100% during the ensuing weeks as the flight proceeded (**Figure 3**). They attained this 100% mated status more slowly than did females in the check plots, which were 100% mated beginning at day 1 (**Figure 3**).

Analysis of the frequency of mating by the European corn borer females captured in the disruptant treated plots versus those from the check plots showed that throughout the entire flight females from the disruption plots were attaining matings at a significantly lower rate than those from the check plots (Fadamiro *et al*., 1999b) (**Figure 4**). The mating disruptant was impairing the ability of females to attract and mate with males on a constant, daily basis but it did not completely eliminate mating. The application of this MSTRS formulation has subsequently been shown to reduce damage to corn by an average of 50–70% in various trials (Baker, unpublished data). Thus, as demonstrated in studies on the oriental fruit moth (Rice and Kirsch, 1990) and codling moth (Knight, 1997), mating disruption success does not require keeping the population of females virgin, but rather just needs to impede females' ability to attract males and attain their first or even subsequent matings. Thus, we must now expect to only retard, not eliminate, mating by females as a benchmark for successful population suppression through the application of mating disruption formulations.

How would delayed mating produce such significant population reductions? A follow-up study by Fadamiro and Baker (1999) investigated the effects of several manipulations on the timing and frequency of European corn borer females' matings during their lifetimes. With regard to delaying the first mating of these females, a delay of first mating to day 4 compared with day 1 produced a greater than 30% overall reduction in the number of fertile eggs laid during their 16-day lifetimes. Further delaying first mating until day 7 resulted in no fertile eggs laid at all, even though these females lived for 16 days total (Fadamiro and Baker, 1999). These results mirrored those of Knight (1997) that experimentally

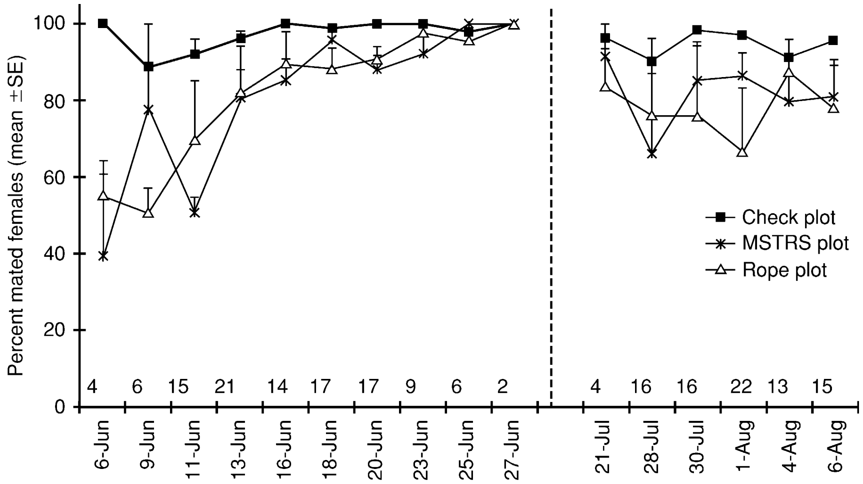

Figure 3 Delayed mating imposed by mating disruption of the European corn borer (*Ostrinia nubilalis*) in Iowa as measured by the percentage of feral, free-flying European corn borer females that were found to have mated at least once on the indicated dates in mating disruptant treated plots or in untreated check plots. Females were captured by hand-netting on the dates shown in grassy areas within and between corn fields and examined for the presence of male spermatophores. During the first of the two flight periods (left panel) 50% of the first females to emerge were kept unmated by the mating disruption treatments, either MSTRS aerosol-based spray machines (MSTRS plot), or by Shin-Etsu polyethylene tubes (rope plots). Over the course of the flight, the percentage of mated females increased to finally reach 100% by the end of the flight period. In check plots the proportion of mated females was nearly 100% from the first days of the flight and continued at that level throughout. During the second flight (right panel), hand-netting did not begin early enough to measure mating success at the beginning of the flight and ended before the flight period ceased. (Reproduced from Fadamiro, H.Y., Cossé, A.A., Baker, T.C., **1999b**. Mating disruption of European corn borer, *Ostrinia nubilalis* by using two types of sex pheromone dispensers deployed in grassy aggregation sites in Iowa cornfields. *J. Asia-Pacific Entomol. 2*, 121–132.)

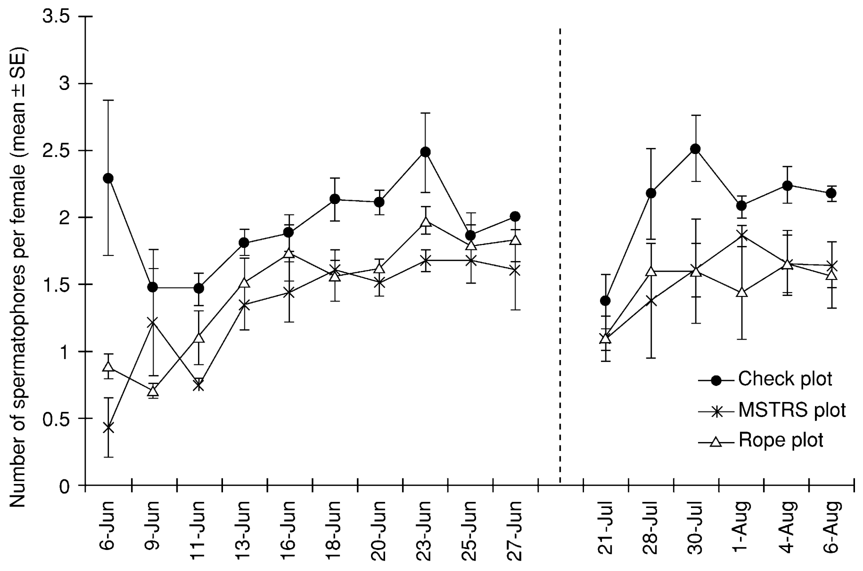

Figure 4 The frequency of mating by European corn borer females in disruptant-treated fields (''MSTRS plot'' or ''rope plot'') is lower than in untreated check plots, as measured by the mean number of male spermatophores found in females collected by hand-netting on the indicated dates. Females' ability to attain matings on any date during the first (left panel) or second flights (right panel) was impaired continuously throughout the flights by the presence of mating disruption dispensers. Thus not only is a female's ability to mate for the first time delayed by mating disruptant dispensers, but so is the second mating. The propensity of females in check plots to mate more than once also suggests that one mating is not sufficient to lay a full complement of fertile eggs. (Reproduced from Fadamiro, H.Y., Cossé, A.A., Baker, T.C., **1999b**. Mating disruption of European corn borer, *Ostrinia nubilalis* by using two types of sex pheromone dispensers deployed in grassy aggregation sites in Iowa cornfields. *J. Asia-Pacific Entomol. 2*, 121–132.)

delayed the first matings of codling moth females (see above).

Fadamiro and Baker (1999) also investigated the effects of reducing multiple mating, because the majority of females from the check plots in the field experiments had mated two or more times (two or more spermatophores), implying that there is an advantage for feral females to obtain a second mating. Therefore, another set of experiments was performed to examine the effects of allowing females to mate more than once (Fadamiro and Baker, 1999). Females allowed to mate only once at day 2 laid only 50% as many fertile eggs during their lifetimes as those that had been allowed to mate twice. Thus, another mechanism by which mating disruption of this species can help suppress populations is by significantly reducing fertile egg production by impeding females' ability to achieve a second mating. When one considers other factors such as mortality of females over time due to predation and other natural causes, these ancillary factors could conceivably augment the fertility effects produced by delayed mating and result in even more profound levels of population reduction.

6.12.5.4.4. Assessing the efficacy of mating disruption

6.12.5.4.4.1. Damage reduction Of primary importance to growers and to companies marketing mating disruption products is the ability of a formulation to reduce crop damage to acceptable levels. In this context, "successful" mating disruption means assessing crop damage in pheromone treated plots versus check plots and finding that damage in mating disruption plots is lower. This process is problematic, but considered by many to be a major outcome. The assessment is relatively straightforward, but it is essential that plots be large enough to reduce the probability that significant numbers of gravid females can fly in from nearby untreated plots and confound the damage data in the pheromone treated plots.

The choice of an appropriately large size for the plots depends on the propensity of females of a particular species to move long distances . It also depends on the damage acceptance levels for a particular pest, with direct-damage pests such as codling moth having lower damage tolerances than indirect-feeding pest species that may have higher damage acceptance levels. As a starting point for all species, 2 ha plots could be considered to be a minimum size for assessing damage reduction. But for direct-feeding pests and perhaps also a greater tendency of females to fly far, 10 ha would be a safer plot size for such testing. True replication, with check plots having to be many hundreds of meters away from the treated plots to reduce the possibility of drift effects, is difficult to attain, if not questionable with regard to ideal statistical design. However, these are the constraints under which such experiments need to be designed.

For tree fruit crops such replication is achievable and less scientifically debatable, but for field crops such as corn, it is virtually impossible to meet all the objections that arise when trying to compare damage and crop yield. This is because, for instance for corn, finding plots planted to identical cultivars is not the entire problem; differences in planting date and crop phenology can confound comparisons among identical cultivars. In corn, oviposition by European corn borer females is notoriously affected by the height of the corn, which in turn is affected by planting date or temperature differences between fields located even a few miles apart. A difference of only 2 or 3 days in planting date can produce 0.3 or 0.6 m differences in plant height, and so even if two fields are chosen for an experiment that have been planted to the same cultivar, damage may differ significantly between the two fields merely because the taller plants in the earlier planted field are targeted preferentially by ovipositing females.

Being an indirect measure, damage assessment evaluates the end result of many processes that are of interest to those operating in commercial integrated pest management and agronomic arenas. Conclusions that mating disruption was "successful" in the context of suppressing damage and being cost-effective can be arrived at without knowing exactly to what degree the formulation affected the behavior of males to reduce mating by freely flying feral females.

6.12.5.4.4.2. Assessing reduction of mating by use of tethered females Considered over many years to be the ultimate test of mating disruption efficacy, tethering females either on a thread or by clipping their wings and placing them on open arenas so that they cannot move from the location at which they are placed has been a good tool in assessing mating disruption efficacy (Evendon *et al.*, 1999a, 1999b). However, although it looks as if it is a direct and appropriate assessment tool, it is actually only one of several other indirect measures, and it can be argued that these other measures may be even better indicators than are tethered females as to what is happening to the actual female population in the field.

Tethered females are placed on stations in the field and allowed to remain overnight to determine whether they are able to attract and mate with males either in disruptant treated fields or in check fields.

They are retrieved and dissected in the laboratory to look for the presence of spermatophores, which, if present, would mean that one or more males had been able to detect, locate, and mate with the female by means of her pheromone. One limitation to this technique is that tethering or otherwise restraining females limits their ability to find the best location in the foliage to try to attract males. It is true that a relative difference in mating by tethered females in check plots compared with disruptant treated plots can be valuable, but translating this directly into conclusions about the absolute ability of a disruption formulation to similarly reduce the matings of feral females is inadvisable.

For example, if the adult moths in the natural population reside in a more clumped distribution in some preferred substructure of the vegetative habitat, placing females on artificial stations outside of each of these clumps will overestimate the efficacy of the disruption formulation with regard to preventing mating of feral females. The formulation in effect will only be being assessed for its ability to prevent the tethered females from attracting males out of their aggregation sites, and this long distance attraction will be easier to disrupt than will be the disruption of males from locating females that are within the same clumps as the males.

Another limitation to this technique is that researchers only get an all-or-nothing, yes-or-no indication from each female as to how well the disruptant is working in the field. Once a female mates with the first male arriving at her station, she emits no more pheromone and the ability to assess disruption of communication using that female ends. The data are binomial, with no opportunity for a graded assessment from individual females as to how many males they could have attracted had they been calling for the entire activity period that night and not mated.

6.12.5.4.4.3. Trap capture of males by using caged, calling females In this technique, a few virgin females are placed in small screen cages within which is a sugar water source to keep the females alive and hydrated (Baker *et al*., 1997b). The cage is situated within a sticky trap, and so males that are attracted to the calling virgin females become ensnared before reaching the females. Males that do manage to land on the cage containing the females without getting trapped will still not be able to mate with any female in the cage. This technique has many advantages over other indirect measurement techniques such as the use of tethered females.

First, as with tethered females, the caged females are emitting their natural blend at its natural emission rate. However, unlike tethered females, the caged females in traps provide a graded assessment of their ability to attract males. If males are able to get close enough to the calling females that they can be trapped, they certainly would have mated if given that opportunity at such close range. The final step, mating, is an unnecessary one to examine because if the disruptant was not able to prevent a male's long distance orientation to the female's plume, certainly it will not be sufficient to stop the male's orientation to the female over the last 10–20 cm or so. Thus, this technique allows a more robust assessment of females' ability to attract males in disruption treated plots than is available from seeing whether tethered females mate.

6.12.5.4.4.4. Trap capture of males by using lures emitting synthetic pheromone blends The most widely used technique for assessing the disruption of mate-finding communication by disruptant formulations is the use of standard pheromone monitoring traps in which are placed synthetic pheromone lures (Rice and Kirsch, 1990; Knight, 1997; Staten *et al*., 1997; Baker *et al*., 1998b; Fadamiro *et al*., 1998, 1999b). This technique can be as informative as the use of caged calling females if the lure that is used has been shown previously in untreated check plots to be able to attract equivalent numbers of males as do caged calling females. Using synthetic lures that are either too strong or too weak (or emit a suboptimal blend composition) will provide data that are not relevant to what is happening with calling females' ability to attract males. However, if a synthetic blend composition emitted at levels that approximate the attraction ability of caged females is used, then conclusions about the ability of a formulation to disrupt attraction to calling females can be valid.

Again, the advantage of assessing trap capture reduction is that it provides a robust, graded data set from these continuously emitting sources. The disruption formulation is challenged throughout the attraction period each night or evening for its ability to continuously suppress the ability of males to locate "females." Using monitoring traps baited with a good synthetic lure is also significantly easier and less problematic than is the use of live, calling females.

Although assessing mating disruption efficacy by means of synthetic pheromone baited traps is an optimal technique when the appropriate synthetic monitoring lures have been developed, it does not mean that there will always be concomitant demonstration of damage reduction when successful trap shutdown occurs. There are many other factors that play into the latter, and there are several species

of moths, including the obliquebanded leafroller, *Choristoneura rosaceana*, and the peach twig borer, *Anarsia lineatella*, where trap capture is routinely reduced by 95% or more, and little to no effect is seen on the damaging population. Perhaps this has something to do with some of these species having aggregation or mating site habits that have been overlooked and the monitoring traps only measure the ability of the disruptant to prevent males from flying out of their aggregated area out to the monitoring traps. Alternatively, perhaps the disruption plots have not been large enough to prevent immigration of gravid females, whose propensity to move great distances perhaps may have been underestimated in these species.

Regardless, trap capture data have proven to be useful indicators in the early tests performed in the development of disruption formulations; they measure the potential of a formulation to be effective and provide graded data sets that are more informative and easier to obtain. In addition, such tests are useful in determining the longevity of a formulation with regard to its effect on male behavior under natural temperature and wind conditions, which is more relevant to measuring the longevity of a formulation than are emission rate data.

6.12.5.4.4.5. Wind tunnel and other laboratory tests Although there have been many attempts to assess the efficacy of a potential mating disruption blend or formulation in the wind tunnel over the years, the major contribution of such studies has been to elucidate, after the fact, possible behavioral mechanisms that are at work in producing successful disruption. The wind tunnel enables researchers to observe and record individual male behavior in response to disruptant dispensers, or the dispensers' ability to interfere with responses to normal strength pheromone plumes. A key example is the work of Cardé *et al*. (1993, 1997) in investigating the behavior of pink bollworm males when exposed to hollow fibers or Shin-Etsu ropes (see Section 6.12.5.4.2). Evendon *et al*. (2000) were able to deduce from a series of laboratory wind tunnel experiments the possible mechanisms that could be at work in disrupting *C. rosaceana* sex pheromone communication in the field.

As useful and informative as these experiments can be, however, it is impossible in a laboratory wind tunnel to create a spatial array of dispensers that mimics the plume dynamics and plume flux exposures that a male would encounter farther downwind under shifting wind conditions in the field. Disruption dispenser arrays that in the field need to be spaced even as moderately widely as the ropes (and especially with yet more widely spaced, extremely high emission rate dispensers such as MSTRS and "puffers") cannot be scaled down to laboratory wind tunnel size. Wind tunnel tests have been useful to explore some of the physiological and behavioral limits that certain kinds of close-range exposure to plumes of various strengths and structures impose on males' olfactory pathways.

6.12.5.4.5. Pheromone component blend composition in the disruptant formulation In considering the cost of formulating and registering pheromone blends for commercial use, it is crucial to balance efficacy of the registered blend with the cost of the product. If an effective product is too expensive and is not able to be competitive with other available products, it will not be purchased and will "fail," despite its good biological activity and despite all the applied research that has been performed. In general, the fewer components that need to be formulated and still retain good efficacy, the less expensive and more competitive the final product will be. However, the cost of the product is also dependent on the amount of a.i. that needs to be applied per hectare, and so a blend formulation that is more effective at lower amounts of a.i. for a longer period under field conditions may prove to be more economically competitive, despite the inclusion of more pheromone components. For a multicomponent pheromone, how many of the minor components play a significant role in effective disruption and how many can therefore be left out of a final formulated product must be decided.

Minks and Cardé (1988) and Cardé and Minks (1995) reviewed results from many key sex pheromone communication disruption experiments and concluded that for a given species, the synthetic blend compositions and ratios most closely mimicking the natural blend for that species should be the most effective mating disruptants at a given dose per hectare because they will be able to make use of more of the mechanisms (see Cardé and Minks, 1995) that result in disruption than will suboptimal, partial blends or off-ratios. Although the majority of field experimental evidence supports this conclusion, this does not mean that one or more of the more minor components, due to their more subtle effects, might be able to be eliminated from the final formulated product and still retain sufficient efficacy.

Also, there are a few apparent exceptions to Cardé and Minks' general rule. Evendon *et al*. (1999a, 1999b, 1999c, 2000) have thoroughly explored sex

pheromone communication in the western population of the obliquebanded leafroller. They performed experiments exploring the underlying mechanisms likely involved in disruption and also conducted field tests in small plots by using different blend compositions that affect both *C. rosaceana* and a sympatric leafroller pest, the threelined leafroller, *Pandemis limitata*. Their results and insightful discussions have been in instructive in helping to conceptually and experimentally guide researchers as to how to pick apart the many mechanisms that may, depending on the species, play larger or smaller roles in successful sex pheromone communication disruption.

Evendon *et al.* (1999a) found in small plot (0.1 ha) field experiments that the four-component sex pheromone blend of *C. rosaceana* emitted from Conrel hollow fiber tapes deployed at a density of 500 dispensers per ha was effective in reducing successful mating of tethered females to a level of only 5% mating, but it was no more successful than a partial three-component or even a two-component blend containing the major component, (*Z*)-11-tetradecenyl acetate plus (*E*)-11-tetradecenyl acetate emitted at the same rate per hectare. Even at emission rates that they determined were at threshold levels for suppressing mating with tethered females or by deploying disruptant dispensers at reduced densities, the two-component blend was as effective as the four-component blend in suppressing mating. Tests of the competition attractiveness of the disruptant dispensers themselves via tests of attraction of males into traps showed that the two- and three-component hollow fiber tapes were ineffective in attracting males to traps, whereas the four-component fiber tapes resulted in high male trap captures.

Other studies (Evendon *et al.*, 1999b, 1999c, 2000) had demonstrated, in detailed wind tunnel and field experiments, that the attraction competition mechanism as well as long-term habituation were likely not very significant contributors to communication disruption in this species. Rather, sensory adaptation plus plume camouflage seemed to be implicated as playing more dominant roles in thwarting attraction to females. Importantly, even disruptant blends that contained the large amount of the heterospecific antagonistic compound, (*Z*)-9-tetradecenyl acetate, that is emitted by *P. limitata* females were as effective as conspecific blends in disrupting attraction to *C. rosaceana* females. Even these, too, were unattractive to *C. rosaceana* males and would therefore not be able to work via the competition mechanism (Evendon *et al.*, 1999b, 1999c). The ability of *P. limitata* males to locate and mate with tethered conspecific females is likewise disrupted as effectively by *C. rosaceana*-related blends emitting no (*Z*)-9-tetradecenyl acetate, and these are not effective for attracting *P. limitata* males.

The results emphasize again that even with moderately strongly emitting and moderately widely spaced dispensers (Evendon *et al.*, 1999b, 1999c), mechanisms other than attraction competition seem to have been dominating in these studies to result in disruption of sex pheromone communication in these two species. The inclusion of heterospecific antagonists in disruption dispensers was similarly found to be as effective as the conspecific blend in mating disruption studies of the pea moth, *Cydia nigricana* (Bengtsson *et al.*, 1994; Witzgall *et al.*, 1997). Because in Evendon *et al.*'s studies (Evendon *et al.*, 1999a, 1999b, 1999c, 2000), sensory adaptation and also perhaps plume camouflage were shown to be so strongly implicated as the dominant disruption mechanisms, the vulnerability of *C. rosaceana* males to sensory adaptation alone (Evendon *et al.*, 2000) may explain why nonoptimal, nonattractive blends can be so effective at sex pheromone communication disruption. Indeed, other studies using partial and completely unattractive blends dispensed in moderately strong and widely spaced dispensers have shown that effective disruption can be attained (Flint and Merkle, 1983, 1984); presumably, this comes from mostly sensory adaptation or habituation to the ambient pheromone that the unattracted males are exposed to.

Previous studies on a different, eastern population of *C. rosaceana* (Roelofs and Novak, 1981) contrast sharply with results from the western population (Evendon *et al.*, 1999a). Roelofs and Novak (1981) found that the optimal, natural female-emitted three-component blend for eastern *C. rosaceana* imposed better disruption than did partial blends. Evendon *et al.* (1999a) used tethered females for their assessment of disruption and as the authors themselves pointed out, Roelofs and Novak used the "more robust" (Evendon *et al.*, 1999a) assessment of measuring the numbers of males captured. As discussed above, tethered females provide a binomial, mated–unmated measure that does not allow for a graded assessment of how many more males would have been attracted to the females had they not mated with the first one arriving.

The mechanisms affecting mating disruption will operate to different degrees in different species under different environmental conditions and pheromone disruptant deployment schemes (Bartell, 1982; Minks and Cardé, 1988; Cardé, 1990; Cardé and Minks, 1995). There do seem to be differences in the behavior and neurophysiology of the various species that have been targeted and these may allow us to use surprisingly unattractive blends

for effective mating disruption. Whether this is always related to each species' vulnerability to sensory adaptation and plume camouflage as opposed to other mechanisms, the studies discussed above suggest that this is one possible conclusion to be made. The only way to optimize a disruptant formulation with regard to the blend used as the a.i., the dispenser loading and longevity, dispenser deployment density, and the overall cost and efficacy, is with extensive trial-and-error field testing.

6.12.5.4.6. Successful mating disruption in population control by using commercial dispensers

6.12.5.4.6.1. Codling moth In the final two decades of the 1900s, apple and pear growers in California and the Pacific Northwest were facing a variety of factors making untenable the continued use of conventional broad spectrum insecticides. Among these factors were the increasing development of resistance of the codling moth to organophosphate insecticides, and also new federal legislation, the Food Quality Protection Act (FQPA), that would require review and reregistration of traditional broad spectrum insecticides such as the organophosphates (Brunner *et al*., 2001). During this same period, beginning with initial small plot studies (Cardé *et al*., 1977; Charmillot, 1990) using hollow fiber and other dispensers, research on mating disruption of the codling moth had proceeded to the point where effective population suppression using improved, long-lasting mating disruption formulations such as Shin-Etsu ropes seemed feasible (Knight, 1996; Gut and Brunner, 1998).

Due to the reduced efficacy of traditional insecticide applications, the need for more insecticide applications to gain effective control, and the looming specter of FQPA legislation, growers in the early 1990s began using commercially available mating disruption formulations. The number of hectares that was treated with mating disruptants against the codling moth grew from a few hundred in 1990 to approximately 5000 in 1994. Due in part to the increasing grower acceptance of this population management tool, a Codling Moth Areawide Management Program (CAMP) was proposed and then approved. Five sites in the Pacific Northwest were identified, with three of them in Washington State and one each in California and Oregon. A total of approximately 1240 ha was included for codling moth mating disruption application over all five sites.

One overall goal of this study was to achieve an 80% or greater reduction of the use of broad spectrum conventional insecticides by the end of the 5-year program. A subsidy was provided to all participating growers of \$125 ha^{-1} for the first 3 years of the project to help defray the cost (\$275 ha^{-1}) of the mating disruption treatments (Brunner *et al*., 2001). For the final 2 years, growers had to pay the full cost of the treatments themselves. Standard high-dose codling moth monitoring traps were used to assess trap capture reductions, and damage assessments were made for all blocks within the CAMP project and compared with fruit from non-CAMP participating grower blocks.

The largest site in the project was at Howard Flat, Washington, more than 440 ha. Data from this site are representative of the trends in the other four CAMP sites (Brunner *et al*., 2001), although their differences in weather, topography, and horticultural practices were many, including the fact that the California and Oregon sites were planted mainly to pears. In 1995, the first year of the CAMP program, codling moth mating disruption formulations (mostly the Shin-Etsu ropes, IsoMate CM) were applied to the CAMP hectarage, and at the end of the year in Howard Flat, trap capture of males had been reduced by 80% and fruit damage at harvest averaged 0.55% for the entire hectarage of the project. The previous year's at-harvest damage had averaged 0.8%. Moreover, the number of conventional insecticide sprays targeting the codling moth averaged only 1.2 ha^{-1}, whereas during the previous, non-CAMP year it had averaged 2.9 ha^{-1} (Brunner *et al*., 2001).

During 1996, the average trap capture of males was reduced further from the levels in 1995, with only 1.5 moths captured per trap compared with 8.8 per trap in 1995. Damage at harvest was reduced to only 0.2% and most of the damage (sometimes reaching 25%) occurred in the few blocks of trees at Howard Flat in which one or two growers had refused to participate in the CAMP program. Higher damage also occurred in mating disruption treated blocks of trees of CAMP participants that bordered these untreated, high-infestation sources. In subsequent years these blocks of trees were leased by neighboring growers who wanted to eliminate these last remaining codling moth infestation foci, and these hot spot infestations were subsequently fully reduced. During 1996, the number of insecticide applications against codling moth fell further to only 1.1 application per hectare (Brunner *et al*., 2001).

During the next 2 years, trap capture fell further to exceptionally low levels, with 90% of the traps capturing zero males during the entire 2 years. During 1998, the average number of insecticide applications fell to only 0.5 application per ha and

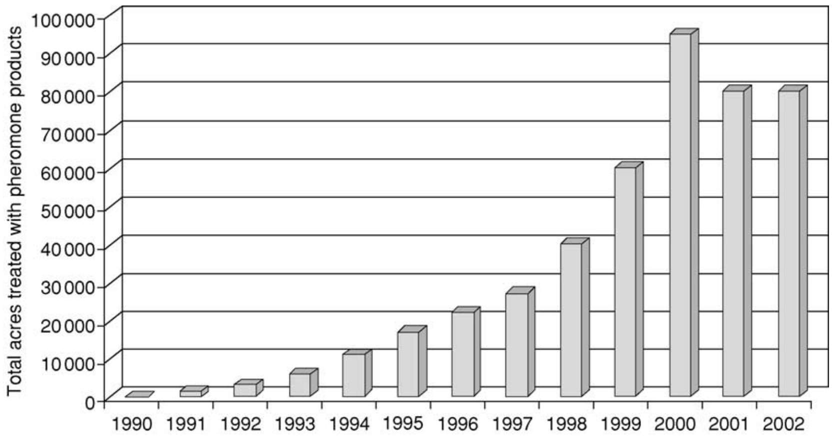

Figure 5 The number of acres treated each year with codling moth (*Cydia pomonella*) commercial mating disruption products in Washington State, USA from 1990 to 2002 (Brunner *et al*., 2001; Years 2001 and 2002 provided by Brunner, personal communication). In 1995 the Codling Moth Areawide Management Project (CAMP) began, with subsidized mating disruption applications provided to growers. The three CAMP sites in Washington State comprised a constant 760 ha during the 5 years of the program (1995–99).

crop damage at harvest reached an all-time low of between 0.01% and 0.03% damaged fruit. These levels were accomplished in 1998 with one-half the density of dispensers per hectare, because this was the first year without a cost subsidy from the program. Also, mating disruption had been so effective in reducing codling moth populations the first 3 years that there was little perceived threat of incurring increased damage by reducing dispenser density. By doing so, growers kept their expenses the same as during the previous 3 years.

It is clear from the continued increase in acreage using commercial codling moth mating disruption formulations in Washington State (**Figure 5**), that growers statewide were satisfied with the population suppression and their economic balance sheets involved in using codling moth mating disruption. The CAMP program served as a focal point for providing mating disruption efficacy data that guided growers statewide as to what was happening on their own mating disruption treated acreage. Not only did the growers in the CAMP program achieve a 75% reduction in insecticide applications while reducing damage to unprecedented levels, but also secondary pests did not arise with the reduced insecticide pressure, as had initially been feared would occur. On the contrary, comparison plots under conventional practice experienced higher levels of secondary pests and often lower levels of beneficial insects and mites than did the CAMP program plots (Brunner *et al*., 2001).

6.12.5.4.6.2. Pink bollworm A similar history of successful area wide use of sex pheromones for mating disruption exists for another key agricultural pest, the pink bollworm (Staten *et al*., 1997). The Parker Valley of Western Arizona, planted to more than 10 000 ha of cotton, was overrun with pink bollworms that had developed resistance to every insecticide on the market. The grower groups in the valley mandated an areawide program of using mating disruption against this pest, and the entire valley had various commercial mating disruption formulations applied from first moth emergence through to August. The formulations included the Shin-Etsu ropes and (the formerly Conrel, now Scentry) hollow fibers. The fibers had been commercially available since 1978, and growers were already knowledgeable about them and about the ropes as well. However, before the start of the program in 1989, virtually no hectarage in Parker Valley had had mating disruptants applied, even though their use had been prevalent in neighboring southern California desert valley cotton hectarage (Staten *et al*., 1997).

As in the codling moth CAMP program, damage diminished year by year in the Parker Valley with continued area wide application of pheromone mating disruption formulations. By 1993, the average season-long capture of males in monitoring traps in Parker Valley was reduced to only 0.5 moth per trap, whereas the statewide average in conventional practice farms grew to greater than 30 per trap (averaging 23 moths per trap for all 3 years). Most importantly, whereas the percentage of infested bolls out of the tens of thousands that were sampled each year was more than 25% during mid-August of year 1, during the same August period in year 2 (1990) damage was only 5.9% (Staten *et al*., 1997) (**Table 3**). At the mid-August point of year 3 damage was only 0.03% and by 1993, out of more than 22 000 bolls sampled season-long, not a single

Table 3 Pink bollworm damage to cotton bolls in Parker Valley mating disruption project, Arizona, USA

	Larvae per 100 bolls

infested boll was found (0% damage) (Table 3). In contrast, the central Arizona average infestation rate for conventionally insecticide treated hectarage in 1993 was 9–10% by mid-August (Staten *et al.*, 1997).

6.12.5.4.6.3. Other successes and some limitations Growers of peaches have had mating disruption successes similar to the above, by deploying Shin-Etsu polyethylene tubes over a wide area against the oriental fruit moth in Australia (Vickers, 1990), in California (Rice and Kirsch, 1990), and in South Africa (Barnes and Blomefield, 1997). The above results from areawide mating disruption against three different species and cropping systems indicate that efficacious mating disruption formulations applied on large areas over a 3-year period can result in the near elimination of pest population problems. During year 1 of a program, high pest populations may not appear to be well controlled, but during year 2, the mating disruption effects from year 1 become evident. Lower populations are present at the beginning of the season, and mating disruption during year 2 is better able to exert its full effect. By years 3 and 4, populations have often been reduced to such low levels that growers decide that they can apply reduced rates of the disruption formulations. This has its dangers in that it can result in less effective mating disruption, allowing populations to build back up again.

Charmillot (1990) summed up lessons he and his coworkers learned concerning when it is that mating disruption becomes less effective for codling moth population suppression. His lessons regarding codling moth are applicable to mating disruption efforts on other pests as well. First, mating disruption works best when applied on an area wide basis and is not advisable on very small hectarage (less than 1 ha). The crop borders represent vulnerable edges for immigration of mated females from adjoining untreated crop areas, and they also serve as a zone that concentrates females along the borders when there is no nearby hectarage of the same crop. Due to geometry, small hectarage accentuates the problem because the edge-to-area ratio becomes greater. Also, the use of more widely spaced dispensers requires that borders be given special attention to reduce the presence of pheromone-free clean air "holes" along the borders; this can be accomplished either by decreasing the spacing between dispensers, or else through the use of different dispenser technology along borders, such as sprayable microcapsules. Mating disruption will be more problematic when crop borders are especially irregular or when the fields are too elongated; in these cases again the crop's edge-to-area ratio becomes too high. This important effect of field geometry is especially exaggerated for very widely spaced high-release-rate disruption formulations.

6.12.5.4.7. Constraints to successful adoption of mating disruption

6.12.5.4.7.1. Upfront cost A primary obstacle to the use of pheromone mating disruption on any crop is that it must be applied no later than the start of the first adult flight period, that is, before a grower knows for sure that there is even going to be a pest problem that season. The requirement of this upfront investment in pheromone puts mating disruption at a disadvantage compared with curative pest management tools that provide a wait-and-see option. Insecticide applications can be made after a preliminary assessment of the population density during the first flight of adults or even after oviposi-

tion when larval damage can be assessed. Pheromone mating disruption cannot be used curatively that way.

In the areawide mating disruption successes discussed above, growers had no other recourse other than mating disruption because their usual curative insecticide tools had been rendered ineffective due to pest resistance. Here, mating disruption no longer represented an upfront cost, but rather became a viable option that growers readily embraced and accepted.

6.12.5.4.7.2. Appearance of secondary pests Except for a few small groups or pairs of species, pheromones are extremely species-specific. The replacement of broad spectrum insecticides in some IPM systems with mating disruption that targets only one species in a pest complex can lead to increases in the populations of species that had been only secondary pests before mating disruption was used (Rice and Kirsch, 1990). No pheromone disruption formulation has been created thus far that functions effectively as a "broad-spectrum" formulation. Evendon *et al*. (1999b, 1999c) experimented with single blend formulations targeting *C. rosaceana* and *P. limita*, with some success. Perhaps there are other situations where effective multispecies blend formulations can be developed, although there are still none that have attained commercial success.

Choristoneura rosaceana disruption seems to depend less on attraction competition and habituation, and more on sensory adaptation (Evendon *et al*., 2000). It remains to be seen whether development of multispecies disruptant formulations can be successful on more sets of species. Certainly when widely spaced, high-emission-rate dispenser systems are used there should be less of a chance for this to work, because attraction competition that facilitates habituation seems to be more essential for success with these formulations (Baker *et al*., 1998b).

6.12.5.4.7.3. Cost of mating disruption formulations Pheromone mating disruption formulations have to this point been expensive compared with curative applications of insecticides. Although growers of many crops are now well aware that mating disruption "works" as a pest management tool, pheromones' expense plus the upfront nature of the cost has put them at a disadvantage relative to curative pest management tools. The a.i., the pheromone itself, is the most expensive part of a formulation. Costs per gram of even the least expensive pheromone components are approximately \$1.00, and many other more expensive major pheromone components cost \$3–20 g^{-1}. Formulating the a.i. into specialized dispensers adds to the cost, but nevertheless, if cheaper organic synthetic routes to the a.i.s can be developed, costs of the final formulated products could be reduced substantially.

Unfortunately the best and cheapest routes for large scale syntheses have apparently been discovered and are already the ones in use by pheromone manufacturers. Therefore, finding other ways to emit behaviorally effective amounts of the active ingredients more judiciously while maintaining efficacy and extending the longevity of dispensers under field conditions is a much-needed area of research. Below, we present some ideas for how to do this as we try to bring together some of the advances in recent basic knowledge about male moth upwind flight behavior with applied aspects of pheromone use in the field.

6.12.6. New Frontiers

6.12.6.1. New Ideas for Reducing the Cost of Pheromone Mating Disruption

6.12.6.1.1. Widely spaced, high emission rate dispensers Widely spaced, high emission rate dispensers offer an advantage for future cost-saving measures to make mating disruption more economically competitive with other tools such as insecticides. Because these dispensers can be deployed at very low densities, from one to 15 dispensers per ha (Shorey and Gerber, 1996a, 1996b; Shorey *et al*., 1996; Baker *et al*., 1997b, 1998b; Fadamiro *et al*., 1998, 1999b), the labor cost for their deployment is lower than for other hand-applied dispenser types. Importantly, widely spaced dispensers are the only type whose density per hectare goes down as the area of crop they are applied to goes up, regardless of starting grid-spacing distance. This is at first not easy to comprehend because it is counterintuitive.

In the example shown in **Figure 6**, high emission rate dispensers are hypothetically deployed on a 1 ha orchard, using a 25 m spacing between dispensers (center square, large dots). The density needed to treat the 1 ha orchard calculates out to be 25 dispensers per ha. However, if a 9 ha orchard needed to be treated using this same 25 × 25 m grid pattern, the cost per hectare is reduced, because over the 9 ha plot the density has been reduced to 18.8 dispensers per ha (**Figure 6**, second square, small dots). For a 25 ha orchard, the cost per hectare is reduced further as the density falls to 17.6 dispensers per ha, still keeping this same grid spacing (**Figure 6**, outermost square, no dots); and to treat 100 ha the dispenser density goes down to 16.8 dispensers per ha.

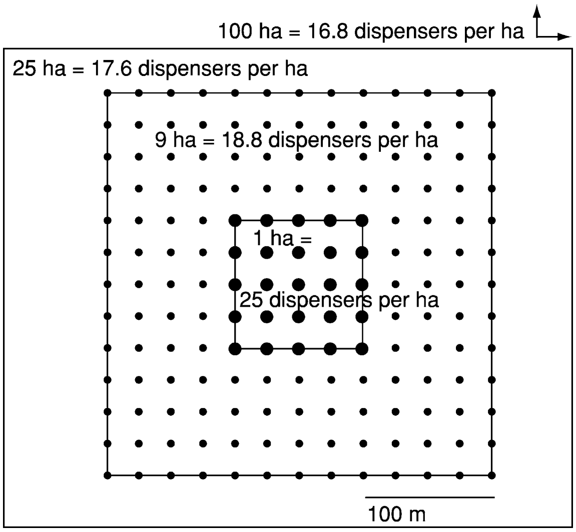

Figure 6 Widely spaced, high emission rate dispensers are the only type of dispenser whose density per hectare diminishes significantly as the area of crop they are applied to increases. In this example, such dispensers are deployed with a 25 m spacing on 1 ha (interiormost square, large dots); here dispenser density calculates to 25 dispensers per ha. Treating 9 ha (intermediate square, smaller dots) while keeping the same 25 m dispenser spacing results in a reduced density of 18.8 dispensers per ha. Enlarging the treated area still further to 25 ha (outer square) and 100 ha (beyond outer square) while keeping the same grid spacing of dispensers results in even lower dispenser densities of 17.6 ha^{-1} and 16.8 ha^{-1}, respectively.

If the starting dispenser grid pattern is less dense than this, the reduction to low densities upon scaling up to very large hectarage is even more striking. Starting with a dispenser spacing twice the above (50×50 m), treating the 1 ha orchard with a grid pattern requires a density of 9 dispensers per ha. Treating a 9 ha orchard reduces the density to 5.4 per ha, and treating 25 ha requires only 4.8 dispensers per ha. The 100 ha orchard needs only 4.4 dispensers per ha.

In the Farkas *et al.* (1974) initial experiments demonstrating that widely spaced, high dispenser loadings work as well as closely spaced, low loadings, they emphasized that the amount of active ingredient per hectare should be maintained. This aspect needs to be explored more with many more trials, because if this turned out to be a strict requirement, then no cost savings from reduced dispenser number per hectare would be gained from this surprising phenomenon of geometry that provides a numerical advantage to wide spacing. But as emphasized in the discussions above, it is not the overall concentration of pheromone that moths respond to, it is the changes in flux provided by the pheromone plume-strands. Therefore there may be previously unrealized opportunities to further reduce the cost of pheromone per hectare by designing dispensers that optimize, with regard to plume-strand strength, what is emitted and not what is applied.

6.12.6.1.2. Strong plume strand emitting dispensers The existing dispensers that have been used for insect mating disruption have emphasized emission aspects related to field longevity that are calculated on the total amount of pheromone emitted per hectare per unit time. Work on improving these previous devices has largely ignored recent findings that have shown that males fly upwind in response to individual strands of pheromone comprising the fine structure of the plume.

An insect's antennae can only sample a small volume of an odor plume, and the strands and pockets of clean air give the olfactory neurons on the antenna rapid fluctuations in stimulation (2–10 Hz). Mating disruption dispensers and deployment spacing schemes that can maximize changes in flux will be able to elicit attraction competition from farther downwind than will less well-designed types. Olfactory pathway habituation, which accompanies attraction competition (Cardé *et al.*, 1997), is known to be optimally imparted by strong pulses of pheromone and not by continuous stimulation, which only will produce sensory adaptation (Bartell and Lawrence, 1977a, 1977b; Bartell, 1982).

It became apparent while working on optimizing the emission rate from MSTRS high release rate pads that, within a few days, the pads became loaded with an amount of pheromone beyond which adding more pheromone did not further increase the emission rate. If the size of the pad were to be increased, the pad's total emission rate would be raised proportionately. However, we also realized that because the insects' antennae are so small, any increase in the diameter of the pad will not increase the strength of the individual pheromone strands that contact the antennae. The amount emitted per dispenser, or per hectare per unit time, will seem to researchers to create greater and more powerful amounts of pheromone to affect behavior, but in fact it will not at all increase the amount that strikes an insect's antenna.

It became clear during our studies that smaller point sources will be better at generating large plume-strand flux, but only if the emission rate of the small point source can be kept the same as the rate that large surface area dispensers emit across their total area. The effect will be to pack more molecules into a smaller space, thereby increasing pheromone strand flux. One way to accomplish this

would be to add energy to the small point source that would generate heat and increase the evaporation rate. Energy could also be used to generate ultrasonic vibration of the point source and increase evaporation rate by increasing air movement over the source. However, both such types of dispenser might be unnecessarily expensive and subject to technical malfunction.

The authors propose that pheromone flux of individual strands can be increased very simply by using an entirely passive technique that allows strands to be enriched before they are sheared from the downwind end of the dispenser surface. The dispenser needs to be asymmetrically shaped and either of a planar or cylindrical design. It then needs to be suspended so that it is allowed to align itself parallel to (along) the wind line. Each parcel of air that passes over the dispenser–surface air boundary will progressively accumulate more molecules as it traverses along more of the dispenser surface, enriching the parcel with increasingly higher concentrations of pheromone before the resulting odor strand is shed from the dispenser's downwind end.

Measurements of plume-strand flux downwind of a rectangular planar dispenser taken in our laboratory using a solid phase microextraction (SPME) fiber approximately the size of a moth antenna have confirmed the large strand enrichment effect of orienting the plane along the wind line (parallel to the wind) (Baker and Park, unpublished data). A greater than 40-fold increase in flux across the SPME fiber (across a moth antenna) resulted, compared with a cross-wind orientation (perpendicular to the wind line). As expected, there were no apparent differences in emission rate from the dispenser when the overall release rates of the planar dispensers were measured using the older method of drawing air over the dispensers housed in a wide tube and collecting the entire volume of the tube onto a cartridge filled with Tenax adsorbent beads (Baker and Park, unpublished data).

From this concept, it follows that if such a planar dispenser (or a cylindrical one) is made much longer than it is wide and its long axis is then aligned along the wind line, pheromone strand concentration and plume flux will be proportionately increased according to dispenser length. Therefore, this method for passively creating the strongest possible odor strands anticipates that odor strand flux can be maximized by using a more linear shaped dispenser, and then keeping the longest axis of its release surface (planar, cylindrical) aligned parallel to the wind. Under variable wind directions, as occur in the field, this wind alignment can be done simply by the use of a wind vane that rotates the emission

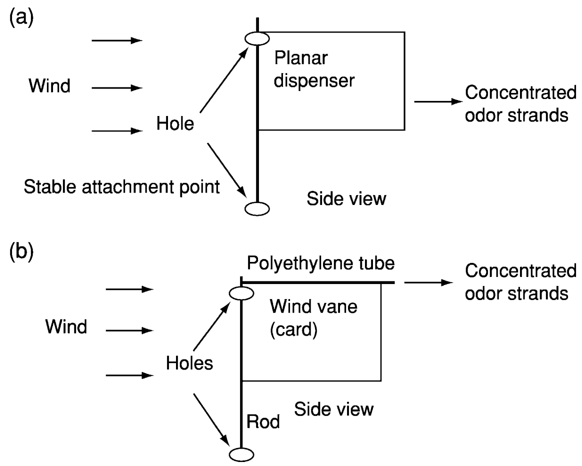

Figure 7 An illustration of how to easily and passively (without the addition of heat or other energy) enrich the strength of the pheromone signal (odor strand) that emanates from a dispenser. The dispenser must be planar-shaped (a) or cylindrical–tubular-shaped (b). The dispenser should be allowed to rotate freely so that the dispenser's long axis will align along the wind line. This can be accomplished by attaching the tubular dispenser to a wind vane (b), or else by allowing the planar dispenser to function as a wind vane (a). It follows from this priniciple that the amount of enrichment for a given evaporative surface area will be further optimized by making the dispenser much long than it is wide, with the increase in strand concentration being proportional to the increase in dispenser length that is aligned along the wind line.

source to follow all the changes in wind flow direction to keep the surface perfectly aligned to allow odor concentration to occur along the long axis (Figure 7b). Alternatively, the long axis of a planar dispenser itself can be allowed to swing in the wind to act as a wind vane, by using single attachment points to a stable surface and either wire, string, or swivel-type rotating fasteners to allow the dispenser to swivel freely in the wind (Figure 7a).

The authors emphasize that this concept for increasing plume flux by increasing odor strand concentration differs from the multitude of previous studies over the years that have used planar filter paper dispensers aligned cross-wind versus parallel to the wind to widen or narrow the plume (Mafra-Neto and Cardé, 1994), or else have used obstacles upwind of the source (Willis *et al.*, 1994) to create different plume structures or plume concentrations. In such previous studies, the effort was only to preserve the plume-strand structure and flux *after* the strands had already been shed from the dispenser. Previous work on optimizing plume shape in the field downwind of pheromone traps likewise focused on minimizing turbulence and preserving plume structure (Lewis and Macaulay, 1976), and not on enriching pheromone strand concentration before pheromone leaves the dispenser surface. This

present method suggests a novel way to enrich odor strands *before* they are shed from the dispenser, thereby maximizing the flux of pheromone in individual odor strands and hence maximizing the resulting changes in flux across the antenna stationed within a plume.

It is realized that the highly concentrated plume-strands from such wind-aligned dispensers are vulnerable to break-up by the turbulent mixing imparted as they travel through surrounding foliage, and their ability to affect male behavior far downwind might be compromised. Nevertheless, there may be ways to take advantage of this system, especially in the deployment of mating disruption dispensers above canopy level against pests of field crops. Over short grass, the ability of such small point source generated strands to stay highly concentrated as they travel downwind has been demonstrated; very strong strands of ionized air do occur at great distances from the source, but not as frequently as they do close to the source (Murlis, 1986, 1997). It is possible that extremely long length, strong plume-strand emitting dispensers can be deployed on wind vanes from very few locations outside very large fields to protect the interiors.

The high emission rate, small point source concept also is instructive with regard to the evolution of lepidopterous female pheromone glands. Female moths likely have, as hypothesized by Greenfield and Karandinos (1979), been selected to emit very little pheromone per unit time because judicious emission of small amounts of pheromone is a form of sexual selection that allows females to discriminate for only the fittest (most sensitive) males that are able to locate females from far downwind.

We would propose in addition that females may be able to economize and use such low amounts of pheromone because they emit it from an extremely small piece of tissue situated on the tip of their abdomens. Although the amount of time-averaged pheromone emitted seems to be very small, the plume-strands that are shed are perhaps optimized with regard to the flux over the male's antenna that they produce. Studies aimed at measuring plume-strand flux from calling female moths on various plant species and foliage substrates may be very informative in investigating this idea further.

The confluence of applied and basic pheromone research and the synergy of ideas is apparent from new lines of inquiry such as these. We must continue to create new blends in this manner.
